In the method of production described by Reid and Lewis,[187] ammonia and ethylene oxide are brought into reaction by passing a stream of a solution of one of the reacting substances at a temperature below 50° C. along a porous wall and diffusing the other reactant through the wall. In another procedure, the olefin oxide is added to an aqueous solution of ammonia.[188] Thus, 2600 parts of ethylene oxide are added slowly to 3870 parts of 25 per cent aqueous ammonia at 25° to 30° C. to give 90 to 95 per cent yield of triethanolamine. If 352 parts of ethylene oxide are added to 3400 parts of 25 per cent ammonia solution at 10° C., monoethanolamine is formed almost exclusively.[189]

[186] Knorr, *Ber.*, 1897, 30, 909. Germann and Knight (*J.A.C.S.*, 1933, 55, 4150) described the preparation of pure triethanolamine.

[187] Canadian Patent 298,851, 1930; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1930, 24, 2756.

[188] I. G. Farbenindustrie A.-G., French Patent 650,574, 1929; *Chem. Abs.*, 1929, 23, 3232; British Patent 306,563, 1927; *Brit. Chem. Abs.* B, 1929, 315. Also Reid and Lewis, U. S. Patent 1,904,013, April 18, 1933; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1933, 27, 3222.

[189] Cyclohexylethanolamines are similarly made from cyclohexylamine and ethylene oxide, I. G. Farbenindustrie A.-G., German Patent 535,049, 1927; *Chem. Abs.*, 1932, 26, 995.

Arnold[139a] formed secondary and tertiary amines by passing alcohol and ammonia in the proportions of 3 to 4 parts alcohol to 1 part ammonia over a catalyst (alumina or thoria), 85 per cent of the ammonia being converted.

The boiling points of the three bases are as follows:

Monoethanolamine, $NH_2CH_2CH_2OH$, 171° C. at 757 mm.
Diethanolamine, $NH(CH_2CH_2OH)_2$, 217° C. at 150 mm.
Triethanolamine, $N(CH_2CH_2OH)_3$, 277° C. at 150 mm.

The three ethanolamines differ slightly in their chemical and physical properties. They are miscible in all proportions with water, the ordinary alcohols, acetone, glycerol and ethylene chlorohydrin but not with diethyl ether and some aldehydes. The salts with the higher fatty acids are emulsifying agents and soaps.

Monoethanolamine is a colorless, slightly viscous, very highly hygroscopic liquid with a faint but agreeable ammoniacal odor. The dinitrate of this compound may be prepared by dissolving the ethanolamine in excess nitric acid, distilling off the excess *in vacuo* and precipitating the dinitrate by pouring it into cold alcohol or alcohol-ether mixture.[140] The yield is said to be 88 to 97 per cent. The dinitrate has been proposed as an explosive either alone or mixed with other substances.

Diethanolamine is a colorless and odorless liquid having a viscosity like that of glycerol. Diethanolamine trinitrate has been proposed as an explosive.[141]

Triethanolamine, when pure, is a white crystalline solid at room temperatures. Commercial triethanolamine is a clear, viscous, and very hygroscopic liquid of d^{20}_{4} 1.124, soluble in most organic liquids containing oxygen, but only slightly soluble in hydrocarbons. Despite its feeble alkalinity (dissociation constant, 2.5×10^{-6}), stable salts are formed with most acids although its abietic acid salt is almost completely hydrolyzed in aqueous solution.

APPLICATIONS OF THE ETHANOLAMINES

Mixtures of the ethanolamines may be used in the purification of gases from carbon dioxide and hydrogen sulphide. A 50 per cent aqueous solution of a mixture of di- and tri-ethanolamines is employed for absorbing these acidic gases by countercurrent washing at room temperature. The resulting solution of the acid sulphides or carbonates of the ethanolamines readily decomposes at temperatures above 50° C. with regeneration of the absorbent.[142] A 50 per cent aqueous solution of triethanolamine ("Girbotol") will absorb 6.7 cu. ft. of carbon dioxide (measured under standard conditions) per gallon under a pressure of 760 mm. of mercury at 95° F.[143] The advantages of the ethanolamines in gas purification are: less liquid is required for a given quantity of carbon dioxide than with sodium carbonate; the vapor pressures of the absorbents are low enough to obviate loss of material by evaporation; and corrosion troubles are not encountered. The ethanolamines form more stable salts with sulphur dioxide, and hence are unsuitable for the removal of this substance from gases.

Stanier[144] suggested using the ethanolamines for extracting phenols from tar oils. The ethanolamine extract is diluted with water and then saturated with carbon dioxide or hydrogen sulphide to recover the phenols. Ethanolamines have been proposed as extraction agents for the refining of mineral oils.[145] The addition of a small proportion (0.05 to 1.0 per cent) of butyldiethanolamine to lubricating oils stabilizes their color.[146]

The ethanolamines have also been applied in the preparation of photographic films,[147] and of wetting agents,[148] as plasticizers with cellulose esters,[149] as soaking and softening agents for hides and pelts,[150] and as catalysts in the formation of phenol-aldehyde condensation products.[151] These amines have served as preservative agents in rubber compositions,[152] as stabilizers for lead tetra-alkyls,[153] as inhibitors of iron corrosion by methyl and ethyl alcohols, glycol, or glycerol,[154] for the dehydration of acetic acid,[155] and in conjunction with boric acid or rosin for the electrolytic deposition of solid films of high dielectric strength.[156] Dissolved in water or alcohol[156a] or in the form of their borates[157] the ethanolamines are of therapeutic value.

Any one of the ethanolamines, as well as the technical mixture, combines readily with fatty acids to produce soaps,[158] whose consistency depends more upon the fatty acid employed than upon the particular ethanolamine. Monoethanolamine oleate has the consistency of petroleum jelly and the oleates of the other ethanolamines are only slightly less viscid. The stearate is a hard, wax-like solid. These soaps are soluble in water, the usual organic solvents (benzene, toluene, turpentine) and to a limited extent in lubricating and petroleum oils. Ethanolamine oleate possesses frothing and emulsifying properties and may be used for promoting oil-in-water emulsions.

Among the many proposed applications for ethanolamine soaps the following may be mentioned: as a flux in soft soldering,[159] for increasing the electrical conductivity of light petroleum distillates[160] (to minimize danger of sparking and explosion when cleaning with these materials), as ingredients for spray compositions for agricultural purposes,[161] in the preparation of sizes[162] and greasing agents[163] for textile fibers, and in the degumming of silk.[164]

An account of the industrial applications of ethanolamine soaps is given by Smith, *Soap*, 1931, **7** (12), 27; *Chem. Abs.*, 1932, **26**, 866. For the use of ethanolamine soaps as detergents see Moscowitz, U. S. Patent 1,847,437, March 1, 1932; *Chem. Abs.*, 1932, **26**, 2613; Hoyt, U. S. Patent 1,833,899, Dec. 1, 1931; assigned to Larkin Co.; *Chem. Abs.*, 1932, **26**, 1147. Kruege (*Seifensieder-Ztg.*, 1933, **60**, 310; *Chem. Abs.*, 1933, **27**, 5206) describes the preparation of a triethanolamine ricinoleate soap.

Monoethanolamine oleate has been suggested as a component of cleaning and polishing mixtures,[165] and the soaps of triethanolamine and oleic acid, or high molecular weight carboxylic or sulphonic acids, may be used as auxiliary agents (disinfectants or lubricants) in the textile, leather and paper industries.[166]

The various soaps of triethanolamine (particularly the oleate and the linoleate) are useful for emulsifying[166a] and other purposes. The oleate is a viscous soap completely miscible with many organic liquids including hydrocarbons, except certain heavy mineral oils and fatty glycerides which may require the addition of an excess of acid to yield a clear solution. The use of triethanolamine soaps for emulsification purposes has been discussed by Wilson.[167] Combinations of triethanolamine with fatty acids, oils, and solvents to be employed as detergents, lubricants, and dry cleaning compounds were described by Harvey.[168] The preparation of various water emulsions for orchard-spraying purposes was given by Hockenyos.[169]

The salts of triethanolamine with oil-soluble sulphonic acids[170] or with sulphonated castor or fish oils[171] are said to be detergents, and the resinates or naphthenates have been proposed as sizes for textile threads.[172] Other uses for the triethanolamine soaps are as dispersing agents for dyes[173] and in the preparation of wick fibers.[174]

DIOXAN (DIETHYLENE DIOXIDE)

The close structural relationship of dioxan, , and the olefin oxides renders a description of this substance appropriate at this stage.

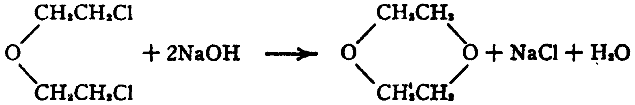
Dioxan is made in a number of ways, among which the following may be mentioned:

(1) By heating ethylene bromide with ethylene glycol.[175]

(2) By the combination of ethylene oxide and ethylene chlorohydrin.[176] Other products, however, are formed at the same time.

(3) By the action of sodium hydroxide on $\beta\beta'$-dichlorodiethyl ether,[177] according to the reaction:



A 22 per cent yield of dioxan is obtained, the other product being β-chloroethyl vinyl ether. Heating $\beta\beta'$-dichloroethyl ether with metallic oxides, e.g., mercuric, lead, silver or cupric oxides, has been suggested.[178]

(4) By the action of dehydrating agents (for example, phosphoric acid) on ethylene glycol or by heating ethylene oxide with sodium hydroxide.[179]

The method of preparation, which is also employed industrially, is that originally proposed by Faworski,[180] who obtained dioxan together with some ethyl acetal by distilling glycol with 4 per cent of sulphuric acid. Distillation of diethylene glycol (dihydroxydiethyl oxide) or a monoether derivative with sulphuric acid also yields dioxan.[181] Van Alphen[182] described a method of converting ethylene glycol into dioxan by heating it with anhydrous ferric sulphate, a procedure appearing to give good results. Mixtures of dioxan homologues may be obtained by treating mixtures of glycols with dehydrating catalysts.[183] For example, twenty-five parts of olefin glycols (made from cracking gas) and 1 part of concentrated sulphuric acid are heated to boiling in an acid-resisting distilling vessel, further amounts of the glycol mixture being added in amount corresponding to the quantity of dioxans distilling off. The yield of mixed dioxans, boiling point 95° to 150° C., was 80 per cent of the theoretical. On distilling 25 parts of propylene glycol and 1 part of concentrated sulphuric acid in the manner previously described, an 80 per cent yield of dimethyldioxan was obtained. A similar yield of diethyldioxan may be had from 1,2-butylene glycol in the same manner. High molecular weight polyglycols or polymers of alkylene oxides, when distilled in the presence of a dehydrating catalyst, are also said to yield dioxan and its homologues.[183a]

PROPERTIES OF DIOXAN

Dioxan is a liquid of faint odor, boiling at 102° C., melting at 11° C. and d_4^{20} 1.0329. Its heat of fusion is 33.8 calories per gram and molal heat of combustion, 554.6 calories.[184] It is soluble in water and in many organic solvents and is a fair solvent for resins and fats. It has been suggested as a solvent for cellulose esters[185] and also for the hydrolysis of cellulose acetate.[186] The technical product usually contains some ethylene acetal as well as a peroxide probably derived from the latter. Both these substances can be removed by boiling the crude dioxan with one-tenth its volume of normal hydrochloric acid for several hours.[187] Dioxan can be used for the extraction of lithium chloride from mixtures with the chlorides of sodium and potassium.[188]

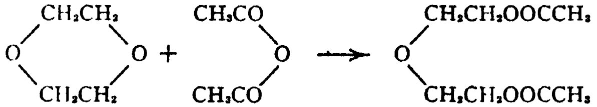
[183a] I. G. Farbenindustrie A.-G., German Patent 570,674, 1933; *Chem. Abs.*, 1933, **27**, 4252.

The explosive properties of dioxan-air mixtures were studied by Jones, Seaman and Kennedy.[188a] The lower inflammable limit of dry dioxan-air mixtures at room temperatures and pressures was 1.97 per cent by volume. The upper limit at atmospheric pressure and temperatures of 100° to 110° C. was found to be 22.25 per cent by volume.

From a purely chemical standpoint dioxan is of interest because of the ease with which it forms crystalline double compounds with halogens, metallic chlorides and other reagents. Of these the dibromide, m.p. 65°-66° C., and the diiodide, m.p. 84°-85° C., are characteristic.[189] With sulphuric acid it forms a compound of the formula, $C_4H_8O_2.H_2SO_4$, which may be crystallized from benzene and which melts at 101° C. With nitric acid in the cold it yields the addition product of the formula $3C_4H_8O_2.4HNO_3$, which melts at 14° C.[190] Double compounds with stannic chloride have also been described.[191]

Acetylation of dioxan with acetic anhydride in the presence of anhydrous ferric chloride yields small quantities of glycol diacetate together with $\beta\beta'$-diacetoxydiethyl ether[192] (diethylene glycol diacetate), boiling at 110° to 135° C. at 16 mm.



Direct chlorination of dioxan at 90° C. produces 2,3-dichlorodioxan,[193] and ultimately, of several isomeric tetrachlorodioxanes.[194]

Dioxolanes. Bogert and Roblin[194a] prepared a series of cyclic acetals (1,3-dioxolanes) in yields of 25 to 35 per cent by the reaction of ethylene oxide with aldehydes and ketones in the presence of anhydrous stannic chloride. The properties of these compounds are given in Table 107.

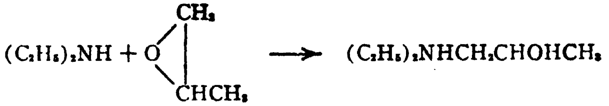
2,4-Dimethyl-2-phenyl-1,3-dioxolane	105

HOMOLOGUES OF ETHYLENE OXIDE

Of the higher olefin oxides only propylene oxide will be considered in any detail since the properties of the higher oxides have been little investigated.

Propylene oxide,  , is a liquid, boiling point 35° C., which may be prepared by methods analogous to those for ethylene oxide. In chemical properties it is very similar to ethylene oxide though its reactivity is somewhat less.[195] It can be hydrated to propylene glycol and reduced to n-propanol. It reacts with alcohols and phenols to yield monoethers of propylene glycol, and with organic acids to form esters of this glycol. Like ethylene glycol it reacts with ammonia and amines. Thus, 1 mole of this oxide when heated with 2 moles of diethylamine in aqueous solutions (of either 33 or 70 per cent concentrations of amine), gives 65 per cent of 3-diethylaminopropanol-2, a liquid boiling at 158° to 159° C. (760 mm.).[196]



Similarly, propylene oxide condenses with benzylamine at 100° C. to yield 1-benzylamino-2-propanol and with isoamylamine to give 1-isoamylamino-2-propanol.[197] The presence of water accelerates these combinations and increases the yields.

Propylene oxide, like other oxides of the type,

 and 
contains an asymmetric carbon atom and therefore exhibits stereoisomerism.

BUTENE OXIDES

Three α-oxides of the butene series are known, namely:

1,2-Butene oxide,  boiling point 58.5°–58.9° C.

---

[195] Boyd and Marle, *J.C.S.*, 1914, 105, 2117.

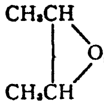
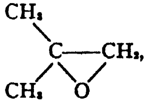
2,3-Butene oxide,



boiling point 56°-57° C.

Isobutene oxide,

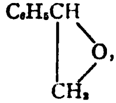


boiling point 51°-52° C.

Isobutene oxide is remarkable on account of the ease of combination with water, a reaction which takes place at ordinary temperatures with the evolution of heat.[198] It reacts with ammonia to yield aminotrimethylcarbinol as well as large amounts of secondary and smaller amounts of tertiary amines.[199]

The number of the isomers of the olefin oxides increases greatly with increasing molecular weight. Little is known of these higher oxides and they are of little industrial significance. Of the pentene oxides, isopropylethylene oxide is hydrated to the corresponding glycol with difficulty. Its reactions with ethylamine and diethylamine have been investigated by Krivonos.[200]

Styrene oxide,



is an interesting aryl-substituted olefin oxide which could be produced in quantity if an industrial application of it were discovered. This oxide is prepared from crude styrene chlorohydrin which generally contains some of the corresponding dichloride.[201] The crude chlorohydrin is decomposed with aqueous potassium hydroxide to yield 90 per cent of the oxide (b.p. 70° C. under 5 mm. pressure) and the styrene dichloride is recovered unchanged. Styrene oxide is remarkable for the ease with which it isomerizes to phenylacetaldehyde in the presence of dilute acids.[202] It readily combines with hydrogen cyanide to give the cyanohydrin of phenylacetaldehyde.

Chapter 24

Miscellaneous Reactions of Olefins (I)

A number of industrially important addition reactions of the simple olefins, notably with sulphuric acid and halogens and halogen acids, have already been discussed in some detail.[1] In the following account some further reactions of these olefins, mostly of an additive character also, are more briefly described. Though many of these miscellaneous reactions are imperfectly understood and perhaps of only academic interest, there are indications that at least some of them may ultimately assume a position of importance in chemical industry. In one or two cases a single chemical reaction will convert olefins into chemical products which could previously be synthesized only with difficulty by a complicated series of steps from other materials. Thus, for example, olefins can be converted into higher ketones by a reaction which proceeds smoothly and gives good yields. It is more than likely that some of these less-known reactions of the lower olefins will equal, if not exceed in importance such well-known and technically important processes as the combination with sulphuric acid for the manufacture of alcohols or the reaction with hypochlorous acid in the synthesis of chlorohydrins and their related compounds. Since almost inexhaustible supplies of the lower olefins are available at very low cost, the potentialities of some of the reactions discussed in this chapter, most of which are completely unexplored from a technical standpoint, in organic chemical synthesis are great indeed.

CONDENSATION OF OLEFINS WITH AROMATIC HYDROCARBONS

The condensation of olefins with aromatic hydrocarbons in the presence of catalysts is a reaction which leads to the production of alkyl derivatives of the aromatic hydrocarbon. The importance of this reaction resides not only in the ease with which hitherto unknown or difficultly preparable alkylated aromatic hydrocarbons may be synthesized but also in the fact that certain of these alkylated hydrocarbons, particularly the polyalkylnaphthalenes, are possible synthetic lubricant hydrocarbons and their sulphonated products possess emulsifying and wetting properties. This appears to be a most fruitful field of research in organic chemistry, not only from a purely scientific standpoint but also in connection with the production of technically important organic substances. The best catalyst which has been found for bringing about this condensation is anhydrous aluminum chloride but undoubtedly other anhydrous metallic halides such as boron trifluoride, ferric chloride, or stannic chloride may be used, especially in the case of the more reactive olefins. In the presence of aluminum chloride double compounds of this chloride and hydrocarbons are frequently formed. These pasty double compounds must be decomposed with ice-water before the isolation of the desired product is attempted. Sulphuric acid will effect these condensations and catalytic addition in the vapor phase in the presence of phosphates has also been proposed. The direct combination of ethylene with benzene in the presence of aluminum chloride to produce a mixture of ethylated benzenes was studied by Balsohn[2] in 1879 and somewhat later by Gattermann, Fritz and Beck,[3] and Schleicher and Büttgenbach.[4] To effect this addition a stream of dry ethylene is passed through a suspension of aluminum chloride in dry benzene. Milligan and Reid[5] found that the reaction is considerably facilitated by high-speed stirring. This mode of ethylation, in which ethylene is not to be considered merely as a substitute for ethyl chloride, produces all the possible ethylated benzenes, including hexaethylbenzene. According to Berry and Reid,[6] the best proportion of aluminum chloride appears to be 1 mole to 13 moles of benzene and the optimum temperature is 70° C. When the stirring is stopped the reaction mixture separates sharply into two layers: a colorless top layer which contains only a trace of aluminum chloride, and a lower dark and more viscous layer in which the aluminum chloride is associated with about its own weight of hydrocarbon. It was shown that each of the hydrocarbons was partitioned between the two layers but the aluminum chloride holds the higher ethylated benzenes in preference to the lower. From mono- to tetra-ethylbenzene, the concentrations in the two layers do not differ greatly but there is a marked accumulation of pentaethylbenzene in the lower layer. Table 108 shows the proportions of the products obtained by continuously passing ethylene through 100 moles of benzene in the presence of aluminum chloride at 70° C., with efficient stirring.

---

[1] See Chapters 11, 13, 14, 16, and 20.

TABLE 108.—*Products Obtained by Passing Ethylene Through Benzene in the Presence of Aluminum Chloride at 70° C.*

Ethylene Moles of	Products (Per Cent by Weight of Ethylbenzenes)						
Absorbed	C_6H_6	Mono-	Di-	Tri-	Tetra-	Penta-	Hexa-
0.20	87.9	10.9	1.24	—	—	—	—
0.56	80.5	15.2	1.67	0.71	—	—	—
1.14	31.6	35.2	21.1	4.0	2.4	2.8	2.82
1.38	37.3	30.1	11.6	6.7	3.0	3.2	8.2
1.68	35.4	23.4	13.6	6.3	4.2	3.6	13.4
3.66	0.2	1.1	10.6	56.2	11.6	1.5	18.7
5.24	—	—	—	7.0	18.8	2.4	71.8
5.74	—	—	—	—	8.5	0.9	90.6

It will be seen that continued absorption of ethylene favors the production of hexaethylbenzene. This hydrocarbon, which is a crystalline solid, is also produced in good yield by the action of ethylene under pressure at room temperature on benzene in the presence of aluminum chloride.[7]

Berry and Reid[8] also investigated the condensation of ethylene and propylene with other aromatic hydrocarbons in the presence of aluminum chloride at 70° C. Toluene was ethylated more rapidly by ethylene than benzene and the products contained a complex mixture of ethyltoluenes as well as ethylbenzenes and xylenes. Ethylation, therefore, was accompanied by splitting and rearrangement of alkyl groups. Propylene was found to combine with benzene much more slowly than ethylene under the same conditions. The reaction mixture separated into two layers, the lower being relatively larger and more difficult to decompose with water than that obtained in the ethylation of benzene. The product consisted of a mixture of isopropylated benzenes, from the higher fractions of which was isolated a crystalline solid melting at 117° C. and boiling at 260° C. at 775 mm. This compound was thought to be 1,2,4,5-tetraisopropylbenzene. Two aliphatic hydrocarbons, which boiled at 28° C. and 56° to 59° C. (diisopropyl) were also produced, probably by splitting off of alkyl groups under the influence of aluminum chloride. Table 109 shows the relative proportions of the products in the experiments of Berry and Reid on the propylation of benzene.

TABLE 109.—*Products Obtained by Passing Propylene Through Benzene in the Presence of Aluminum Chloride at 70° C.*

Moles of Propylene Absorbed	Products (Per Cent by Weight of Isopropylbenzene)					
	C_6H_6	Mono-	Di-	Tri-	Tetra-	Residue
0.6	16.3	42.5	27.0	6.1	2.1	6.1
0.75	18.9	52.0	20.0	3.0	1.3	4.8
1.97	1.4	0.6	3.9	87.6	3.3	3.3
1.93	1.3	15.6	46.7	46.7	5.4	—

Examination of the diisopropylbenzene fraction showed that about 65 per cent was the meta-compound (boiling point 203.5° to 204.5° C.), whereas 1,2,4-triisopropylbenzene (boiling point 237° to 237.5° C. at 752 mm., 97° to 97.5° C. at 4 mm., D_0^0 0.8764, N_D^{25} 1.4855) constituted 75 per cent of the triisopropyl fraction.

Toluene was found to react with propylene at 70° C. in the presence of aluminum chloride much more rapidly than benzene and the products consisted of xylenes, triethylbenzenes, and m- and p-cymene, with a preponderance of p-cymene. Treatment of 276 grams of benzene with 290 grams of cyclohexene and 60 grams of aluminum chloride at 55° C. yielded 50 grams of cyclohexylbenzene, which boiled at 230° to 245° C., and a large proportion of high-boiling products.

The production of mono- and poly-alkylated aromatic hydrocarbons from aromatic hydrocarbons and olefins appears to be a general reaction in the presence of aluminum chloride. The production of tertiary-butylxylene by condensation of isobutylene with xylene in the presence of aluminum chloride has been also effected.[9] Essner and Gossin[10] obtained liquid amyltoluenes by the action of amylene on toluene in the presence of this reagent. Bodroux[11] effected the combination of cyclohexene with benzene, toluene, m-xylene, mesitylene, cymene, diphenyl, diphenylmethane, dibenzyl, naphthalene, and tetrahydronaphthalene, in the presence of aluminum chloride in carbon disulphide solution to yield cyclohexyl- and dicyclohexyl-derivatives of these hydrocarbons. From the products of the action of propylene on naphthalene in the presence of aluminum chloride at 90° C., Berry and Reid[12] isolated isopropylnaphthalene.

Cracked gasoline and kerosene fractions can be condensed with aromatic hydrocarbons in the presence of aluminum halides to yield alkylated aromatic products. The influence of the concentration of olefins (their relative proportion in the mixture), the amount of catalyst, the reaction temperature, and the method of adding the catalyst in such alkylations was studied by Tilicheyev and Kuruindin.[13] Table 110 shows the fractions which were separated from cracked paraffin and made to react with benzene, by adding them slowly to a ten-fold proportion of benzene, the olefin content of each, and the yield of products:

195°–196° C.	48.3	44% undecylbenzene
129°–139° C. at 5 mm.	28.8	48% cetylbenzene

A considerable number of processes have been developed for the production of alkylated aromatic hydrocarbons by the condensation of the lower aromatic hydrocarbons with olefins in the presence of aluminum chloride. The raw materials may be aromatic hydrocarbons such as benzene and its homologues or polynuclear hydrocarbons such as naphthalene[14] and the olefin may be one of the simple monolefins, for example, the lower gaseous unsaturated hydrocarbons. Davidson proposed to make alkylbenzenes, which can be blended with motor fuels, by condensing benzene or an alkylbenzene with olefins in the presence of aluminum or ferric chloride.[15] The reaction can be advantageously conducted with vigorous agitation, under pressure, in a countercurrent system, at a temperature near the boiling point of benzene. The production of alkylated naphthalenes by the condensation of naphthalene with gaseous olefins under pressure at a temperature above 50° C. has been suggested by Michel.[16] The products are said to be usable as lubricants for ice-machines,[16a] as insulating oils,[16b] and as motor lubricants. Michel[17] also produced alkylnaphthalenes by a similar condensation with gaseous olefins or olefin mixtures at 50° to 200° C. in the presence of aluminum chloride. For example, 128 kilograms of naphthalene and 4 kilograms of anhydrous aluminum chloride are stirred with ethylene under 20 atmospheres pressure at 100° to 200° C. The reaction is started by passing in a little dry hydrogen chloride. The ethylene is replenished until 38 kilograms have been absorbed. On distillation there are separated 25 kilograms of unchanged naph-

[14] The Edeleanu extract of kerosenes has been proposed as an appropriate aromatic material for this condensation by the I. G. Farbenindustrie A.-G., British Patent 316,274, 1929; *Brit. Chem. Abs.* **B**, 1931, 55. This patent is an addition to British Patent 299,086, 1927; *Brit. Chem. Abs.* **B**, 1928, 919.

[15] British Patent 303,505, 1928; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1929, **23**, 4568. According to Davidson (U. S. Patent 1,879,118, Sept. 27, 1932; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1933, **27**, 401), the alkylbenzene serves to diminish spontaneous evaporation without substantially raising the end point or increasing detonation of casing-head gasoline.

thalene, 110 kilograms of oil boiling at 250° to 400° C. (which consists of a mixture of β-monoethylnaphthalene, di- and poly-ethylnaphthalenes and dinaphthyl derivatives), and 25 kilograms of undistillable residue. An oil which boils between 240° C. and 340° C. is obtained by treating 132 kilograms of tetrahydronaphthalene with 2 kilograms of aluminum chloride and ethylene under pressure at 100° C.

According to Michel,[18] homologous olefins such as propylene and butylenes will react with naphthalene hydrocarbons, partially hydrogenated naphthalenes (e.g., tetrahydronaphthalene) or halogenated naphthalenes (e.g., α-chloronaphthalene or monochlorotetrahydronaphthalene) in the presence of a catalyst such as aluminum chloride, at normal or even at reduced pressures and temperatures. Under these conditions ethylene is substantially unaffected. Ethylene may then be recovered from mixtures which contain other olefins.

By passing propylene into a mixture of 128 parts of naphthalene and 4 parts of aluminum chloride at 80° C., with stirring, for example, the propylene is completely absorbed and the reaction is complete when the increase in weight amounts to 168 parts. The reaction mixture may be decomposed with water, to give propylated naphthalenes from which it is possible to separate a crystalline hydrocarbon (tetraisopropylnaphthalene melting at 125° to 126° C.) by distillation.

Treatment of 256 parts of naphthalene and 5 parts of aluminum chloride with butylene (a mixture of 1-butene and 2-butene) at 80° C. until the total increase in weight amounts to 260 parts, yields a mixture which, on distillation *in vacuo,* gives a principal fraction boiling at 200° to 250° C. at 20 mm. and consists of polybutylnaphthalenes.

Michel [19] proposed to carry out the condensation of naphthalene, or its oxygen-free derivatives, with olefins in the presence of aluminum chloride and an inert solvent such as decahydronaphthalene. Mono- and di-ethylnaphthalenes (boiling between 140° and 200° C. at 20 mm.), tetraisopropylnaphthalene, tetrabutylnaphthalene (boiling at 186° to 190° C. at 5 mm.), and other condensation products can be thus obtained.

The direct combination of olefins with aromatic hydrocarbons may be effected with catalysts other than aluminum chloride or anhydrous metallic halides. It has long been known that sulphuric acid catalyzes the direct combination of olefins with aromatic substances. Brochet [20] found that benzene and hexene reacted together in the presence of sulphuric acid to yield a hexylbenzene and other products. Kraemer and Spilker [21] showed that styrylxylenes were formed from a mixture of styrene and the xylenes in the presence of concentrated sulphuric acid.

Barbier [22] prepared tert-butyl-p-cymene by treatment of a mixture of tert-butyl alcohol and p-cymene with concentrated sulphuric acid at temperatures below 0° C. Verley [23] proposed to make alkylated aromatic hydrocarbons by shaking a mixture of an aromatic hydrocarbon, such as benzene, and an alcohol with a mixture of sulphuric acid and an alkali pyrosulphate.

Pospiech [24] obtained compounds possessing wetting and emulsifying properties by condensing aromatic sulphonic acids with olefins at 85° to 100° C. The products of this condensation are alkylated or arylalkylated aromatic sulphonic acids. For example, propylene is condensed with a mixture of α- and β-naphthalene sulphonic acids in the presence of an excess of concentrated sulphuric acid at a temperature below 100° C., or naphthalenesulphonic acid (made by sulphonating 100 kilograms of naphthalene with 150 kilograms of concentrated sulphuric acid at above 100° C.) is treated with 135 kilograms of tetrahydrobenzene and 135 kilograms of concentrated sulphuric acid at 85° to 90° C., to yield about 330 grams of a viscous condensation product. DeGroote and Keiser[24a] and DeGroote, Monson, and Wirtel[24b] used similar alkylated sulphonated aromatic compounds for breaking petroleum emulsions.

Instead of employing free olefins for this condensation it has been suggested that substances be used which give rise to olefins under the conditions of the condensation, for example, alcohols of more than three carbon atoms, secondary- and tertiary-alkyl halides, or sulphuric acid esters of alcohols. Alkylated naphthalenesulphonic acids may be produced by condensing naphthalenesulphonic acids with isopropyl or sec.-butyl alcohols, in the presence of sulphuric acid.[25] Not only secondary and tertiary alcohols, but even primary alcohols can be dehydrated to olefins under favorable conditions. Thus, the production of n-butylnaphthalene by condensation of naphthalene with n-butanol in the presence of sulphuric acid at elevated temperatures has been described.[26]

The condensation of olefins with aromatic hydrocarbons may be carried out in the vapor or liquid phases in the presence of catalysts. For this purpose catalysts consisting of activated hydrosilicates or silica obtained therefrom have been proposed.[27] Bleaching earths, clays, or kaolins, are treated with acids, e.g., 25 per cent sulphuric acid, at 100° to 120° C. and the product is washed and dried. It is stated that polyethylnaphthalenes are formed on treating naphthalene at 250° C. with ethylene under 20 to 40 atmospheres pressure in the presence of activated bleaching earth. Similarly, cyclohexanol and benzene yield cyclohexylbenzene, and benzyl alcohol and benzene give diphenylmethane. Tetraisopropylnaphthalene[28] and other products are formed by passing propylene under pressure into a hot solution of naphthalene in decahydronaphthalene or benzine containing bleaching earth or fuller's earth as catalyst. The condensation of olefins with aromatic compounds at 300° to 400° C. at 15 to 50 atmospheres pressure in the presence of cerium metaphosphate or other phosphate, borate, or arsenate, that is, catalysts which are not reduced by hydrogen under these conditions, has also been suggested.[29] The condensation of ethylene with naphthalene, toluene, tetrahydronaphthalene, and anthracene, of propylene with toluene and of styrene with naphthalene also may be carried out.

Products which resemble lubricating oils or soft resins have been obtained by the condensation of olefins with cyclic hydrocarbons which have more than one ring in their structure.[30] This condensation may be carried out in the presence of an inert solvent, or the usual condensing agents such as aluminum chloride, zinc chloride, or activated aluminum or zinc powder. The process may be varied by allowing the condensation reactions to take place in two stages, the resins being removed at the end of the first stage. Other compounds possessing wetting properties have been prepared by condensing hydrocarbons containing three-ring nuclei (or their halogen derivatives) such as phenanthrene or anthracene with olefins in the presence of aluminum chloride and hydrogen chloride.[30a] Other catalysts and higher temperatures are used in the successive stages.

Michel[31] employed the so-called Edeleanu extract as a source of lubricating oils, by condensing it with olefins in the presence of catalysts. For example, an Edeleanu extract of viscosity 1.4° Engler at 20° C. is treated with ethylene under 20 atmospheres pressure at 140° C. in the presence of anhydrous aluminum chloride until no more ethylene is absorbed. The product is washed with water and distilled to furnish a yellow oil of viscosity 4° Engler at 20° C. and a resinous residue. According to Michel, Pungs and Galle,[32] the viscosity of mineral lubricating oils is increased by condensation with olefin gases under pressure in the presence of a catalyst, for example, by treatment with a gas containing 24 per cent of ethylene and its homologues under a pressure of 20 atmospheres at 100° C. in the presence of anhydrous aluminum chloride.

Olefins or alkyl chlorides and aromatic hydrocarbons (or alkylated aromatic hydrocarbons[32a]) can be condensed with dibasic acid anhydrides, such as phthalic, in the presence of aluminum chloride to give ketonic acids, according to Bruson.[32b] The cobalt, manganese, and lead salts of such acids (secondary amylbenzoyl-o-benzoic or p-cymoyl-o-benzoic acid, for example) are said to be driers for paints and varnishes.[32c] Similarly, olefins or low-test gasoline can be condensed with phthalic anhydride to give acids[32d] whose metallic salts can also be used as driers,[32e] or for preparing oil-soluble soaps. Salts such as those of p-secondary-butylsalicylic acid have also been suggested as siccatives for paints.[32f]

No evidence has yet been reported to demonstrate whether olefins can be condensed with completely saturated hydrocarbons, such as paraffins or cycloparaffins, to produce alkylated derivatives of these hydrocarbons.

CONDENSATION OF OLEFINS WITH PHENOLS

Just as olefins can condense with aromatic hydrocarbons to produce alkylated hydrocarbons, so alkylated derivatives of phenol can be produced also by condensation of olefins with phenols in the presence of condensing agents. Catalysts for this reaction appear to be anhydrous metallic halides, concentrated sulphuric acid, or certain activated bleaching earths.

Sulphuric acid has been employed by a number of observers to effect the condensation of olefins with phenols. Koenigs[33] and Anschütz and Beckerhoff[34] obtained p-alkylated phenols by the action of olefins such as styrene and isoamylene on phenol in the presence of this condensing agent and Schrauth and Quasebarth[35] condensed cyclohexene with phenol under similar conditions to produce 17 per cent of p-cyclohexylphenol. It was shown by Niederl and Natelson[36] that at low temperatures, condensation of olefins such as diisobutylene with phenols (e.g., m-cresol) yield ethers, such as m-cresol diisobutyl ether. Since some of these ethers can isomerize at higher temperatures in the presence of dehydrating agents, to the corresponding p-alkylated phenol, the reaction probably proceeds as follows:

$$C_6H_5\ OH + C_nH_{2n} \longrightarrow C_6H_5\ O\ C_nH_{2n+1} \longrightarrow C_nH_{2n+1}\ C_6H_4\ OH$$

Additional evidence in support of this reaction mechanism has been advanced by Sowa, Hinton and Nieuwland,[37] who made a careful investigation of the condensation of propylene with phenol in the presence of boron trifluoride as catalyst. A whole series of isopropylated phenols and their isopropyl ethers was obtained, the quantitative relationship between the various products depending mainly upon the reaction temperature. The reactions which occurred were represented as follows: Propylene + phenol → isopropyl phenyl ether → o-isopropylphenol → o-isopropylphenyl isopropyl ether → 2,4-diisopropylphenol → 2,4-diisopropylphenyl isopropyl ether → 2,4,6-triisopropylphenol → 2,4,6-triisopropylphenyl isopropyl ether. By carrying out the reaction at 0° C., the main product obtained was isopropyl phenyl ether, which, however, was only present to a small extent when the reaction was effected at 20° C. At 40° C., the only reaction products isolated were 2,4,6-triisopropylphenol and its isopropyl ether, the latter predominating. The condensation appears to stop at this stage, for no higher products were obtained.

The condensation of cyclohexene with phenol in carbon disulphide solution under the influence of aluminum chloride was studied by Bodroux,[38] who found the main products of the reaction to consist of o- and p-cyclohexylphenols, cyclohexyl chloride, and cyclohexyl phenyl ether. The propylation of m-cresol in the presence of sulphuric acid to yield mainly thymol (together with small amounts of 1,3,5-isopropylcresol and 1,3,4-propylcresol) is described by Blagden.[39] He has also treated sulphonated phenol and o-nitrophenol with propylene and sulphonated m-cresol with ethylene.

Linner[40] suggested the condensation of olefins with phenols in the presence of aluminum chloride, ferric chloride, or zinc chloride, with a small proportion of alkyl halide or halogen acid to initiate the reaction. In the presence of a small proportion of ferric chloride, tertiary amyl chloride and phenol readily

react, with the liberation of hydrogen chloride, to give para-tertiary-amylphenol.[41] Olefins absorb hydrogen chloride[42] to form the alkyl chloride. The mechanism of this Linner process can be thus inferred.

The condensation of propylene with o-, m-, or p-cresol in the presence of catalysts has also been described.[43] Catalysts include alumina, aluminum phosphate, and thorium or tungsten oxides (alone or on carriers), zinc chloride and anhydrous acids. Olefins have also been condensed with phenols in the presence of certain activated hydrosilicates.[44] The propylation of 6-chloro-m-cresol by propylene in the presence of such catalysts to yield ultimately 6-chloro-thymol has been carried out. Bleaching earth or fuller's earth has also been used to effect the condensation of olefins with phenols.[45]. Thus, propyl tolyl ether and propylated cresols are formed by passing propylene into a hot solution of m-cresol in an inert solvent containing a bleaching earth, until absorption is complete.[45a] Substituted phenols can also be produced by the condensation of phenol with ethylene under pressure at 200° to 500° C. in the presence of catalysts (such as cerium metaphosphate).[46]

The condensation of phenols with olefins in the presence of surface catalysts has been effected.[47] For example, phenol when heated with propylene under 15 to 20 atmospheres pressure at 140° C. in the presence of 10 per cent of tonsil for a short time, yielded the isopropyl ether of phenol together with a little n-propyl ether. Longer periods of heating at higher temperatures produced p-isopropylphenol and p-propylphenol. Under similar conditions. phenol and cyclohexene condensed to yield the cyclohexyl ether which then isomerized to p-cyclohexylphenol. Cresol and cyclohexene first form the ether which then rearranges to 1-methyl-4-cyclohexyl-3-hydroxybenzene. Alkylated cresol ethers are obtained by condensing olefins of more than two carbon atoms with cresol ethers in the presence of condensing agents such as aluminum chloride, sulphuric acid, or phosphoric acid.[48] The condensation of m-tolyl methyl ether with isobutylene furnishes 3-methoxy-4-tert-butyltoluene, boiling at 228° C., and with propylene, a mixture of methyl ethers of isomeric thymols, which boil at 215° to 230° C.

It appears, therefore, that the catalytic condensation of olefins with phenols is likely to prove a valuable synthetic method for the preparation of alkylated phenols and other substances.[49] These new products, commercial quantities of which have become available, are finding some application as new raw materials for the manufacture of oil-soluble synthetic resins.[50] Christiansen and Lott[50a] condensed cresol with amylene in the presence of sulphuric acid at less than 10° C. to obtain amylcresols which may be used as bactericides. The possible extension of these reactions to condensation of olefins with purely aliphatic hydroxy-compounds has also been indicated.[51] Thus, tertiary olefins can be made to react with aliphatic alcohols in the presence of sulphuric acid to yield the corresponding ethers, e.g., isobutylene can be condensed with methanol to furnish tert-butyl methyl ether. Olefins can also be condensed with unsaturated substances containing one or more carbonyl or carboxyl groups, for example, maleic acid, crotonic acid, maleic anhydride, crotonaldehyde, acrolein, and quinone.[51a] Thus, "amylene succinic acid" has been prepared by heating amylene for 2 hours at 180° C. with 20 per cent by weight of maleic anhydride. After cooling, the residue, from which unreacted amylene has been distilled, is treated with 20 per cent alkali. Two layers are formed, the upper of which consists of oily polymerization products. From the lower aqueous layer the dibasic acids formed can be precipitated with a mineral acid and purified by recrystallization from water.

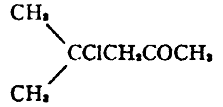
[50a] U. S. Patent 1,922,153, Aug. 15, 1933; assigned to E. R. Squibb and Sons; *Chem. Abs.*, 1933, **27**, 5153.

Morrell and Egloff[51b] heated polymeric hydrocarbons such as those obtained from cracked distillates with phenolic material to 150° C. in the presence of chlorine, air, ozone, or oxides of chlorine until the mixture thickened sufficiently. The product was said to be usable for molding under pressure.

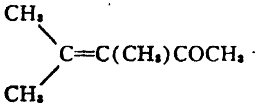
CONDENSATION OF OLEFINS WITH ORGANIC ACID CHLORIDES

The condensation of acyl chlorides with olefin hydrocarbons was observed by Kondakow,[52] who found that isobutylene reacts with acetyl chloride in the presence of zinc chloride as catalyst to produce a chloroketone of the formula



$$(CH_3)_2CClCH_2COCH_3$$

which was unstable and which, on heating, evolved hydrogen chloride with the production of mesityl oxide. In the same way, trimethylethylene reacted to produce a chloroketone which was decomposed to a methylmesityl oxide derivative. The latter reaction was also investigated by Zelinski,[53] who obtained from trimethylethylene and acetyl chloride in the presence of aluminum chloride, the unsaturated ketone



$$(CH_3)_2C{=}C(CH_3)COCH_3$$

The condensation of a cyclic hydrocarbon, C_8H_{14} (1,1,2-trimethyl-2-cyclopentene or isolaurolene), with acetyl chloride in the presence of aluminum chloride was found by Blanc[54] to furnish the corresponding unsaturated ketone. Condensation of the simple olefins, ethylene to octylene, with acetyl chloride was also investigated by Krapivin,[55] who obtained, as products, a series of unsaturated ketones of the type $CH_3.CO.CR{=}CH_2$.

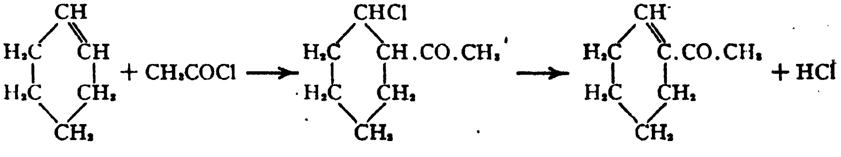
A very careful investigation of this reaction in the case of cyclohexene and acetyl chloride was made by Darzens.[56] From the reaction of 82 grams of cyclohexene with 78 grams of acetyl chloride in the presence of 138 grams of aluminum chloride in 600 grams of carbon disulphide in the cold, was obtained a chloroketone which was readily decomposed into cyclohexenyl methyl ketone by a weak base. The yield of this unsaturated ketone was 50 grams or about 42 per cent of the theoretical. The reaction mechanism proposed by Darzens is represented by the following scheme:



In order to recover the reaction product it was necessary to decompose the aluminum chloride complex with ice-water. Darzens tested the efficacy of various other anhydrous metallic halides in promoting this reaction. The chlorides of sulphur, copper, mercury, and stannous chloride were inactive; the trichlorides of boron, iron, and antimony catalyzed the reaction but with lower yields than those with aluminum chloride, and titanium tetrachloride was satisfactory. However, stannic chloride was found to give even better results than aluminum chloride. Thus, treatment of 82 grams of cyclohexene and 78.5 grams of acetyl chloride in 600 grams of carbon disulphide with 250 grams of stannic chloride produced ultimately 60 grams of cyclohexenyl methyl ketone, which corresponded to a yield of 50 per cent.

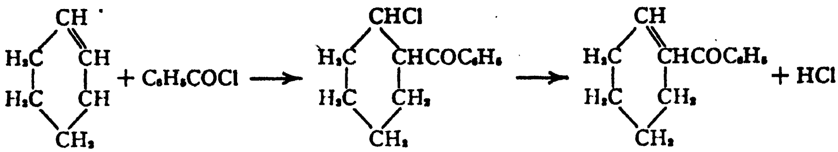
The condensation of ethylene with benzoyl chloride in the presence of aluminum chloride in carbon disulphide solution was investigated by Norris and Couch[57] and found to yield phenyl vinyl ketone as follows, though the yield was poor:

$$C_2H_4 + C_6H_5COCl \longrightarrow CH_2{=}CHCOC_6H_5 + HCl$$

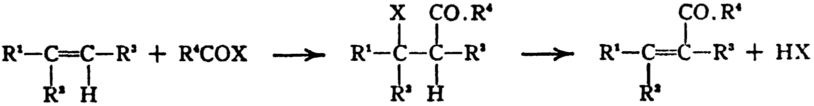
Wieland and Bettag[58] examined similar reactions, namely, the condensation of cyclohexene and trimethylethylene with acetyl and benzoyl chlorides in carbon disulphide solution in the presence of aluminum chloride at low temperatures. In this way the unstable β-chloroketones were isolated in the form of their semicarbazones. It was also shown that, on warming in carbon disulphide solution with aluminum chloride, these intermediate chloroketones are readily converted into vinyl ketones with elimination of hydrogen chloride. For this reason, unless a low temperature is maintained during the condensation of olefins with acyl chlorides, the unstable intermediate chloroketones are converted into the unsaturated ketones. Wieland and Bettag explained the reaction on the assumption of the formation of an aluminum chloride-acid chloride complex. Treatment of 20 grams of cyclohexene, and 30 grams of acetyl chloride in 75 grams of carbon disulphide with 35 grams of anhydrous aluminum chloride at low temperatures yielded 15.8 grams of chlorocyclohexyl methyl ketone which, in turn, readily lost hydrogen chloride to form tetrahydroacetophenone (cyclohexenyl methyl ketone). Similarly, benzoyl chloride and cyclohexene yielded 2-chlorocyclohexyl phenyl ketone which was converted into tetrahydrobenzophenone:

---

[56] *Compt. rend.*, 1910, 150, 707; *Chem. Abs.*, 1910, 4, 2093.
[57] *J.A.C.S.*, 1920, 42, 2329.
[58] *Ber.*, 1922, 55, 2246.



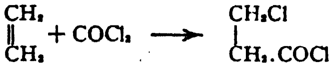
It is evident from the foregoing results that the condensation of olefins with acid chlorides is a very general reaction leading to the formation of an unstable β-chloroketone which loses hydrogen chloride to yield an alkyl vinyl ketone. This general reaction may be written:



$$R^1{-}\underset{R^2}{C}{=}\underset{H}{C}{-}R^3 + R^4COX \longrightarrow R^1{-}\overset{X}{\underset{R^2}{C}}{-}\overset{CO.R^4}{\underset{H}{C}}{-}R^3 \longrightarrow R^1{-}\underset{R^2}{C}{=}\overset{CO.R^4}{C}{-}R^3 + HX$$

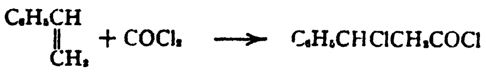
where R^1, R^2, R^3, and R^4 are alkyl or aryl groups and X is a halogen atom. The condensation can apparently be effected by aluminum chloride, stannic chloride or titanium tetrachloride. Since aluminum chloride tends to polymerize olefins, for condensing the more reactive olefins with acid chlorides the milder catalysts such as stannic chloride can be employed with advantage. As the higher olefins are much more stable it would appear quite feasible to use aluminum chloride in condensing these substances with acid chlorides to produce higher ketones. The above reaction is worthy of further study not only on account of its obvious technical significance in the synthesis of higher ketones, but also because of its undoubted scientific interest.

The condensation of ethylene with acyl chlorides in the presence of a Friedel-Crafts condensing agent has been employed to produce substituted vinyl ketones.[59] A special case of this reaction is the condensation of phosgene with unsaturated hydrocarbons to yield chloro-acid chlorides. The reaction of phosgene with ethylene under the influence of light to yield β-chloropropionyl chloride according to the scheme,



$$\begin{matrix}CH_2\\ \| \\ CH_2\end{matrix} + COCl_2 \longrightarrow \begin{matrix}CH_2Cl\\ | \\ CH_2.COCl\end{matrix}$$

was observed by Lippmann,[60] and later Pace[61] showed that this reaction can take place under the influence of aluminum chloride. The reaction is carried out by passing phosgene into a solution of the olefin in toluene at 35° to 40° C. in the presence of aluminum chloride until no more is absorbed. Under these conditions, ethylene yields β-chloropropionyl chloride, which boils at 144.5° C.; and isoamylene, β-chloro-γ-methylvaleryl chloride, which boils at 168° C. Styrene and phosgene react to yield β-chloro-β-phenylpropionyl chloride (which melts at 139° C. with decomposition). This latter reaction may be represented thus:



$$\begin{matrix}C_6H_5CH\\ \| \\ CH_2\end{matrix} + COCl_2 \longrightarrow C_6H_5CHClCH_2COCl$$

This synthesis of β-chloroacid chlorides appears to be of interest because of its possible large-scale use in the production of acids similar to acrylic acid and its homologues, since β-chloro acids readily lose hydrogen chloride to form unsaturated acids of that type. For example, esters of acrylic acid are said to be produced by heating esters of β-chloropropionic acid in the presence of catalysts such as barium phosphate, concentrated sulphuric or phosphoric acid, or zinc chloride.[62]

CONDENSATION OF OLEFINS WITH BASES

The combination of ammonia and amines with olefins is a typical example of reaction which, although extremely promising from a scientific and technical standpoint, has received practically no attention from those interested in the chemical utilization of the olefins. On the purely scientific side, Taylor and Emeléus[63] studied the photochemical reaction of ethylene with ammonia and although the production of organic basic products was noted, the exact chemical nature of these products was not determined. Evidence from other sources, however, leads to the conclusion that the catalytic combination of olefins with ammonia results primarily in the formation of an alkylamine, thus:

$$C_2H_4 + NH_3 \longrightarrow C_2H_5.NH_2$$

and this reaction is in all probability reversible within certain temperature limits. At higher temperatures, secondary changes may occur with the production of nitriles and cyclic bases.

The direct catalytic combination of ethylene and ammonia in the vapor phase at elevated temperatures and increased pressures is stated by Wietzel[64] to produce ethylamine. The product obtained by reducing ammonium molybdate in a current of hydrogen, can be used as a catalyst for this process. The direct combination of ethylene and primary or secondary amines at temperatures up to 400° C., in the presence of a catalyst to furnish secondary and tertiary organic bases, has also been suggested by Nicodemus and Schmidt.[65] Activated hydrosilicates may be used as catalysts for the alkylation of ammonia and amines by ethylene under pressure.[66] The condensation of aniline with ethylene to produce substituted anilines, as well as tertiary bases containing heterocyclically combined nitrogen, has also been stated to take place in the presence of cerium metaphosphate (or other phosphate, borate, or arsenate not reducible with hydrogen) at 200° to 400° C. under pressures above atmospheric.[67]

Alkaline earth cyanamides have been prepared by passing ammonia and olefins over oxides or carbonates of the alkaline earths at 400° to 1000° C.[67a]

The condensation of ethylene with ammonia with the production of acetonitrile has been effected, for example,[68] by passing a mixture of 10 volumes of ammonia, 10 volumes of ethylene, 30 volumes of hydrogen, and 5 volumes of nitrogen over zinc sulphate on silica gel at 450° C. A 95 per cent yield of acetonitrile is thus obtained. The formation of acetonitrile can be explained on the assumption that ethylamine, which is first formed, undergoes thermal dehydrogenation to acetonitrile:

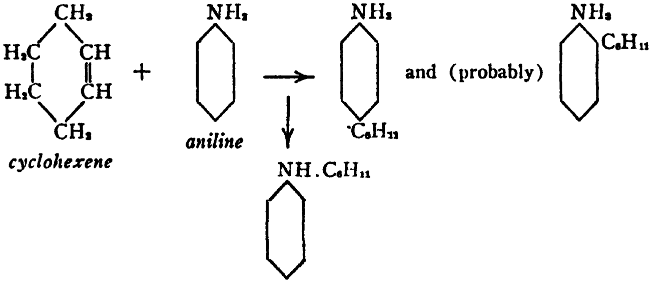
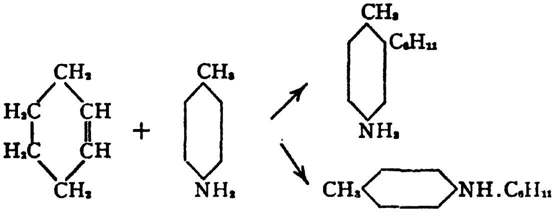
$$C_2H_4 + NH_3 \longrightarrow CH_3CH_2NH_2 \longrightarrow CH_3CN + 2H_2$$

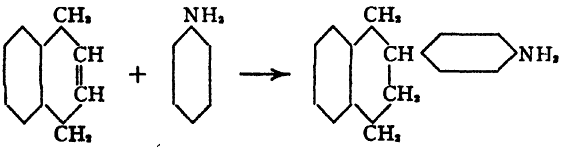
Olefinic hydrocarbons can be condensed with aniline or similar arylamines by heating the reactants together in sealed tubes to temperatures up to 270° C. Hickinbottom[69] found that trimethylethylene reacted with aniline cobaltochloride, cobaltobromide, or hydrobromide, to yield the corresponding salts of p-amino-tert-butylbenzene. Later[70] he observed that cyclohexene condensed with aniline and its hydrochloride, when heated in sealed tubes at 200° to 270° C., to produce 4-aminophenylcyclohexane together with an isomeric primary base, probably 2-aminophenylcyclohexane, and also some cyclohexylaniline. The reaction can therefore be represented as follows:



In a similar way, cyclohexene and p-toluidine yielded a mixture from which 4-amino-3-cyclohexyltoluene and cyclohexyl-p-toluidine were isolated.



The condensation of 1,4-dihydronaphthalene with a mixture of aniline and its hydrochloride by heating in a sealed tube at 200° to 300° C. yielded mainly 2-p-aminophenyl-1,2,3,4-tetrahydronaphthalene, as represented:



It is evident, therefore, that two main types of condensation occur in the condensation of olefins with primary arylamines under the conditions studied by

---

Hickinbottom, namely (1) a direct alkylation of the aromatic nucleus with the production of an alkylated primary arylamine, and (2) alkylation of the amino-group with the formation of a secondary base.

Resinous condensation products of carbazole (or its derivatives) with olefins have also been described.[71] Mono- or poly-alkylated carbazoles or higher condensation products are said to be obtained by heating carbazoles with olefins at 100° to 200° C. in the presence of aluminum chloride, fuller's earth, tonsil, or frankonite,* in an inert solvent such as light petroleum. Propylene condenses with carbazole to give a soft resin, which boils at 210° to 240° C. at 1 mm. and which is probably diisopropylcarbazole, and with N-ethylcarbazole also to form a soft resin which boils at 200° to 230° C. at 1 mm. Cyclohexene and carbazole yield a hard resin which distils at 270° to 340° C. at 1 mm.

Chapter 25

Miscellaneous Reactions of Olefins (II)

In the preceding chapter were discussed some of the miscellaneous reactions of the simpler olefins with the more generally known types of organic compounds, such as aromatic hydrocarbons and phenols. In this chapter are included reactions with a number of other substances such as sulphur dioxide, ketones, and nitrogen trichloride. The action of sulphonating agents on olefins to yield derivatives of ethionic acid is discussed in Chapter 46. With the exception of those reactions involving the use of oxides of nitrogen, which have been employed for the oxidation of petroleum hydrocarbons (see Chapter 39), these reactions apparently have been applied industrially to only a limited extent. Some of them, however, are the basis for analytical procedures, e.g., the estimation of unsaturated hydrocarbons with iodine monochloride (particularly for edible oils and fats), or with sulphur monochloride or mercuric acetate (for the lighter petroleum distillates). These reactions are of some interest both from the standpoint of the general properties and possible derivatives of the simpler olefins obtained from petroleum hydrocarbons, especially those from cracking operations.

CONDENSATION OF OLEFINS WITH KETONES

Little work has been reported of the direct combination of olefins with ketones. Brown,[1] however, synthesized higher ketones, for example, methyl propyl ketone, by condensation of an olefin (ethylene) with a ketone (acetone). Pressures of over 50 atmospheres and a catalyst—a mixture of zinc and chromium oxides and zinc chloride—which accelerates hydrogenation and dehydrogenation are recommended. If this reaction should prove to be a general one for the alkylation of ketones, it would present an interesting aspect. Presumably ethylene and acetone react in the following manner:

$$C_2H_4 + CH_3COCH_3 \longrightarrow C_3H_7COCH_3$$

REACTION OF SULPHUR DIOXIDE AND SULPHITES WITH OLEFINS

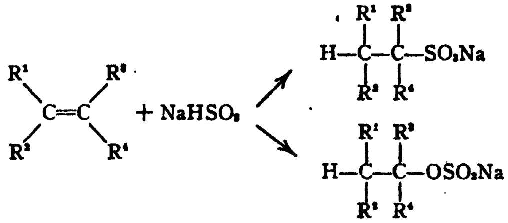
Sulphur dioxide, sulphurous acid, or sulphites combine directly with many olefins under appropriate conditions.[2] The products, unlike those obtained by the action of sulphuric acid on the monolefins, are not esters of the corresponding alcohols, but are very frequently stable sulphonic acids or condensed sulphur compounds of the sulphone type. In both of these types of compounds, the sulphur atom is linked directly to a carbon atom and hydrolysis to an alcohol is impossible. The reaction with sulphurous acid is greatly influenced by the introduction of a carbonyl group in a position adjacent to the double bond, as in the α-unsaturated ketones. This discussion, however, is limited to the reactions of the simple monolefin hydrocarbons.

---

[1] U. S. Patent 1,757,830, May 6, 1930; assigned to Commercial Solvents Corp.; *Chem. Abs.*, 1930, 24, 3247.

[2] The addition of sulphites to acrylic, crotonic, cinnamic and other unsaturated acids was studied by Hägglund and Ringbom (*Z. anorg. allgem. Chem.*, 1926, 150, 231; *Chem. Abs.*, 1926, 20, 1165).

Matthews and Elder[3] stated that sulphur dioxide can combine with butylene and the amylenes under the influence of heat and light with the production of amorphous horn-like solids, that from butylene having the composition $(C_4H_8SO_2)_n$. The direct combination of ethylene hydrocarbons with sodium, potassium, or ammonium bisulphite was studied by Kolker and Lapworth.[4] The main products of the reaction were the salts of alkylsulphonic acids, admixed with variable proportions of other salts, possibly alkyl bisulphites. Kolker and Lapworth expressed this result by the general reaction:



Cyclohexene was shaken with 0.25 molar ammonium bisulphite solution and kieselguhr at ordinary temperature for several days. Kieselguhr, used as an emulsifying agent, was found to have a favorable influence on the yield of sulphonate, especially when excess bisulphite was used. The product was cyclohexanesulphonic acid, isolated as its soluble barium salt. Ethylene and 0.25 molar ammonium bisulphite solution at ordinary temperature and pressure yield ethanesulphonic acid (amide, m.p. 59° to 60° C., soluble in water) and technical amylene yielded 86 per cent of crude soluble barium salts consisting of true sulphonic acid derivatives. From dipentene there was obtained mainly barium menthanedisulphonate.

Seyer and King[4a] found that pure cyclohexene did not react with dry sulphur dioxide. The presence of oxygen, however, caused the formation of an insoluble compound, $(C_6H_{10}SO_2)_x$. Cyclohexadiene, on the other hand, reacted readily even in the absence of oxygen to form a white amorphous compound, $(C_6H_8SO_2)_x$.

The direct combination of styrene with bisulphites was investigated by a number of workers[5] but with somewhat inconclusive results.

Sulphur dioxide reacts with diolefins[6] to form polymerized sulphones, of the type $(C_nH_{2n-2}SO_2)_n$. It has been stated, however, that in the presence of stabilizing substances, particularly polyhydric phenols, unpolymerized sulphones can be obtained.[7]. For example, butadiene, liquid sulphur dioxide, and 1 per cent of quinol react slowly at 15° C. to yield the sulphone

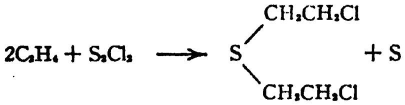
Corresponding products may be obtained from substituted butadienes and from isoprene. All such products are decomposed by heating to 120° C.

On treating unsaturated fatty acids or esters (e.g., train oil) with air and a sulphite or bisulphite a mixture containing partly oxidized and partly sulphited products which form emulsions with hot water results. Such emulsions can be used for the treatment of leather.[7a]

REACTIONS OF SULPHUR AND SELENIUM CHLORIDES WITH OLEFINS

The reaction of sulphur chloride and ethylene was first investigated by Despretz,[8] the product being an unpleasant-smelling viscous liquid. Guthrie [8a] later described a product made in a similar manner, which was isolated without distillation and which had the empirical formula $C_4H_8Cl_2S_2$. Pope [9] subsequently showed that this was merely a solution of sulphur in ββ′-dichlorodiethyl sulphide and that the reaction proceeded in the following manner:



$$2C_2H_4 + S_2Cl_2 \longrightarrow S\begin{cases} CH_2CH_2Cl \\ CH_2CH_2Cl \end{cases} + S$$

It was found that the reaction must be carried out at temperatures below 70° C. to prevent considerable decomposition which otherwise ensues. The further remarkable fact was demonstrated, namely, that almost quantitative yields of ββ′-dichlorodiethyl sulphide are obtained by using ethylene containing a trace of alcohol vapor, whereas pure ethylene does not yield so pure a product.

ββ′-Dichlorodiethyl sulphide was used extensively during the World War as a poison gas (mustard gas or yperite) and was the most toxic of all such gases then available. As far as is known it is not employed in chemical synthesis, though it offers distinct possibilities in that direction.[10] Dichloroethyl sulphide may be used in the preparation of paints for the protection of ship bodies from deposits of shells.[10a]

The reaction of sulphur chloride with other olefins has been little investigated, but polymerization appears to be the main result. When propylene is treated with sulphur chloride at 50° to 60° C., condensation to dark colored semi-solid materials occurs.[11]

Mineral oils which had been subjected to the influence of light in the presence of aluminum sulphate can be converted to a rubber substitute, according to Girón,[11a] by heating with sulphur or sulphur chloride and magnesium oxide.

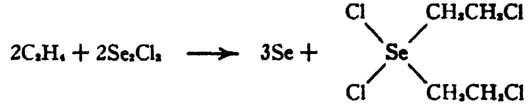
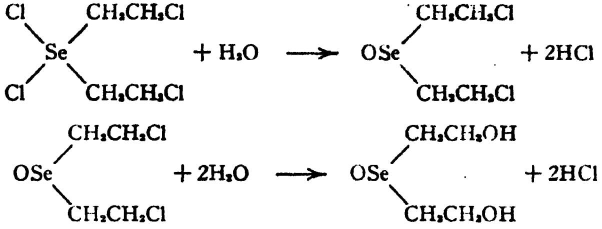
Ethylene reacts with *selenium monochloride*[12] to yield free selenium and ββ'-dichlorodiethyl selenide dichloride, thus:



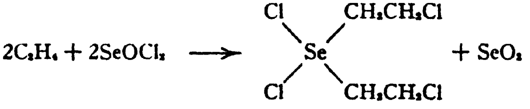
It was shown by Boord and Cope[13] that this reaction actually takes place in two stages, the free selenide being produced in the presence of an excess of ethylene while the selenide dichloride is always formed when the selenium monochloride is in excess. Similar reactions were observed in the case of propylene and butylene.

Hydrolysis of these selenide dichlorides results in the elimination of the chlorine.[14] In this manner ββ'-dichlorodiethyl selenide dichloride is converted to ββ'-dichlorodiethyl selenide oxide and this in turn to ββ'-dihydroxydiethyl selenide oxide.



Heating ββ'-dichlorodiethyl selenide dichloride to 120° to 130° C. gives selenium and ethylene chloride.

The reaction between *selenium oxychloride* and several of the monolefins has been studied by Frick.[15] It was found that the corresponding chloroalkyl selenide dichlorides are always produced regardless of whether the olefin or the oxychloride is in excess. Since selenium dioxide is the only other product of the reaction, the change can be represented, in the typical case of ethylene, by



or, generally

$$2C_nH_{2n} + 2SeOCl_2 \longrightarrow (ClC_nH_{2n})_2SeCl_2 + SeO_2$$

Thus, on passing dry ethylene into a solution of selenium oxychloride in anhydrous chloroform, ββ'-dichlorodiethyl selenide dichloride was obtained as white crystals, which melted at 121.5° C. In the same way propylene, butene-2 and amylene yielded the corresponding propyl, butyl, and amyl derivatives, respectively.

Lenher[16] recommended selenium oxychloride as a solvent for the removal of unsaturated hydrocarbons from mixtures with saturated hydrocarbons, as the latter do not dissolve in this solvent.

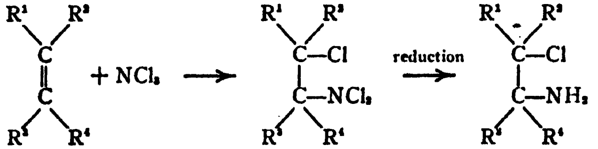
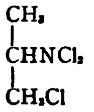
Reactions of Nitrogen Trichloride and Nitrosyl Chloride with Olefins

Nitrogen trichloride combines directly with many olefins in dry carbon tetrachloride solution at low temperatures (—10° C.) with the formation of C-chloro-N-dichloramines, many of which readily undergo reduction in the presence of dry hydrogen chloride to yield monochloro-derivatives of aliphatic amines. These reactions may be represented in the following general manner:



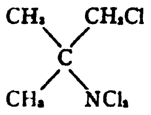
They have been investigated by Coleman and his collaborators.[17] Great differences were found in the rate of reaction of the individual simple olefins with this reagent. This difference is indicated by the fact that at 20° to 25° C., two weeks or more are required for the completion of the reaction with ethylene, while with isobutylene the reaction, even at —45° to —50° C., is complete within two or three hours.

Ethylene reacts with nitrogen trichloride to form nitrogen, ammonium chloride, ethylene dichloride, and 2-chloro-1-dichloramino-ethane, the latter compound being converted by hydrogen chloride into 1-amino-2-chlorethane. Propylene reacts more rapidly than ethylene to yield similar products, but only one of the two possible chloramines is formed:



$$\begin{array}{l} CH_3 \\ | \\ CHNCl_2 \\ | \\ CH_2Cl \end{array}$$

With isobutylene, a stable chloramine of the constitution

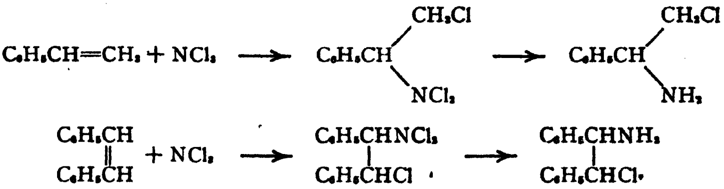


was formed. This compound was not reduced by hydrochloric acid (as were its homologues) but was converted into its hydrochloride. Butene-2 combines with nitrogen trichloride fairly rapidly with the formation of a moderate yield of 2-chloro-3-dichloraminobutane, readily convertible into 2-chloro-3-aminobutane. Butene-1 yields only one of the two possible isomers, namely, 1-chloro-2-dichloraminobutane. Trimethylethylene yielded no chloramine but only chlorinated derivatives. Stable compounds were obtained from pentene-2 and cyclohexene.

The behavior of certain aryl-substituted olefins toward nitrogen chloride was also investigated. Styrene and stilbene react fairly rapidly with nitrogen trichloride in carbon tetrachloride solution to form nitrogen, the dichloride of the hydrocarbon, a small amount of ammonium chloride and a C-chloro-N-dichloramine, which in each case is readily convertible to the corresponding C-chloramine. The constitution of the bases formed are as follows:

---

[17] Coleman and Howells, *J.A.C.S.*, 1923, 45, 3084; Coleman, Mullins and Pickering, *J.A.C.S.*, 1928, 50, 2739; Coleman and Campbell, *J.A.C.S.*, 1928, 50, 2754.

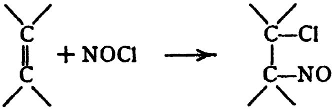


Several other aromatic olefins were studied, namely, 1,1-diphenylethylene, 1,1-diphenylpropene-1, triphenylethylene, and tetraphenylethylene. None of these yielded stable addition products with nitrogen trichloride.

The reaction of *nitrosyl chloride* with unsaturated hydrocarbons was first observed with the terpene hydrocarbons by Tilden and Shenstone.[18] It soon proved a valuable reagent for the study of these complex substances, with which it frequently forms characteristic crystalline addition compounds useful for identification purposes.[19] The first observation of the addition of nitrosyl chloride to simple olefins appears to have been made with amylene.[20]

Of the olefins which are capable of combining additively with nitrosyl chloride, the following types may be mentioned: trimethyl- and tetra-methylethylenes,[21] cyclohexenes,[22] ethylene derivatives of the type $R_2C{=}CH_2$, and hydrocarbons,[23] having a semicyclic double bond and a side chain, such as methylenecyclopentane. As a general rule, unsaturated hydrocarbons possessing the structure $>C{=}CH_2$ or $—CH{=}CH_2$ do not normally yield crystalline products with nitrosyl chloride. On the other hand those with the structure $R_2C{=}CR_2$ usually form crystalline nitrosochlorides.[24]

The action of nitrosyl chloride on olefins to give nitrosochlorides may be represented by



These nitrosochlorides, which are conveniently prepared by the addition of concentrated hydrochloric acid to a solution of the olefin and ethyl nitrite in glacial acetic acid at 10° C., are generally crystalline, bimolecular solids.[25] On treatment with alkalies they readily yield oximes, from which ketones may be obtained, so that they are often valuable in deciding questions of constitution. For example, on carefully warming the nitrosochloride of trimethylethylene with alkalies the isomeric oxime is obtained.

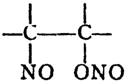
$$\begin{array}{c}(CH_3)_2CCl\\ |\\ CH_3CHNO\end{array} \longrightarrow \begin{array}{c}(CH_3)_2CCl\\ |\\ CH_3C{=}NOH\end{array}$$

Nitrosochlorides may be condensed with amines to yield stable condensation products.

Among the simple olefins, the ability to combine directly with nitrosyl chloride increases with increasing molecular weight and particularly with the introduction of methyl groups into the molecule. While propylene combines with nitrosyl chloride to form both propylene dichloride and propylene nitrosochloride, ethylene forms only ethylene dichloride.[26]

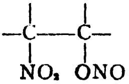
Reaction of Nitrogen Oxides with Olefin Hydrocarbons

When nitrous acid fumes are allowed to react with olefins at low temperatures a number of products are obtained, among which the so-called nitrosites and nitrosates are of importance. These substances, which in the solid state are usually bimolecular and hence are called bisnitrosites and bisnitrosates, are characterized by the following groupings:



$$-\underset{\mathrm{NO}}{\underset{|}{\overset{|}{\mathrm{C}}}}-\underset{\mathrm{ONO}}{\underset{|}{\overset{|}{\mathrm{C}}}}-$$

nitrosites



$$-\underset{\mathrm{NO_2}}{\underset{|}{\overset{|}{\mathrm{C}}}}-\underset{\mathrm{ONO}}{\underset{|}{\overset{|}{\mathrm{C}}}}-$$

nitrosates

The action of pure nitrogen tetroxide (N_2O_4) on olefins gives rise to solid bisnitrosates[27] but the yields are very poor, being often only about 10 per cent of those obtained with amyl nitrite and nitric acid at —10° C.[28] The formation of solid compounds with nitrogen peroxide appears to be a general property of olefins which contain the double bond between a secondary and a tertiary or between two tertiary carbon atoms. The experiments of Schaarschmidt and Hofmeier showed that the addition of nitrogen peroxide to various olefins is accompanied by oxidation and that the addition compounds undergo internal oxidation, particularly if the temperature of the reaction is allowed to rise, resulting in the reduction of nitric oxide residues mainly to nitrogen. It seems probable that the phases of the addition may correspond with the production of the forms

$—CH(NO)CHONO_2—$
$—CH(NO_2)CHONO—$
$—CH(NO_2)CHNO_2—$
and $—CH(ONO)CH(ONO)—$

The bisnitrosates react readily with aniline to give uniform yields (70-80 per cent) of the corresponding nitrolamines. Thus, 2-methylpentene-2 nitrosate condenses with aniline to yield 2-methylpentene-2 nitrolaniline, a solid melting at 86° C.

Demyanov and Williams[29] made addition compounds of nitrogen trioxide and tetroxide with unsaturated hydrocarbons. Some of these were crystalline and stable, while others were liquids and sometimes decomposed violently. They also reported that: (1) reduction of the addition products of nitrogen oxides to unsaturated hydrocarbons may serve for the preparation of diamines or hydroxyamines; and (2) no direct nitration of an unsaturated fatty nitro-compound by nitric acid is known to occur, therefore nitro-compounds formed are decomposition products of the original addition compounds.

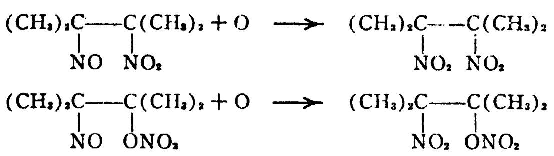
The action of ***nitrogen pentoxide*** on ethylene and related hydrocarbons has been studied by Demyanov.[80] Glycol nitrates and addition products, in which nitrogen is linked to carbon, were formed. Tetramethylethylene gave three crystalline addition compounds: $C_6H_{12}N_2O_6$, $C_6H_{12}N_2O_5$, and $C_6H_{12}N_2O_4$, which were reduced to pinacol, glycolamine and diamine, respectively. No crystalline substances could be isolated from the products of the reaction with ethylene but the nitrate was detected by its explosive character, and diaminoethylene, $(CH_2NH_2)_2$, and glycolamine were obtained after reduction. This seemed to indicate the presence of $C_2H_5N_2O_6$. It was observed also that nitrogen pentoxide added easily to cyclohexene. In addition to the nitric esters, which were the main reaction products in each instance, dinitro-compounds, dinitro-alcohols, and nitro-nitrates were obtained.

Demyanov suggested that the colored nitroso-compounds may be intermediate reaction products, as follows:



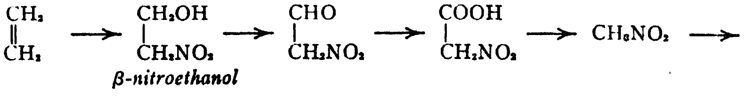
$$\underset{NO}{(CH_3)_2C}\text{—}\underset{NO_2}{C(CH_3)_2} + O \longrightarrow \underset{NO_2}{(CH_3)_2C}\text{—}\underset{NO_2}{C(CH_3)_2}$$

$$\underset{NO}{(CH_3)_2C}\text{—}\underset{ONO_2}{C(CH_3)_2} + O \longrightarrow \underset{NO_2}{(CH_3)_2C}\text{—}\underset{ONO_2}{C(CH_3)_2}$$

Haines and Adkins[81] observed no reaction between nitrogen pentoxide and ethylene, and obtained no crystalline substances from tetramethylethylene or cyclohexene. Stilbene formed addition compounds, and a flame hot enough to melt platinum was produced by the reaction of nitrogen pentoxide with a mixture of pentenes.

Since the nitrosates are readily split by heating with concentrated hydrochloric acid to yield fatty acids, it has been proposed to use them in the determination of the constitution of olefins.[82] From a technical point of view, however, the nitrosates and nitrosites thus far have been of little interest.

The action of ***nitric acid*** upon olefins usually results in violent oxidation reactions, but in the case of ethylene two well-defined reaction products have been isolated. Thus, McKie[83] considered that the reaction occurs in accordance with the following:



$$\begin{matrix}CH_2\\ \|\\ CH_2\end{matrix} \longrightarrow \begin{matrix}CH_2OH\\ |\\ CH_2NO_2\end{matrix} \longrightarrow \begin{matrix}CHO\\ |\\ CH_2NO_2\end{matrix} \longrightarrow \begin{matrix}COOH\\ |\\ CH_2NO_2\end{matrix} \longrightarrow CH_3NO_2 \longrightarrow$$

β-nitroethanol

$CH(NO_2)=NOH \longrightarrow CH_2=(NO_2)_2 \longrightarrow C(NO_2)_2=NOH \longrightarrow CH(NO_2)_3$

nitroform

---

[80] *Compt. rend. acad. sci. U.S.S.R.*, 1930A, 447; *Chem. Abs.*, 1931, 25, 1215.
[81] *J.A.C.S.*, 1925, 47, 1419.
[82] Jegorov, *J. prakt. Chem.*, 1912, (2) 86, 521; *Chem. Soc. Abs.*, 1913, 104 (1), 153.
[83] *J.C.S.*, 1927, 962.

Of the above substances only β-nitroethanol and nitroform were definitely isolated, the yield of nitroform varying with the concentration of the nitric acid. Side reactions, mainly oxidation to oxalic acid, may account for 30 to 40 per cent of the ethylene. These can be partly inhibited by the addition of slightly less than 1 per cent of mercuric nitrate, which accelerates the reaction and increases the yield of nitroform.

When ethylene is passed into a well-cooled mixture of nitric and sulphuric acids an oil separates which consists of a mixture of ethylene glycol dinitrate and β-nitroethyl nitrate.[34] Separation of these compounds may be effected by fractional distillation or the mixture may be used directly as a substitute for nitroglycerol in low-freezing dynamites. Propylene and butylene form corresponding derivatives.

Forrest and Meigs [35] described the preparation of resinous materials by the action of dilute nitric acid on distillates containing high proportions of unsaturated hydrocarbons. Nitric acid is added in small portions to the distillate maintained at about 93° C. (200° F.) and the resins are separated by cooling. They may be combined or mixed with pyroxylin in all proportions in the presence of a mutual solvent.

DOUBLE COMPOUNDS OF OLEFINS WITH INORGANIC SALTS

Many of the olefins form double compounds with inorganic salts or inorganic salt solutions in water, alcohol or other solvents containing hydroxyl groups. Among the inorganic substances which appear to be capable of combining with olefins are aluminum, silver, cuprous, mercuric, platinous and ferrous salts. Many of these double compounds have been prepared in a crystalline condition [36] while others are known only in solution. The majority seem to be ordinary molecular compounds, easily resolved into their components. Thus, aqueous solutions of cuprous and silver salts absorb large quantities of ethylene at low temperatures, but the ethylene is expelled on raising the temperature. The use of aqueous solutions of silver nitrate at 10° C. for absorbing ethylene from gases has been described by Horsley.[37] The ethylene is regenerated by warming the solution to 50° to 70° C. Curme [38] suggested a similar method in which ethylene is absorbed in a solution of a mercury salt, e.g., mercuric sulphate, from which it is easily expelled by heating.

Of the double compounds of olefins with inorganic salts, those with mercury have received the most attention. The gaseous olefins readily form complex mercury compounds [39] from which the olefins may be regenerated by the action of hydrochloric acid. The corresponding reaction of the higher olefins is frequently accompanied by reduction of the mercuric salt to the mercurous salt with simultaneous oxidation of the hydrocarbon. When alcoholic solvents are employed, the solvent also enters into the reaction and the final products contain an alkoxyl group.

The compounds of mercuric acetate with cyclohexene, methylcyclohexene and the terpenes were described by Tausz.[40] He also succeeded in preparing double compounds of amylene and hexene.[41] Hugel and Hibou[42] found that for each olefin the addition compounds with mercuric salts have variable compositions according to the experimental conditions. It was also observed that while the higher olefins react slowly or not at all in aqueous solution (although the reaction is accelerated in alcoholic solution[43]), olefins of the type of tetramethylethylene and the tetra-alkylethylenes as a class definitely do not react.

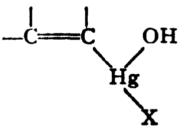
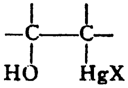
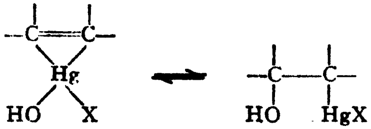
The compounds of ethylene with mercury salts have been most investigated. Considerable controversy has raged on the question of the constitution of these compounds. Manchot[44] regarded them as molecular addition compounds represented by structure I (see below) though the more common theory is that these compounds are true addition compounds of type II. On the other hand, Sand[45] has represented them as an equilibrium mixture between a molecular addition product and the ordinary type of addition compound (type III).



Type I



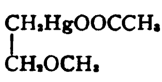
Type II



Type III

The merits of the three structures have been rather fully discussed by Adams, Roman and Sperry.[46] At the present time the evidence seems to show that these compounds are true addition compounds of type II. This is supported by the work of Adams, Roman and Sperry on the addition of mercuric salts to o-allylphenol and the preparation of optically active mercury compounds from olefins of the type $RR^1C{=}CRR^1$ by Sandborn and Marvel.[47]

In the formulas given above, representing the mercury addition compounds, an alkyl group may replace a hydrogen atom in the hydroxyl group when alcoholic solvents are used instead of water. Thus, mercuric acetate in methanol solution readily combines with ethylene to yield the ether,[48]



$$\begin{array}{l}CH_2HgOOCCH_3\\ |\\ CH_2OCH_3\end{array}$$

It is probable that some of these double compounds with mercuric salts will be employed in the future for the preparation of various organic substances. Schoeller[49] has described the preparation of $\beta\beta'$-dihalogeno-ethers therefrom. On shaking an aqueous suspension of mercuric sulphate vigorously with ethylene under pressure, the gas is absorbed rapidly with the formation of soluble dimercurated compounds. On addition of aqueous potassium iodide to the filtered liquid, $\beta\beta'$-bisiodomercuridiethyl ether is obtained in 95 per cent yield together with a little β-hydroxy-β'-iodomercuridiethyl ether. By the action of iodine in warm ethyl acetate, the former substance is converted into $\beta\beta'$-di-iododiethyl ether, a liquid boiling at 93°-94° C. at 1 mm. pressure. The dichloro- and dibromo-derivatives may be similarly prepared and propylene and higher olefins react in an analogous manner. The reaction may be represented as

in which X is a halogen atom. A more complete investigation of such reactions would undoubtedly be valuable.

Kharasch[49a] suggested the use of mercuriated olefins or their chlorine, cyanogen or hydroxyl derivatives in the preparation of seed disinfectant compositions.

OTHER REACTIONS OF OLEFINS

The *hydrogenation* of olefins has been frequently employed for the preparation of some of the higher liquid paraffins. The reaction, within certain limits of temperature, is reversible, hydrogenation being favored by low temperatures and dehydrogenation by higher temperatures. Catalysts for the hydrogenation of olefins include metallic nickel, cobalt and copper, as well as platinum and palladium. A comprehensive investigation of the two latter materials in the hydrogenation of numerous unsaturated substances at 2 to 3 atmospheres pressure of hydrogen at 25° C. has been made by Kern, Shriner and Adams.[50]

The direct combination of *hydrogen sulphide* with olefins should proceed according to

$$C_nH_{2n} + H_2S \longrightarrow C_nH_{2n+1}SH$$

and lead to the production of mercaptans. Nisson and Mandelbaum[51] and Johansen[52] have described the formation of mercaptans in this manner. Both subjected vapors containing olefins and hydrogen sulphide to the action of an adsorptive catalyst (fuller's earth or silica gel). Johansen[53] also suggested that mercaptans be obtained by the reaction between unsaturated hydrocarbons and hydrogen sulphide at ordinary temperatures in the presence of sulphuric or other inorganic acids.

The combination of hydrogen sulphide with ethylene, propylene, butene-1 and amylene at high temperatures (650° to 725° C.) in the presence of silica gel as the contact material has been studied by Mailhe and Renaudie.[54] A wide variety of products was obtained, including hydrogen, methane, saturated and unsaturated hydrocarbons, mercaptans, thioethers, thiophene and its homologues, and carbon disulphide. The thiophenes and thioethers were derived from the progressive decomposition of the mercaptans initially formed. The proportion of carbon disulphide increased with rising reaction temperature. Evidently, in order to obtain good yields of mercaptans, lower temperatures and catalysts more active than those used are necessary.

Duffey, Snow and Keyes[54a] tested the effect of various catalysts, time of contact, and temperature on the reaction of olefins with hydrogen sulphide. Equal volumes of the gases were passed through pyrex glass tubes containing catalyst at 200° to 300° C. Both ethylene and propylene formed mercaptans, with negligible proportions of alkyl sulphides. Maximum conversion of propylene was obtained at 200° C. with a low rate of flow of the gas through the tube and with nickel on kieselguhr or phosphoric acid on charcoal as catalyst. Ethylene gave best results at 250° C. with nickel on kieselguhr.

The direct addition of the disulphide group (–S–S–) to the double bond of styrene and amylene, which could not be effected with hydrogen sulphide, was accomplished by King and Wilkinson[55] by treating these hydrocarbons with hydrogen persulphides.

Keller[55a] prepared sulphurized hydrocarbon derivatives which can be used as insecticides by heating unsaturated hydrocarbons or their halogen, hydroxy or amino derivatives with sulphur, hydrogen sulphide or polysulphides. Thus, a trichlorinated hard paraffin wax may be heated to 140° C. under pressure with potassium hydroxide saturated with hydrogen sulphide.

On passing a mixture of ethylene and acetylene at a high temperature over activated silica-gel mixed with pyrites, products containing thiophene and pyridic substances are said to result.[55b]

It has long been known that the introduction of a carbonyl, cyano, or similar group into an olefin molecule in a position adjacent to the double bond confers upon the resulting $\alpha\beta$-unsaturated ketone (nitrile or similar compound) remarkable powers of condensation with numerous reagents such as ammonia, amines, urea, semicarbazide, mercaptans and hydrogen cyanide. This activity has been regarded as due entirely to the combined ethylene-carbonyl (or ethylene-cyano) group. It is possible that many of the reactions of the ethylene-carbonyl group will be found to be possessed, to a lesser extent perhaps, by the simple olefins when the conditions for the combination of the latter substances have been carefully investigated. It is admitted, however, that in many cases combination appears to be extremely difficult to effect. Experiments on the direct combination of hydrogen cyanide, for example, with olefins including cyclohexene and styrene, have given uniformly negative results.[56]

Birckenbach and Linard[57] described the direct combination of iodine cyanate, prepared by the action of iodine on silver cyanate, with olefins to yield iodo-olefin isocyanates. Thus, cyclohexene in ether at —80° C. readily combines with this reagent to form 2-iodocyclohexylisocyanate (boiling point, 94° C. at 2 mm.) in 72 per cent yields.

It appears that certain "free" radicals, such as the cyanogen and thiocyanogen groups, can unite with olefins directly, provided the radical is generated in the nascent state. Kaufmann and Liepe[58] obtained combination of unsaturated hydrocarbons with "free" thiocyanogen in glacial acetic acid solution. The free thiocyanogen, which possesses haloid properties, was generated *in situ* by the action of bromine on a solution of lead thiocyanate:

$$Pb(CNS)_2 + Br_2 \longrightarrow PbBr_2 + (CNS)_2$$

Some formation of ordinary (bimolecular) thiocyanogen takes place.

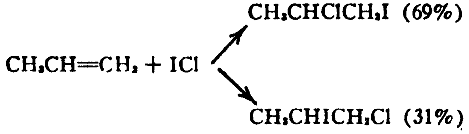
[58] *Ber.*, 1924, 57, 925.

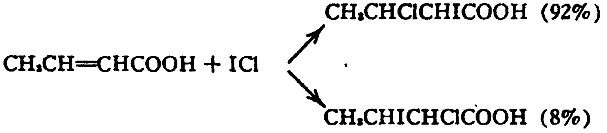
Mooney and Reid[59] showed that neither cyanogen nor cyanogen chloride or bromide react with ethylene at comparatively low temperatures (37° C.), but the reaction between cyanogen iodide and ethylene gives ethylene iodide and cyanogen.

Although iodine monochloride is a common reagent for determining the degree of unsaturation of many substances (e.g., vegetable oils), the manner in which it adds at the double bond has been investigated by only a few workers.[60] Ingold and Smith[61] observed that this substance reacts with the simple olefins to yield largely the α-iodo-compounds. For example, the reaction between propylene and iodine monochloride yields 69 per cent of α-iodo-β-chloro-propane and 31 per cent of α-chloro-β-iodo compound:



$$\begin{tikzcd}[row sep=small] & CH_3CHClCH_2I\ (69\%) \\ CH_3CH{=}CH_2 + ICl \arrow[ur] \arrow[dr] & \\ & CH_3CHICH_2Cl\ (31\%) \end{tikzcd}$$

In the case of olefins containing a substituted negative grouping, such as a phenyl, carboxyl, or sulphonic acid group, the iodine attaches itself to the carbon atom nearest the substitution. For crotonic acid, the addition can be represented by:



$$\begin{tikzcd}[row sep=small] & CH_3CHClCHICOOH\ (92\%) \\ CH_3CH{=}CHCOOH + ICl \arrow[ur] \arrow[dr] & \\ & CH_3CHICHClCOOH\ (8\%) \end{tikzcd}$$

The production of *acrylic acid* or its polymers by the direct vapor-phase combination of ethylene (or ethanol) with carbon dioxide has been described by the Röhm u. Haas A.-G.[62] The reaction is carried out under high pressure at high temperatures in the presence of ultraviolet light radiation (alone or with the silent electric discharge) and catalysts such as acidic gases (sulphur dioxide or oxides of nitrogen) or acid-reacting materials (e.g., acid salts of phosphoric acid or acid metallic oxides). By passing 26 grams of ethylene and 44 grams of carbon dioxide over silica gel or pumice impregnated with ferric phosphate at a temperature of 200° to 350° C. and a high gas velocity, yields of 10 per cent or more of acrylic acid are obtained. Longer heating periods and higher temperatures favor the formation of acrylic acid polymers.

Olefins react with formaldehyde, or better trioxymethylene, in an acetic-sulphuric acid medium to yield the diacetate of a glycol. This can then be hydrolyzed to the corresponding glycol in the usual manner. Such a procedure is applicable to the synthesis of 1,3-glycols of the aliphatic or hydroaromatic series.[63]

Unsaturated compounds obtained in the liquid sulphur dioxide extract from petroleum oils have been treated by Day[63a] with a 40 per cent solution of formaldehyde. A two-layer system was formed. The lower aqueous layer on evaporation left a resin, soluble in acetone and alcohol, which was said to be a substitute for shellac.

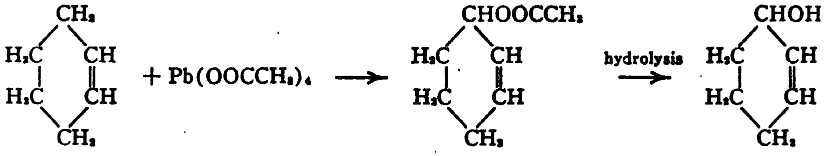
Criegee and Schoeller [64] have suggested a method for the conversion of cyclic monolefins into unsaturated alcohols (or their esters) by treatment with an organic salt of tetravalent lead (e.g., lead tetra-acetate). As an illustration, 45 grams of cyclohexene are stirred for several hours at 80° C. with 250 grams of lead tetra-acetate and 250 cc. of glacial acetic acid. The mixture is diluted with water, extracted with ether, and distilled under reduced pressure. The distillate contains 2-acetoxycyclohexene (boiling point, 68°-71° C. at 12 mm.), which can be hydrolyzed to cyclohexenol-2. The reaction, which is a type of oxidation, can be represented in the following manner:



In a similar manner menthenol acetate is obtained from menthene.

Chapter 26

Polymerization of Monolefins and Diolefins. Production of Synthetic Rubber

Although, strictly speaking, the term polymerization is usually reserved to designate those reactions of a reversible nature in which the union of two or more molecules takes place (exemplified by the well-known acetaldehyde-paraldehyde equilibrium), the term is conveniently used, when applied to hydrocarbons, to cover all conversions into higher molecular weight hydrocarbons of the same carbon-hydrogen atomic ratio, irrespective of reversibility.[1] It appears that the polymerization reactions of hydrocarbons are either completely irreversible or only reversible within very narrow limits.

The power of polymerization is an inherent property of unsaturated hydrocarbons as a class, including monolefins, diolefins, acetylenes, and diacetylenes,[2] and is not possessed by typical saturated hydrocarbons, such as paraffins and cycloparaffins, or by aromatic hydrocarbons. Calculations based upon free-energy data,[3] and upon the Nernst approximation formula,[4] show that the simple monolefins are thermodynamically unstable below about 425° C. Above this temperature there is an increasing tendency for decomposition to occur.[5] The tendency for olefins to polymerize is greatest at lower temperatures and diminishes with rising temperature, a deduction in agreement with the observed highly exothermic character of such polymerizations. Although polymerization is favored by low temperatures, the reaction velocity is usually low under such conditions, hence catalysts are highly advantageous in bringing about low-temperature polymerizations. It is obvious that increased pressures favor polymerization of the gaseous olefins.

According to Tammann and Pape[6] the velocity of polymerization of liquid styrene, vinyl acetate and diolefins increases with increasing pressure more rapidly than in other reactions which occur in the liquid phase, but the form of the relationship between velocity coefficient and pressure varies with the individual hydrocarbon. Increase of pressure also reduces the temperature at which polymerization commences.

The polymerization of olefins may be brought about by heat alone, without the aid of catalysts, but the favorable influence of higher temperatures on reaction velocity is often counterbalanced by a diminishing thermodynamic tendency to polymerization, and an increasing tendency for cracking to occur (see Chapter 2). Although many examples of purely thermal polymerization are known, the initial polymerization products are almost always further decomposed with the production of hydrogen, paraffins, and hydrocarbons with carbon-hydrogen ratios which differ from those of the olefin. A combination of moderate heat and high pressure favors the polymerization of olefins in the gaseous phase. Perhaps the most striking feature of olefin polymerization reactions, however, is the variety of catalysts capable of accelerating them. These catalysts include not only acids (such as sulphuric and phosphoric acids), but aluminum chloride, ferric chloride, boron trifluoride, zinc chloride, sulphur chloride, and other metallic salts, as well as activated charcoal, silica gel, floridin, and other adsorbent earths. The activity of many of these catalysts is increased with increased pressures (on gaseous materials) and with temperatures not exceeding about 400° C. The polymerization of olefins is frequently both initiated and accelerated by certain forms of energy such as ultraviolet radiation, silent electric discharge, and α-radiation. Here again, however, as in the thermal polymerization of olefins, the initial polymerization products frequently undergo further degradation, polymerization and splitting, so that the main reaction becomes obscured by a host of secondary changes.

---

[1] Condensation, on the other hand, is the union of two or more molecules with the splitting out of water, hydrogen chloride, or other substance to produce compounds which are usually not reconvertible by any simple method into the original molecules.

[2] The polymerization of acetylene and diacetylene homologues and derivatives is discussed in Chapter 28.

The products of polymerization of the simple monolefins differ greatly in physical and chemical properties, depending upon the conditions of polymerization and especially upon the catalyst used (if any). These products may vary, for example, from simple low-boiling dimers (substances with the same atomic proportions but with a molecular weight twice that of the parent substance) to viscous high molecular weight polymers, some of which have the appearance and consistency of heavy lubricants. Chemically, the fundamental initial stage of the polymerization is undoubtedly the formation of an olefin with twice the molecular weight of the original. Thus, in the case of ethylene, it has been shown that the first product of the polymerization is 1-butene, formed by the reaction

$$CH_2{=}CH_2 + CH_2{=}CH_2 \longrightarrow CH_3CH_2CH{=}CH_2$$

irrespective of whether heat treatment,[7] silent electric discharge,[8] or catalysts (such as aluminum chloride or boron trifluoride),[9] are employed. Unless conditions are so arranged that the 1-butene is removed rapidly from the sphere of reaction, it frequently undergoes further alteration. Many of the dimers and trimers of the butylenes and amylenes have been shown by numerous workers to be aliphatic olefins.

Although the initial stage of polymerization is undoubtedly the formation of a dimeric olefin, it does not usually stop at that point. Indeed, under the powerful polymerizing influence of such agents as aluminum chloride and boron trifluoride, it usually proceeds much farther, so that very high molecular weight hydrocarbons are produced. The polymerization to higher olefins may also be followed by ring closure of the higher olefins with the formation of saturated cycloparaffins of the formula C_nH_{2n}. The isomerization of the higher olefins to the corresponding cycloparaffins is possible from a thermodynamic standpoint at temperatures below about 400° C. This isomerization of olefins to cycloparaffins was observed by Ipatiev[10] in his work on ethylene. Other reactions may also degrade the higher olefins produced by the straight polymerization, such as the splitting off of paraffin hydrocarbon residues which occurs when aluminum chloride is employed.[11]

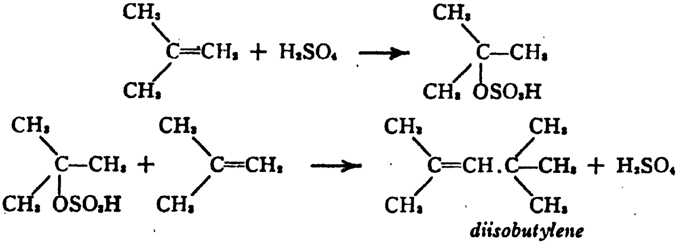
In the polymerization of olefins under the influence of heat, pressure, or catalysts, the initial product appears to be a dimer containing one double bond. However, the dimer is not always a straight-chain olefin, since there is a tendency for the production of a branched carbon chain. This phenomenon may be due to the tendency of olefins to isomerize, under the influence of heat and catalysts, to the corresponding iso-olefin. Thus, as will be mentioned later, isopropylethylene is isomerized by heat and catalysts to the isomeric trimethylethylene. An example of the isomerization of a straight-chain olefin to a branched-chain dimer is provided by the work of Hugel and Cohn[12] on hexadecene. When heated to 300° to 400° C. at pressures above 15 atmospheres this hydrocarbon undergoes polymerization to the dimer, $C_{32}H_{64}$, and the trimer, $C_{48}H_{96}$. A study of the dimeric hydrocarbon fraction led to the conclusion that it contained one solid monolefin of the formula $C_{32}H_{64}$ containing no side chain and with the ethylene bond located in the middle of the chain, together with liquid dimers ($C_{32}H_{64}$) with branched chains. Less of the solid dimer was formed at 400° C. than at 300° C., a result which supports the isomerization theory given above, since more of the straight-chain dimer can be expected to isomerize to branched-chain dimers at the higher temperature.

MECHANISM OF POLYMERIZATION

Although the phenomenon of polymerization is of great importance because of the valuable products produced from relatively simple raw materials, there is perhaps no subject in chemistry more difficult, both experimentally and theoretically, or so little understood. Clark[13] has distinguished two possible broad types of polymerization: (1) Simple kinetic molecules associate to form a singly acting unit by the action of residual or secondary valence forces, and (2) monomeric molecules or residues combine with each other under the influence of primary valence forces to form chains of indefinite length.

The polymerization of olefins by sulphuric acid was considered by Kondakov[14] to proceed through the intermediate formation of an alkylsulphuric acid which may then condense with another molecule of olefin, thus:



The polymerization of olefins by anhydrous metallic halides, such as boron trifluoride or aluminum chloride, undoubtedly involves the intermediate formation of organometallic complex compounds, which are usually obtained in the form of dark pasty masses insoluble in light petroleum.[15] The mechanism of polymerization in other cases, for example, during thermal treatment or under the influence of light or silent electric discharge, is still less understood. Brooks [16] stated that polymerization, in common with certain other phenomena, is really intimately connected with the nature of valence itself and that ordinary graphic formulas, in themselves, only inadequately furnish a plausible explanation. It is extremely likely, however, that as a preliminary to the addition of one olefin molecule to another, activation of the molecule occurs with the production of a reactive "free" radical with two free linkages.[17] The possible formation of free radicals has been definitely proved by positive-ray research on hydrocarbons and by the work of Paneth and Hofeditz [18] on the free methyl radical.

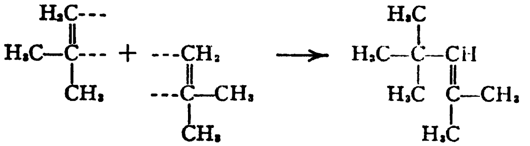
[13] *Ind. Eng. Chem.*, 1929, 21, 128.

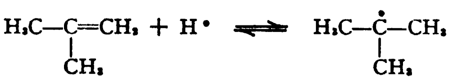
[14] *J. Russ. Phys.-Chem. Soc.*, 1893, 24, 309; *Chem. Soc. Abs.*, 1893, 64, 382; *J. prakt. Chem.*, 1896, (2) 54, 442, 454; *Chem. Soc. Abs.*, 1897, 72 (1), 209; see also Brooks, "Non-Benzenoid Hydrocarbons," Chemical Catalog Co., Inc., New York, 1922, 210; *J. Inst. Pet. Tech.*, 1928, 14, 752.

A graphical interpretation of polymerization has been proposed on the basis of Thiele's theory, according to which the doubly linked carbon atoms possess partial valences or "residues of free affinity." [19] The further assumption is made that the molecules contain a mobile or labile hydrogen atom which shifts from one molecule to another. The polymerization of isobutylene may then be expressed graphically:



$$H_3C{-}\underset{\underset{CH_3}{|}}{\overset{\overset{H_2C---}{\|}}{C}}{---} + \underset{\underset{\underset{CH_3}{|}}{---C{-}CH_3}}{\overset{---CH_2}{\|}} \longrightarrow H_3C{-}\underset{\underset{H_3C}{|}}{\overset{\overset{H_3C}{|}}{C}}{-}\underset{\underset{\underset{\underset{H_3C}{|}}{C{-}CH_3}}{\|}}{CH}$$

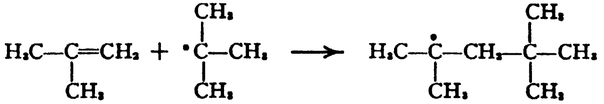
Whitmore [19a] proposed a theory for the mechanism of polymerization based upon the catalytic effect of hydrogen ions present in the reaction mixture. With isobutylene as an example, the first step in the reaction is the addition of a hydrogen ion to the olefin:



$$H_3C{-}\underset{\underset{CH_3}{|}}{C}{=}CH_2 + H^{\bullet} \rightleftharpoons H_3C{-}\underset{\underset{CH_3}{|}}{\overset{\bullet}{C}}{-}CH_3$$

(I) (II)

producing a tertiary butyl group (II) which is positively charged. In the same way that a hydrogen ion reacted with the olefin, the positively charged tertiary butyl group can now react with a molecule of the olefin (I) to yield the intermediate III, which is also positively charged:



$$H_3C{-}\underset{\underset{CH_3}{|}}{C}{=}CH_2 + {}^{\bullet}\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH_3 \longrightarrow H_3C{-}\underset{\underset{CH_3}{|}}{\overset{\bullet}{C}}{-}CH_2{-}\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH_3$$

(III)

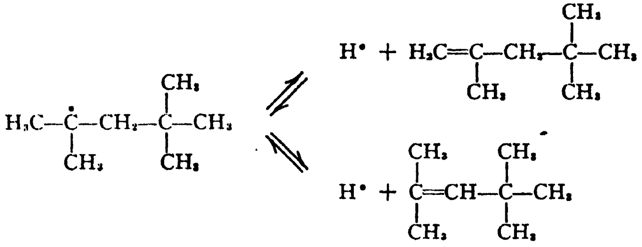
Abs.*, 1910, 4, 2120 (polymerization of styrene).

[19a] ***Ind. Eng. Chem.*, 1934, 26, 94.**

The intermediate III can now either undergo further condensation, or, by loss of a hydrogen ion, form a double-bonded molecule:



$$H_3C-\overset{\bullet}{C}(CH_3)-CH_2-C(CH_3)_2-CH_3 \rightleftharpoons \begin{cases} H^{\bullet} + H_2C{=}C(CH_3)-CH_2-C(CH_3)_2-CH_3 \\ H^{\bullet} + (CH_3)_2C{=}CH-C(CH_3)_2-CH_3 \end{cases}$$

The hydrogen ions regenerated in this change can add to the olefins present and start the cycle again.

In the homologous series of olefin hydrocarbons, the tendency to polymerize increases from ethylene upwards and is at a maximum with the pentenes and hexenes. Structural differences in isomers exert, however, a very marked influence on the ease of polymerization. In general the iso-olefins such as isobutylene and trimethylethylene are more readily polymerized than the straight-chain members. The introduction of electronegative atoms or groups (such as halogen atoms or phenyl groups) into the olefin hydrocarbon molecule very greatly increases the tendency to polymerization.[20] Thus, vinyl halides and styrene are polymerized with very great ease while the parent olefin, ethylene, is relatively resistant to polymerization.

The di- and trimeric polymerization products of the simple olefins are far less easily polymerized than the parent hydrocarbon and show an increasing stability not only as regards polymerization but also against bromine addition and combination with sulphuric acid.

In the following account, a survey has been made of the work on the polymerization of the lower olefins. In previous chapters some mention has been made of the action of heat, sulphuric acid, and aluminum chloride[21] on the lower olefins, so that only brief reference to these reactions, in so far as they relate to the general question of polymerization, need be made. Certain catalysts, however, which have not been previously included, are described in this section.[22]

ETHYLENE

Although ethylene is more resistant to polymerization than its immediate homologues, it can be polymerized under the influence of various agents. The non-catalytic thermal decomposition of ethylene, though complex, results initially, as has been mentioned, in the production of butylene at comparatively low temperatures. Hague and Wheeler[23] found that, on heating ethylene under normal pressure in silica bulbs for 3 hours, the production of butylene was at a maximum at 500° C., corresponding to a content of higher olefins in the resulting gas of 13.7 per cent. Similarly, Pease[24] concluded that the non-catalytic thermal decomposition of ethylene at 400° to 600° C. first yields butylene, evidently by a chain reaction.

[22] The decomposition and polymerization of the olefins have been reviewed by Egloff, Schaad and Lowry, *J. Phys. Chem.*, 1931, 35, 1825. Farmer (*Sci. J. Roy. Coll. Sci.*, 1931, 1, 50; *Chem. Abs.*, 1933, 27, 2131) discussed the polymerizing capacities of olefins and butadienes.

[23] *J.C.S.*, 1929, 378.

[24] *J.A.C.S.*, 1930, 52, 1158.

On the other hand, Lenher[25] observed that considerable propylene was formed during the slow oxidation of ethylene with oxygen at temperatures of 400° C. and over and believed that the purely thermal polymerization of ethylene resulted initially in the formation of propylene and not butylene. Several mechanisms were suggested to explain this transformation, one of which involved the combination of a C_2H_4 molecule with a free CH_2 radical.

As might be expected, the thermal polymerization of ethylene is markedly accelerated by the application of pressure. Ipatiev[26] found that at 70 atmospheres in a steel autoclave and at temperatures above about 325° C., ethylene readily condensed to liquid hydrocarbons. Since the products consisted not only of higher olefins but also paraffins and cycloparaffins, simple polymerization had in this case been followed by splitting and ring-closure. The temperature of polymerization of ethylene under pressure is considerably reduced by the presence of catalysts such as zinc chloride.[27] With aluminum chloride the polymerization of ethylene under pressure takes place at as low as 0° C. and gives rise to a mixture of hydrocarbons, most of which are of high molecular complexity.[28] In a similar way the polymerization of compressed ethylene in the presence of boron trifluoride yields high molecular weight oils.[29] The action of anhydrous aluminum chloride and boron trifluoride on olefins has aroused interest chiefly in connection with the possible synthesis of lubricating oils.

The conclusions of Dunstan, Hague and Wheeler[30] on the polymerization of olefins, particularly ethylene, at pressures of 200 to 2000 pounds per square inch and temperatures of about 350° to 600° C. were as follows[31]: (1) The temperature range is lower (700° to 900° C.) for the pyrolysis of olefins than for paraffins, and the percentage conversion (36 to 40 per cent) is higher. (2) Under operating conditions at 150 pounds per square inch pressure, 575° C. appears to be the approximate temperature distinguishing polymerization from decomposition with ethylene. (3) A reduction in volume takes place in polymerization. (4) The liquid polymerization products are not aromatic and the yields approach the theoretical. The liquid, of which 86 per cent boils below 200° C., has a high antiknock value[32] (engine test, five-sixths that of benzene). (5) Products which vary from gaseous higher olefins to synthetic lubricating oils can be produced at will by control of temperature, pressure, contact surface, and time of contact.

Molten sodium has a polymerizing effect on ethylene at 150° C. Walker[33] obtained a colorless liquid polymer in this manner and the sodium was converted to sodium ethylene carbide. Ethylene is polymerized by iron at 360° C. to a colorless oil.

The kinetics of the thermal polymerization of ethylene under pressure has been studied by Pease,[34] who showed that at temperatures of 350° to 500° C. in a static system at pressures up to 10 atmospheres, the reaction is roughly bimolecular and has an activation energy of about 35,000 calories per mole.

Ramage [35] proposed to effect the polymerization of ethylene to butylene merely by compressing this gas into kerosene or some other heavy hydrocarbon solvent under a pressure of 80 to 200 pounds per square inch, at about 0° C., and recovering the polymerization products from the charged solvent by distillation. Besides butylene, the distillate was reported to contain small amounts of amylene, octylene, and decylene. The polymerization of olefins with anhydrous aluminum or boron halides has been accelerated with certain double compounds of the halide, for example, ansolvo-acids [36] or the double complexes of aluminum halides with organic compounds such as nitrobenzene, nitromethane, or ketones.[37]

Ethylene and its homologues are also polymerized by heating them under pressure without catalysts but in the presence of an inert liquid, such as a mineral or vegetable oil.[38] For example, ethylene is heated with paraffin oil to 420° C. under 45 atmospheres pressure to yield liquid hydrocarbons.

Polymerization in the vapor state of monolefins having 2 to 5 carbon atoms, at 40° to 300° C. in the presence of volatilizable inorganic halides, such as those of aluminum, tin, antimony, zinc, copper, or iron, is stated to yield higher liquid olefins when the contact time is 1 to 65 seconds.[39] The polymerization of ethylene to butylene can be accomplished by passing a slow stream of that gas over a catalyst of active charcoal containing 1 per cent of cobalt at 200° C., according to Schuster.[40]

Other catalysts are also capable of polymerizing ethylene, especially under pressure. Ethylene is fairly stable in the presence of sulphuric or ethylsulphuric acids at temperatures below 100° C. at ordinary or moderate pressures, but at high pressure some tendency to polymerization is observable. This tendency is greatly increased by the addition to the sulphuric acid of metallic salts such as cuprous and mercurous salts,[41] particularly the latter.[42]

The photochemical polymerization of ethylene in ultraviolet light from a mercury lamp was observed by Berthelot and Gaudechon [43] to yield a liquid which boils below 100° C. and has an odor of rancid fat. Similar results were also obtained by Landau,[44] but Bates and Taylor [45] attributed this polymerization not to the influence of ultraviolet light *per se* but to the agency of excited mercury atoms.

The polymerization of ethylene under the influence of the silent electric discharge was studied by Mignonac and Vanier deSaint Aunay,[46] who found that on subjecting ethylene under conditions such that the products of the reaction were

rapidly withdrawn from the reaction zone, the primary product was 1-butene from which 1-hexene was formed, thus:

$$(1)\ CH_2{=}CH_2 + H.CH{=}CH_2 \longrightarrow CH_3.CH_2.CH{=}CH_2$$

$$(2)\ CH_3.CH_2.CH{=}CH_2 + H.CH{=}CH_2 \longrightarrow CH_3.CH_2.CH_2.CH_2.CH{=}CH_2$$

However, if the products of reaction are not removed, ethylene yields a complex mixture of saturated and unsaturated hydrocarbons.

By the action of the silent discharge on ethylene, Collie[47] obtained a mixture of liquid hydrocarbons, boiling from 60° C. upwards and containing C_nH_{2n} hydrocarbons with 6 to 15 carbon atoms and in which was also indicated the presence of cycloparaffins. Demyanov and Prianischnikov,[48] with a silent discharge of 13,000 volts on ethylene, obtained liquid unsaturated hydrocarbons from C_6H_{12} upwards. The later work of Prianischnikov[49] on isobutylene showed that the process is not merely a simple polymerization but is accompanied by a splitting out and a redistribution of hydrogen atoms. Similar results have been reported by Stratta and Vernazza[50] on exposure of ethylene to the silent discharge.

The action of alpha-rays from radon (radium emanation) on the polymerization of ethylene and acetylene has been studied by Lind, Bardwell and Perry.[51]

POLYMERIZATION OF OLEFINS WITH BORON FLUORIDE

Although boron fluoride (BF_3) was first prepared by Gay-Lussac and Thénard[52] in 1808, its possibilities did not attract commercial attention until about 1925. It was first prepared by heating a mixture of 1 part boric oxide (B_2O_3) with 2 parts of fluorspar (fluorite, substantially CaF_2) in a closed gun barrel in an inclined position to white heat. Later, it was made by Davy[53] by gently heating 1 part boric acid with 2 parts of fluorspar and 12 parts of sulphuric acid. The direct synthesis of boron fluoride from its elements was accomplished by Moissan[54] in 1904. The product obtained from boric acid, fluorspar and sulphuric acid[55] melted at —127° C. and boiled at —101° C., but the synthetic product melted at —126° C. and boiled at —99° C. According to Ruff[56] and his co-workers, boron fluoride usually contains silicon fluoride as an impurity. They found that a sample containing 1.7 per cent of silicon tetrafluoride had a melting point of —128° C. and a boiling point of —101° C. at 760 mm. pressure. Boron trifluoride, which has now come into some prominence, can be produced by heating a mixture of a fluoride and boric acid or a borate, with fuming sulphuric acid or, alternatively, boric acid can be treated with fluorosulphonic acid.[57]

Butlerov and Gorianov[58] appear to have been the first to observe the polymerizing action of boron fluoride. They found that this material did not polymerize ethylene even at 200° C. but that propylene and butylene, on the other hand, were polymerized very readily even at room temperature. They stated that propylene, in the presence of boron fluoride, was polymerized to products more complex than a trimer at room temperature but Sowa, Hinton and Nieuwland[59] observed no such action, though their experimental conditions were entirely different.

As early as 1877 Landolph studied some of the reactions of boron fluoride with, for example, benzaldehyde,[60] ethylene,[61] amylene,[62] anethol,[63] and camphor.[64] Boron fluoride and ethylene reacted under light and heat at 30° C. to give an ethereal liquid boiling at 124° to 125° C. This liquid was called fluoborethylene or ethylene fluoboric acid and had the formula $C_2H_3.BF_2$. Amylene gave a yellow liquid which boiled at 160° C., and anethol ($CH_3.CH{=}CH.C_6H_4.O.CH_3$) was polymerized. The reaction of boron fluoride with acetonitrile was investigated by Patein[65]; and with methyl and ethyl alcohols, acetone, resorcinol, cetyl alcohol, glycol, glycerol, ethylene and amylene by Gasselin.[66]

Boron fluoride can be substituted for aluminum chloride in Friedel-Crafts syntheses, as well as in other reactions catalyzed by the latter compound. For example, Hofmann and Wulff[67] state that it can be used to effect condensations of aromatic hydrocarbons with aliphatic chlorides, the splitting of hydrocarbon oils[68] and the addition of hydrogen halides to olefins.

Nieuwland and his associates studied the reactions of boron fluoride with alcohols, acids, nitriles, esters, ethers, acid anhydrides and amides[69]; the preparation of esters from acetic and propionic acid-boron fluoride compounds and aliphatic alcohols[70]; the rearrangement of alkyl phenyl ethers under the influence of this compound[71]; the cleavage of ethers in the presence of organic acids and boron fluoride to give esters and alcohols[72]; and the condensation of propylene with phenol.[73] Meerwein[74] observed that boron fluoride added to olefins: formed a compound with dioxan; yielded dialcoholates with aliphatic alcohols; and combined with aliphatic acids and acetic anhydride. Accordingly, like aluminum chloride, boron fluoride can be used to effect many types of reactions, hence with its production on a commercial scale, it will probably attract even wider interest. This discussion must necessarily be limited, however, to the polymerizing action of boron fluoride on olefins, some examples of which have already been mentioned. Various other uses of this compound have likewise received some attention in other chapters.[75]

Otto[76] studied the polymerizing action of boron fluoride on ethylene and its immediate homologues under pressure. In the presence of this reagent isobutylene polymerized readily with the production of a water-white oil which boiled at 200° C. Propylene was more resistant, but, under high pressure, polymerization took place at ordinary temperatures with the formation of a yellow oil of high viscosity and with an initial boiling point of 120° C. at 15 mm., half of which distilled below 300° C. at this pressure. High molecular weight oils were also obtained from ethylene. Hofmann and Otto[77] found that this polymerization was accelerated by the use of finely divided metals such as nickel and that the double compounds of boron fluoride could likewise be used.

The polymerization of olefins, such as ethylene, propylene, and cyclohexene, with boron fluoride can also be accelerated by the presence of water, halogen acids, or halogen hydrocarbons capable of reacting with aromatic hydrocarbons in the Friedel-Crafts reaction, according to Hofmann, Otto and Stegemann.[78] For example, propylene was polymerized when treated with boron trifluoride and hydroiodic acid, ethyl fluoride or chloride. Butylene is produced in considerable proportions when liquid ethylene, together with a small quantity of boron trifluoride, is passed over a nickel catalyst at 150° C.[79] In most cases organic halogen compounds such as ethyl fluoride, and hydroxy-compounds, such as alcohols and water, have an accelerating effect on the reaction.

These polymerizations with boron fluoride can be utilized for many purposes. Pier and Christmann[80] treated fractions (obtained from a cracked paraffin oil and separated by treatment with solvents such as sulphur dioxide, aniline, or phenol) with boron fluoride, aluminum chloride, zinc chloride, or phosphorus oxychloride to obtain products usable as lubricating oils. The liquid fraction of a cracked paraffin wax, with an iodine value of at least 150 to 200, can be polymerized similarly.[81] Mineral oils have been refined by treatment with halides of boron, glucinum (beryllium), or bismuth,[82] or with gaseous or liquid hydrogen fluoride with or without the addition of metal halides.[83] Lubricating oils can also be produced by treating liquid olefins with liquid paraffin hydrocarbon mixtures, such as the product obtained by the hydrogenation of brown coal, in the presence of boron fluoride, aluminum chloride, or stannic chloride.[84] Gaseous olefins may be passed into the mixture during condensation.

Since boron fluoride is a gas which readily decomposes with moisture and is difficult to handle because of its corrosive and poisonous nature, double compounds with this substance, as has been previously mentioned, can be substituted for it in various reactions. Landolph[85] used the ethereal liquid condensate of ethylene and boron fluoride (ethylene fluoboric acid) with camphor. The previously mentioned boron trifluoride-acetic acid is another example. A double compound of ether and boron fluoride has been employed to condense saturated compounds with olefins[86] (see Chapter 24). Bruson[87] used an aryldiazonium fluoborate, phenyldiazonium fluoborate, $C_6H_5—N_2—BF_4$, for polymerizing indene, styrene, cyclopentadiene, coumarone, turpentine; also for treating rubber. When 20 per cent of phenyl tetrazonium difluoborate (obtained by diazotizing para-phenylenediamine, followed by coupling with fluoboric acid) was added to a highly unsaturated cracked gasoline (boiling range of 90° to 200° C.), which consisted of 45 per cent olefins, about 20 per cent of the reaction product boiling above 200° C. was a colorless oil containing a large proportion of resin. For raising the melting point of petroleum residues and soft paraffins Daitz[88] recommended treatment with ammonium or potassium bifluoride at a temperature below that of distillation.

PROPYLENE

Propylene is polymerized somewhat more readily than ethylene. Pyrolysis converts propylene into a complex mixture of liquid and gaseous hydrocarbons in which a hexene has not yet been identified. Possibly, under these conditions, the dimer, initially formed, undergoes rapid decomposition with the production of both saturated and unsaturated substances.

A considerable number of chemical substances exercise a strong polymerizing action on propylene. The pronounced tendency of propylene to polymerize to liquid hydrocarbons in the presence of concentrated sulphuric acid has been referred to previously. The polymerization of propylene in the presence of aluminum chloride[88a] and of boron trifluoride[89] is more rapid than that of ethylene and leads to the formation of a mixture of hydrocarbons, some of which are of high molecular weight. Michel[90] proposed to utilize the greater ease of polymerization of propylene and its homologues for the separation of ethylene from mixtures of these olefins. This is effected by passing the gas mixture through a suspension of aluminum chloride in an inert solvent (e.g., decalin) at atmospheric, or reduced pressure so that higher olefins are polymerized and the ethylene passes on substantially unchanged. Horsley[91] used cadmium phosphate for the same purpose, the ethylene being subsequently converted to ethyl alcohol.

The activity of floridin and other finely divided siliceous earths in polymerizing the amylenes was first noted by Gurwitsch.[92] Lebedev and Filonenko,[93] from a study of the polymerization of olefins by floridin at ordinary pressure, enunciated the generalization that only those olefin hydrocarbons are polymerized which are derivatives of the asymmetrical di- or tri-substituted ethylenes of the types $RR^1.C:CH_2$ and $RR^1C:CH.R^{11}$, while the mono-substituted or symmetrical di- and tetra-substituted olefins do not polymerize even over long periods in the presence of this material. In agreement with this generalization the above workers found that propylene was unaffected by floridin which, however, readily polymerized isobutylene. Later, however, Van Winkle[94] found that although propylene did not change in contact with activated floridin at atmospheric pressure, it did undergo condensation under increased pressures. After contact for two months, polymers were isolated which corresponded in boiling points with the dimer and trimer. At the end of one year's contact the products contained no dimer but only higher polymers (trimer, tetramer, and higher).

Gayer[95] observed that the activity of floridin in polymerizing propylene at 350° C. can be increased by treatment with hydrochloric acid, which can be conveniently generated by the introduction of a small proportion of alkyl chloride. Traces of alkali or large quantities of water or oxygen poison the catalyst, but organic sulphur compounds do not impair its activity. Synthetic aluminum silicate has approximately the same activity as floridin but alumina adsorbed on a precipitated porous silica surface was about twenty times as active. Precipitated silica and synthetic ferric and magnesium silicates have no catalytic effect on the polymerization of propylene. The liquid polymer, obtained in 90 per cent yield from the crude product, is a colorless, practically gum-free volatile fuel having an octane number of 87. The fraction boiling up to 150° C. consists of olefin homologues from C_5 to C_9, inclusive (principally C_6).

The polymerization of propylene under the influence of the silent electric discharge was found by Prianischnikov[96] to produce a liquid product of density, 0.827; refractive index, n_D^{20} 1.4578; and mean molecular weight, 233; which consisted probably of the pentamer and higher polymers. The polymerization of propylene and cyclopropane with alpha-rays from radon (radium emanation) has been studied by Heisig.[97]

The polymerization of ethylene, propylene, and other olefins is said to be catalyzed by phosphoric acid or phosphorus pentoxide in the presence of a carrier such as active charcoal at temperatures below 400° C. and at increased pressure, to yield liquid products.[98]

It has been demonstrated by Lenher[99] that the presence of oxygen activates the thermal polymerization of propylene, and causes it to occur at much lower temperatures than in the absence of oxygen. By passing a mixture of propylene and oxygen (with the former in excess) through a fused-silica tube at 500° C. with a contact time of 7.8 seconds, 52 per cent of the propylene was polymerized to higher monolefins while the remainder (48 per cent) was oxidized to various oxygenated compounds. In the absence of oxygen, no polymerization could be detected under these conditions. The polymers formed at temperatures of 490° to 530° C. were found to consist entirely of higher monolefins, of which butylenes, amylenes and hexylenes were undoubtedly present. The oxygen-activated polymerization of propylene is therefore similar to that of ethylene (mentioned previously) in giving rise to a series of homologous monolefins. To explain this, Lenher advanced a mechanism which involves the activation of the double bond by the rupture of one of the carbon double bonds, and to the separation of free radicals by scission of the two carbon double bonds. The immediate homologues of propylene are thus considered to be formed by the reaction of the free methylene or ethylidene residues with propylene, yielding butylenes and amylenes, respectively.

BUTYLENES

Of the three isomeric butylenes, isobutylene is considerably more reactive than the others and especially so in its tendency to polymerize. The thermal treatment of isobutylene at temperatures of the order of 600° C. and at atmospheric pressure leads to the production of a complex mixture of liquid hydrocarbons of various types, in which it is difficult to distinguish the initial products of polymerization.[100] Under a pressure of 70 atmospheres at 380° to 400° C. isobutylene condenses to a mixture of higher paraffin, olefin, and cycloparaffin hydrocarbons, which resemble the products obtained by a similar treatment of ethylene, except that the fraction boiling below 150° C. is richer in olefins.[101] The olefins present were considered by Ipatiev to be a dimer and trimer of isobutylene. Evidence that the initial stage in the thermal polymerization of isobutylene is the production of higher olefins was presented by Lebedev and Koblianski,[102] who obtained what they considered to be triisobutylene (as well as higher polymers) by heating isobutylene at 200° C. in hard glass tubes for 14 days.

Isobutylene polymerizes very readily in the presence of a large number of catalysts. The polymerization of this hydrocarbon by boron trifluoride at ordinary temperatures to yield high molecular weight oils has been described by Otto[103] and also by Butlerov and Gorianov.[104] The polymerization of a liquefied mixture of isobutylene and 2-butene at —10° C., in the presence of aluminum chloride or ferric chloride, is reported to yield a mixture of naphthenes.[105] The polymerization of isobutylene, as well as of other monolefins and diolefins, is effected with double complexes of aluminum chloride with nitrobenzene, nitromethane, acetone, benzophenone or diphenylsulphone and inorganic compounds such as silver chloride or cuprous chloride. Thus, 16.5 liters of isobutylene are passed at a gas rate of 4 liters per hour through a mixture of 10 grams of aluminum chloride, 10 grams of diphenylsulphone and 100 grams of benzene. As a result, 13.5 liters of the isobutylene are fixed with the production of a liquid consisting of 10 per cent diisobutylene, 15 per cent triisobutylene, and 65 per cent of higher polymers boiling above 200° C.[106]

The polymerization of isobutylene in the presence of activated floridin is of interest in that it exhibits a certain degree of reversibility. Lebedev and Koblianski[107] found that isobutylene polymerized readily in the presence of floridin (activated by heating to 300° C.) even at —80° C. At room temperature the polymerization was very rapid but it was retarded at temperatures of 200° C. and over. On passing the gas over the unheated catalyst, a marked evolution of heat (corresponding with the heat of polymerization) occurred. The products obtained by allowing liquid isobutylene to stand with floridin for 4 days at room temperature contained 4 per cent which boiled below 170° C., 25 per cent between 170° and 185° C., and 71 per cent above 185° C. However, by continuous passage of gaseous isobutylene over the catalyst, with removal of the polymers as formed, the product contained larger proportions of lower polymers, of which 18 per cent boiled below 170° C., 51 per cent between 170° and 185° C., and 31 per cent above 185° C. The liquid was further fractionated. Table 111 gives its composition.

The properties of the fractions in Table 111 were further investigated. The diisobutylene could be readily hydrogenated, proving its unsaturated nature, and polymerized to tetraisobutylene with floridin. The trimer, tetramer, and pentamer did not polymerize in the presence of the silicate and could be hydrogenated only slowly. From a mixture of di- and triisobutylene in the presence of floridin, pentaisobutylene appeared to be formed.

Lebedev and Koblianski[108] carried out a number of experiments on the

depolymerization of the higher polymers in the presence of this same catalyst. By passing these polymers over floridin at 200° C., the pentamer decomposed into a mixture of the trimer and dimer, the tetramer into two molecules of the dimer, the trimer into the dimer and isobutylene, and the dimer into two molecules of isobutylene itself. In all cases some monomeric isobutylene was produced, attributed in the cases of the tetramer and pentamer to progressive dissociation of the initial di- and tri-meric forms. Diisobutylene is the most stable polymer. The depolymerization of a mixture (average molecular weight of 840), obtained by distilling off the lower polymers up to and including the heptamer from the polymerized isobutylene, yielded a product containing more than 30 per cent of the trimer.

The polymerization of isobutylene in the presence of floridin has been investigated by Van Winkle[109] and also by Lebedev and Filonenko[110] with results similar to those already outlined. The generalization of the latter workers with regard to the greater tendency of unsymmetrical di- and tri-substituted ethylene to polymerize has already been discussed.[111]

Considerable work has been carried out on the polymerization of isobutylene by sulphuric acid of various concentrations. Comparatively dilute sulphuric acid (50 per cent) suffices to hydrate this olefin to tertiary butanol in the cold but stronger acid concentrations exert a profound polymerizing effect, especially at slightly elevated temperatures. Thus, Butlerov[112] found that, by warming a solution of isobutylene in 50 per cent sulphuric acid to 100° C., diisobutylene mainly is formed, while the introduction of isobutylene into acid of higher concentration (80 per cent and over) in the cold resulted in the formation of triisobutylene. Concentrated sulphuric acid converts isobutylene quantitatively into higher polymers.[113] Little is known of the constitutions of these polymers but they appear to be higher olefins and are far less reactive than isobutylene itself.

Whitmore and Wrenn[114] showed that the so-called "diisobutylene" (produced, for example, by decomposing 2500 grams of tertiary butanol with a mixture of 3300 cc. water and 2700 cc. of sulphuric acid) consists essentially of two isomeric octenes. Careful fractionation of the mixed dimer, which boiled at 100° to 105° C. at 738 mm., demonstrated the presence of 2,4,4-trimethyl-1-pentene and 2,4,4-trimethyl-2-pentene, the former being present in larger amount than the

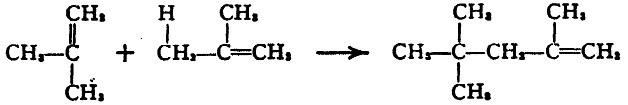
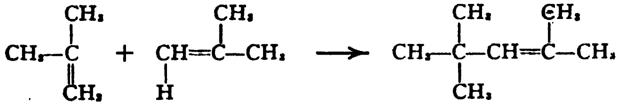
latter. Accordingly, the production of the mixed dimer from isobutylene may be represented graphically as follows:



$$CH_3-\underset{\substack{|\\CH_3}}{\overset{\substack{CH_2\\ \|}}{C}} + \overset{\substack{H\\|}}{CH_2}-\overset{\substack{CH_3\\|}}{C}=CH_2 \longrightarrow CH_3-\underset{\substack{|\\CH_3}}{\overset{\substack{CH_3\\|}}{C}}-CH_2-\overset{\substack{CH_3\\|}}{C}=CH_2$$

2,4,4-trimethyl-1-pentene



$$CH_3-\underset{\substack{\|\\CH_2}}{\overset{\substack{CH_3\\|}}{C}} + \underset{\substack{|\\H}}{CH}=\overset{\substack{CH_3\\|}}{C}-CH_3 \longrightarrow CH_3-\underset{\substack{|\\CH_3}}{\overset{\substack{CH_3\\|}}{C}}-CH=\overset{\substack{CH_3\\|}}{C}-CH_3$$

2,4,4-trimethyl-2-pentene

The structure of these two isomeric diisobutylenes was proved by ozonation by McCubbin and Adkins[115] and later the compounds were isolated by Whitmore and his collaborators.[116]

The manufacture of polymerization products of isobutylene and of trimethylethylene has been accomplished by Müller-Cunradi and Eggert[117] by heating a solution of these gases absorbed in 50 to 60 per cent sulphuric acid for one-half hour at 100° C. Under these conditions the dimers, together with about 20 per cent of higher polymers, are said to separate from the acid. Polymers of iso-olefins, such as isobutylene, have been suggested as additions to lubricants, gasoline, and burning oils to improve their properties.[118]

Little work has been carried out on the polymerization of 1-butene and 2-butene, though it is definitely known that these olefins are more resistant to such changes than the isomeric isobutylene. Mailhe and Renaudie[119] heated 1- and 2-butene in the presence of silica gel at 650° to 700° C. and obtained liquid unsaturated hydrocarbons, benzene, toluene and m-xylene together with 40 per cent of propylene and 40 per cent of methane. In addition, 2-butene gave naphthalene and anthracene.

The condensation of 2-butene under the influence of the silent electric discharge was found by Prianischnikov[120] to yield an oil, having a mean molecular weight of 202, a density of 0.831, and an iodine number of 156, of which 30 per cent boiled below 150° C. The condensation of 2-butene to a dark viscous liquid under the influence of alpha-rays from radon (radium emanation) has been described by Heisig.[121]

AMYLENES

Although the polymerization of various amylenes under the influence of catalysts has been extensively investigated, the initial products of non-catalytic thermal polymerization have not been identified. Thermal treatment of the amylenes at temperatures of 500° C. and above at atmospheric pressure results in the production of both saturated and unsaturated hydrocarbons of higher and lower molecular weights than that of the parent amylene. Under pressure, however, condensation to liquid products occurs at much lower temperatures and consequently with less tendency for degradation of the initial products of reaction. By heating trimethylethylene in sealed glass tubes at 320° C. to 325° C., Engler and Routala[122] obtained complete conversion into products consisting largely of paraffinic and cycloparaffinic, with a relatively small amount of unsaturated hydrocarbons.

The amylenes exhibit to a marked degree the power of isomerizing to a more stable form on heat treatment. For example, isopropylethylene is partially converted into trimethylethylene by passage over aluminum sulphate, phosphoric acid, or alumina at 420° to 500° C., though under the same conditions at 450° to 500° C. both trimethylethylene and 2-pentene are unchanged.[123] Similarly, Ipatiev[124] effected an 80 per cent conversion of isopropylethylene into trimethylethylene in the presence of silica at 500° to 505° C. or alumina at 525° to 535° C. At higher temperatures (670° C.) when passed over silica gel in a quartz tube, isoamylene yields 47 per cent lower olefins, 38 per cent methane, 7 per cent hydrogen and oil.[125] Under identical conditions 2-pentene decomposes to 52 per cent propylene and butylene, 34 per cent methane, 6 per cent hydrogen and an oil.

The greater stability of trimethylethylene and the ease of isomerization of the other amylenes into this substance account for the fact that it usually constitutes the preponderating constituent of the amylene fraction of cracked products. Bruylants[126] pointed out that the migration of a double bond usually occurs when the groups on each side of it possess markedly different residual affinities. In the synthesis of butenes, for example, 2-butene is formed almost exclusively. It appears to be a general rule that olefins of the $RCH_2CH:CH_2$ type (for example, 1-butene and isopropylethylene) are less stable than olefins of the $RCH:CHR$ type (exemplified by 2-butene and trimethylethylene) and tend to revert to the latter under the influence of heat, catalysts, and energy activations.[127] The shift of the double bond from the alpha to the beta position, as occurs in the isomerization of 1-butene to 2-butene and of isopropylethylene to trimethylethylene, also takes place with the higher olefins.[128] This is further exemplified by the ready conversion of 3,7-dimethyl-1-octene to 3,7-dimethyl-2-octene.

The condensation of "amylene" (in most cases consisting mainly of trimethylethylene), in the presence of anhydrous aluminum chloride has been studied by Aschan[129] and by Engler and Routala.[130] The products were similar to those obtained by the polymerization of ethylene under pressure in the presence of this reagent and consisted of saturated hydrocarbons of the paraffin and cycloparaffin series. At ordinary temperatures, condensation takes place in the presence of aluminum chloride with the formation of oils of high molecular weight.[131]

The polymerization of trimethylethylene in the presence of zinc chloride was found by Kondakov[132] to yield considerable proportions of diamylene. The very strong polymerizing action of floridin on "amylene" (mainly trimethylethylene) was also shown by Gurwitsch.[133] On mixing freshly distilled amylene with an equal weight of dried floridin at room temperature, polymerization took place with the evolution of heat, the product being principally the dimer. Polymerization of amylene was also brought about by carbon and by alumina and, with the latter, the heat development was even more pronounced than with floridin.

The polymerization and depolymerization of amylenes under the influence of floridin was studied by Lebedev and Vinogradov-Volzynski.[134] When heated with activated floridin, a mixture of trimethylethylene and methylethylethylene, yielded diamylene, which boiled at 37° to 39° C. This product when heated at 150° to 160° C. with the same catalyst decomposed into gaseous and liquid products, which consisted of methane and a mixture of butenes, isopropylethylene, isopentane, trimethylethylene, 3-methyl-2-pentene, heptene, octene, and nonene.

The polymerization of amylenes in the presence of sulphuric acid of various concentrations has been studied more thoroughly than that carried out in the presence of other agents. The production of "diamylene" by treatment of "amylene" (a mixture of isomers, but mainly trimethylethylene) with sulphuric acid (2 volumes concentrated acid to 1 volume of water) at room temperature was described by Butlerov,[135] Wischnegradsky,[136] von Schneider,[137] and other workers.[138] A comprehensive examination of this reaction was made later by Norris and Joubert.[139] The latter workers found that, of the amylenes, trimethylethylene and unsymmetrical methylethylethylene were polymerized most readily. In the case of these two most reactive isomers, polymerization could be effected with sulphuric acid of relatively low concentration, i.e., with 60 per cent sulphuric acid, at ordinary temperatures. Under these conditions, the products consisted mainly of the dimer. With more concentrated acid, polymerization was greatly accelerated and higher polymers were produced along with the dimer. Of the other three isomers, isopropylethylene was slowly polymerized by 70 to 75 per cent acid to form mainly the dimer, though with more concentrated acid, only higher polymers were formed. Both 1-pentene and 2-pentene were resistant to the polymerizing influence of acids of concentrations lower than about 80 per cent sulphuric acid. Concentrated acid converted these latter amylenes into polymers higher than the dimer. Norris and Joubert observed that relatively small quantities of acid are sufficient to effect this change. Thus, when 5 cc. of trimethylethylene were shaken with 0.65 cc. of concentrated sulphuric acid, polymerization occurred at once with the production of the dimer principally. Five cc. of this hydrocarbon were completely polymerized in 8 days by 0.4 cc. of sulphuric acid of 2:1 concentration. With 0.5 cc. of a more dilute (1:1) acid, about one-half of the hydrocarbon was converted. When 10 moles of isopropylethylene were shaken with 1 mole of concentrated sulphuric acid, a rise in temperature occurred and polymerization was complete in a few minutes, the product boiling above 200° C. Under similar conditions, trimethylethylene yielded mainly diamylene. When 10 moles of isopropylethylene were left in contact with 1 mole of 2:1 acid for 7 days, the product boiled at 153° to 158° C. and consisted almost entirely of the dimer.

The polymerized amylenes, as shown conclusively by Norris and Joubert, were olefins much more resistant to the action of chemical reagents than the parent substances. All the diamylenes decolorized a solution of bromine in carbon tetrachloride and reacted with ozone. The polymers were much more stable toward sulphuric acid than the monomeric amylenes and only reacted very slightly with hydrogen halides. It was found, however, that if the diamylene prepared either from trimethylethylene or isopropylethylene was shaken with sulphuric acid (3:1) for 2 days, a part of the hydrocarbon was converted into higher products, although solution in the acid did not appear to take place. This result explains why diamylenes are formed from amylene only with dilute acids. The action of various oxidizing agents on the diamylenes is of interest since it sheds some light on the constitution of these polymerized olefins. Oxidation with potassium permanganate or chromic acid was very slow but ozone readily combined with the diamylenes to form viscous ozonides. Decomposition of the ozonide of the diamylene from trimethylethylene with cold water yielded acetone, acetic acid, formic acid, and an acid of the formula $C_5H_{11}COOH$, as well as higher ketones. These results appear to indicate that the polymerization of trimethylethylene occurs according to the following[140]:

dimer of trimethylethylene

As mentioned previously, trimethylethylene may be absorbed from gases in 50 to 60 per cent sulphuric acid, and if the solution is heated for one-half hour at 100° C., dimers, together with 20 per cent of other polymers, are formed.[141]

HIGHER OLEFINS

It has already been indicated that the higher dimeric olefins produced from the lower olefins are much more resistant to further polymerization, especially under the influence of sulphuric acid, than the parent olefin.

Thermal treatment of the higher olefins results in the formation of saturated and unsaturated hydrocarbons of both lower and higher molecular complexities (see Chapter 2). In the main, the most important changes involved in the pyrolysis of the higher olefins are rupture of the carbon chain with formation of radicals (probably accompanied by condensation), cyclicization, appearance of double bonds, and loss of hydrogen. Under pressure the polymerization of the higher olefins occurs at comparatively low temperatures and results, exactly as with the simpler members of the series, in the production of polymers and also of saturated hydrocarbons, probably of naphthenic structure. Thus, the condensation of 1-octene at 400° C. at a pressure of 500 kilograms per square centimeter (484 atmospheres) was observed by Hugel and Cohn[142] to furnish hydrocarbons liquid under those conditions. The same workers also found that the polymerization of hexadecene to a dimer and trimer was the only reaction observed when that hydrocarbon was heated to 300° C. at pressures varying from 5 to 1000 atmospheres. The polymerization was accelerated by increasing pressure and was considered to be an equilibrium. Other experiments [143] were carried out by heating hexadecene in tubes either completely or incompletely filled with the hydrocarbon. Distillation of the final products showed that when the olefin was present in the gas phase during the polymerization, a series of hydrocarbons boiling from 40° to 360° C. was obtained, whereas completely in the liquid phase only polymers of the original olefin were formed. The distillation curve in the latter case showed plateaux corresponding to $C_{16}H_{32}$, $C_{32}H_{64}$ and $C_{48}H_{96}$. These polymers of hexadecene were solid products similar to paraffin wax and apparently contained one double bond per molecule. Thermal treatment in the liquid phase under pressure appears to convert hexadecene into higher polymeric olefins. Hugel and Cohn [144] have isolated the dimeric hexadecene as a solid which melted at 53.8° to 54.8° C. and had an iodine value of 47 to 54. This substance was considered to be a straight-chain olefin with the ethylene bond located in the middle of the chain. It was found that, besides this solid dimer, liquid olefins of the formula $C_{32}H_{64}$ were simultaneously produced.[145] The latter substances were probably branched-chain olefins. The relative proportions of the solid and liquid dimers of hexadecene depended upon the experimental conditions, less of the solid polymer being formed under pressure at 400° C. than at 300° C.

The polymerization of the higher olefins by aluminum chloride or boron trifluoride has been little investigated. The work of Szayna [146] on the action of aluminum chloride on 1-octene and diamylene was carried out at such a temperature (100° to 150° C.) that the initial polymerization was obscured by the well-known splitting reactions induced by the aluminum chloride at those temperatures. To obtain polymerization products without fission products (such as lower paraffin hydrocarbons) it appears necessary to employ low temperatures and also, possibly, an inert liquid diluent. Quite recently Sullivan, Voorhees, Neeley and Shankland [147] produced lubricating oils by the action of about 2 per cent of aluminum chloride on olefins (pentenes, trimethylethylene, 1-hexene, 1-octene, and cetene) at 20° to 93° C. The conclusion reached by them was that the polymers produced in this way from the higher normal olefins possess a pronounced superiority over mineral lubricating oils, though this was not true of the polymers from the lower olefins such as ethylene.

Although the polymerizing action of sulphuric acid on higher olefins has been observed by Le Bel,[148] Rossolimo [149] and others, our knowledge of these reactions is due to a large extent to the work of Brooks and Humphrey.[150] These latter workers concluded that the polymerization of olefins under the influence of this reagent may be preceded by alcohol formation. Of the hexenes, tetramethylethylene appeared to be polymerized by sulphuric acid very readily. Thus, 46.5 grams of tetramethylethylene on treatment with 150 grams of 85 per cent sulphuric acid at 0° C. for 1 hour yielded 37.6 grams of a mixture of hydrocarbons in which the dimer predominated. On the other hand, 1-hexene on treatment with excess 85 per cent acid at 0° C. was hydrated to secondary hexanol, practically no polymers whatever being formed. The work of Brooks and Humphrey on the higher olefins is summarized in Table 112.

TABLE 112.—*Polymerizing Effect of Sulphuric Acid on Olefins.*

Olefin	Acid Used Per Cent	Temp. ° C.	Products
3-Heptene	85	15	No polymers, only alcohol.
3-Methyl-2-pentene	95	0	Mainly alcohol, 10% dimer.
5-Methyl-1-hexene	85	—	Considerable proportion of dimer.
2-Octene	85	20	Mainly polymers.
5-Methyl-1-heptene	85	15	Mainly polymers, 50% dimer.
2-Methyl-2-undecene	85	20	Almost entirely dimer.
Hexadecene	85	20	Unaffected.
Hexadecene	95	—	Mixture of polymers.

It appears, therefore, that the action of sulphuric acid on the higher olefins results mainly or almost entirely in the formation of polymers, but as the molecular weight of the olefin increases so also does its resistance to the influence of sulphuric acid.[151] The straight-chain olefins are apparently more resistant to polymerization by this acid than are the highly branched-chain members, such as tetramethylethylene.

ACTION OF POLYMERIZING AGENTS ON CRACKED DISTILLATES

The cracking of petroleum usually gives products which contain considerable proportions of unsaturated hydrocarbons (see Chapter 3). Some methods of refining and purifying these cracked fractions, as has been previously mentioned, appear to be dependent on the polymerization of the olefin constituents, although little is known of the actual chemical mechanism.[152] A few of these processes are considered in so far as they relate to polymerization.

SULPHURIC ACID

The polymerization of individual olefins by sulphuric acid has been previously discussed.[153] Gerr and Tikhomirova[154] separated fractions of the polymerized oil which remained after passing a gas from cracked kerosene through cooled concentrated sulphuric acid. The original gas contained 33.6 per cent of relatively heavy hydrocarbons, 17.4 per cent of hydrogen, and 49 per cent of methane, but after passing through sulphuric acid the composition was 24 per cent heavy hydrocarbons, 20 per cent hydrogen, and 56 per cent methane. This decrease in the heavy hydrocarbon proportion was attributed to the polymerizing action of the sulphuric acid, which also gained 0.3 gram in weight for each liter of gas conducted through. An oil layer, corresponding to 0.0476 gram per liter of gas, was formed on the acid. This was separated into twelve fractions by distillation at a pressure of 2 millimeters. Odorless crystals which melted at 73° to 74° C. and had the empirical formula $C_{15}H_{24}$ were obtained from the fraction boiling at 99° to 130° C. at 2 mm. The fraction separated at 115° to 206° C. at this pressure was a viscous oil similar to lubricating oil. Similar results for a cracked light oil were reported by Bespolov.[155]

---

[153] See, for example, Brooks and Humphrey, *loc. cit.*
[154] *Neft. Khoz.*, 1929, 16, 411; *Chem. Abs.*, 1929, 23, 4811.

An amylene fraction, which contained about 43 per cent of dissolved gases, from the vapor-phase cracking of crude oil, was treated with sulphuric acid at —45° C. by Marcovich and Pigulevski.[156] The product was fractionally distilled and saponified, from 12.8 to 25.5 per cent of the gas being converted into alcohols. They observed that 66 or 75 per cent acid dissolved more polymers than 85 per cent acid.

Ramage [157] treated hydrocarbon oils, which consisted essentially of olefin and aromatic hydrocarbons, with concentrated (66° Bé.) sulphuric acid. The oil was then fractionated. On nitration, the fraction which boiled below 100° C. yielded nitrobenzene, while that boiling between 100° and 120° C. produced nitrotoluene. The fraction obtained between 120° and 145° C. consisted of xylenes and olefins, that between 145° and 300° C. of olefins up to pentadecene, and that between 300° and 450° C. resembled a lubricating oil.

In a process of refining petroleum products or of making gasoline proposed by Brooks,[158] cracked petroleum rich in olefins is subjected to the action of sulphuric acid (specific gravity less than 66° Bé.), after which the oil is separated, treated with an alkali and distilled. Diolefins are resinified, but monolefins are practically unaffected by this treatment. Polymers formed in the refining with sulphuric acid can be removed by distillation over silica gel, charcoal or similar adsorbents.[159] Demant [160] treated solvent naphtha with sulphuric acid to obtain a viscous oil with a freezing point of —10° to —15° C.

ALUMINUM HALIDES

By heating unsaturated hydrocarbons such as ethylene or propylene to 260° to 540° C. under pressures of 40 to 120 kilograms per square centimeter (40 to 120 atmospheres) in the presence of aluminum chloride or bromide, polymerization results.[161] Unsaturated hydrocarbons of high molecular weight can be prepared by directing olefins of low molecular weight at a temperature below 300° C. over vaporizable halogenated compounds such as aluminum chloride, with a time of contact less than 100 seconds.[162]

A number of processes in which synthetic lubricating oils are prepared by polymerization in the presence of aluminum chloride have been proposed (see also Chapter 5). In one such method, solid or semi-solid aliphatic hydrocarbons having a mean molecular weight of not less than 170 (paraffin wax) are polymerized with agents capable of introducing exchangeable substituents such as chlorine, oxygen, and sulphur, in the presence of catalysts such as aluminum chloride.[163] Cyclic or olefin hydrocarbons also may be present. Unsaturated hydrocarbons which result from the cracking of hydrocarbon materials containing a high proportion of normal paraffin hydrocarbons can also be polymerized with aluminum chloride to yield lubricating oils.[164] A double compound of aluminum chloride and ethylene, made by passing ethylene at 40° to 60° C. through a suspension of aluminum chloride in a saturated hydrocarbon, will also effect polymerization, according to Häuber.[165]

To manufacture lubricating oil, Howes [166] polymerized olefins at 15° C. at a pressure of 70 atmospheres in the presence of a catalyst which consists of Florida earth impregnated with finely divided nickel and anhydrous aluminum chloride.

A solid absorptive catalyst capable of polymerizing unstable hydrocarbons, such as Florida earth, has been used by Gray [167] to refine hydrocarbon vapors from which sulphur compounds have been removed previously by basic mercuric acetate. Fuller's earth and similar adsorptive materials,[168] aluminum chloride [168a] and sodium metal [168b] have been used to remove gum-forming and color-imparting substances from cracked distillates. Kalichevsky and Ramsay [168c] studied the factors which influence the refining of lubricating oils with adsorbent clays. Considerable paraffin is lost in the refining with fuller's earth. According to Fussteig [168d] adsorbed paraffin can be recovered by extraction of the spent earth with light gas oil at 90° C. The refining of cracked distillates by subjecting them to the action of liquid sulphur dioxide containing metallic halides (mercuric, stannic, or titanium chlorides) soluble therein was described by Davis.[168e]

POLYMERIZATION BY HEAT

The polymerization of individual olefins by heat has been discussed in other chapters (see Chapters 2 and 4) as well as in this. As previously stated, Dunstan, Hague and Wheeler [168f] observed that below about 550° C., at 150 pounds per square inch pressure, polymerization occurs and that by controlling the temperature, pressure, contact surface, and time of contact, the products may be varied from gaseous liquid hydrocarbons to viscous oils having lubricating qualities.

By distillation of an oil in the presence of an absorbing agent such as fuller's earth, bentonite, or charcoal, Morrell [169] obtained a resinous material which could be removed from the absorbent with alcohol and ether, liquid sulphur dioxide, or other solvents. In one process, liquid hydrocarbons were obtained from olefins by heating them at about 350° to 800° C. under a pressure of about 1000 atmospheres in contact with metals such as tin, zinc, aluminum, chromium, silicon, lead, or their alloys.[170] Catalysts such as aluminum chloride may also be present.

[169] U. S. Patent 1,608,135, Nov. 23, 1926; *Chem. Abs.*, 1927, **21**, 318. Resinous oxygen-absorbing olefin polymers have also been recovered from cracked distillates by Morrell (U. S. Patent 1,888,044, Nov. 15, 1932; assigned to Universal Oil Products Co.; *Chem. Abs.*, 1933, **27**, 1530) and by Hyman (U. S. Patents 1,919,722 and 1,919,723, July 25, 1933; assigned to Versicol Corporation; *Chem. Abs.*, 1933, **27**, 4942).

Ethylene and its homologues, for example, cracked petroleum products or destructive hydrogenation products with olefin properties, can be polymerized to products boiling between 100° and 200° C. by heating them to 420° C. under a pressure of 45 atmospheres without catalysts in the presence of an inert liquid such as mineral or vegetable oil.[171] Wagner[171a] polymerized cracked gaseous distillates to gasoline-like products by heating to between 175° and 375° C. under a pressure above 40 atmospheres in the presence of metals of Group VIII of the periodic system (platinum or palladium).

Electric Discharges

In a previous chapter (Chapter 9) the action of electric discharges on hydrocarbons was discussed. Feiler[172] prepared diolefins from ethylene and other lower olefins by exposing the gases at a high rate of flow to the action of high-temperature electric discharges. The process is carried out in a closed cycle with continuous removal of higher olefins by cooling.

Polymerization products have also been obtained from gases which contain methane, ethylene, acetylene, and their homologues by subjecting them to the action of electrical fields such as high-frequency oscillations at high temperatures (above 900° C.).[173]

Polymerization of Styrene and Other Aryl-Substituted Olefins

The marked influence of the introduction of electronegative groups on the tendency of polymerization of unsaturated hydrocarbons is exemplified by styrene. The polymerization reactions of the aryl-substituted olefins, and particularly of styrene,[174] $C_6H_5.CH{=}CH_2$, are of interest both because of the relative ease of polymerization and the resinous character of many of the polymers produced. The arylalkenes exhibit a behavior similar to that of the simpler conjugated diolefin hydrocarbons. Polystyrene,[175] which is the product of polymerization of styrene either by heat, catalysts or under the influence of light, is a transparent vitreous substance of high molecular weight, insoluble in water, alcohol and petroleum hydrocarbons, but soluble in benzenoid hydrocarbons, chlorinated hydrocarbons and in esters. The physical properties of polystyrene are such as to render it a valuable synthetic plastic and, with the development of methods of producing styrene (e.g., by pyrolysis of ethylbenzene, formed by condensation of ethylene and benzene[176]) there can be no doubt that polystyrene will become of great technical importance.[177]

[174] Other names for this compound are styrol, styrolene, vinylbenzene, phenylethylene and cinnamene.

[175] This polymer has been referred to as "metastyrene" in the past. It appears advisable to replace the prefix "meta," which is used to denote a position of substitution in the benzene ring, by the prefix "poly," as suggested by Staudinger, "Die hochmolekularen organischen Verbindungen," Springer, Berlin, 1932.

The thermal polymerization of styrene proceeds rapidly (½ hour) in a sealed tube at 200° C. and more slowly (3 days) at 100° C.[178] At ordinary temperatures the polymerization of styrene proceeds extremely slowly in the dark,[179] although as demonstrated later, exposure to air results in the production of oxidized material which has a pronounced catalytic action on the speed of polymerization. The polymerization of styrene is accelerated by exposure to light. Exposure of styrene to sunlight at room temperature brought about the production of polystyrene in 3 weeks.[180] The photopolymerization of styrene is said to be incomplete and to lead to an equilibrium, $x\,C_8H_8 \rightleftarrows (C_8H_8)_x$. The partial reconversion of polystyrene to styrene takes place under the influence of sunlight and also by distillation.[181]

The polymerization of styrene (to polystyrene) is accelerated by catalysts, such as sulphuric acid.[182] According to Brooks and Humphrey,[183] 85 per cent sulphuric acid at 0° C. converts styrene into a hard resin. Polystyrene is produced by heating styrene with an aqueous solution of sodium bisulphite at 100° to 120° C.[184]

It has long been known that the presence of air or oxygen increases the tendency of styrene to polymerize.[185] Thus, Stobbe and Posnjak[186] found that styrene which had stood for 14 days was polymerized much more rapidly by heat and light than the freshly distilled hydrocarbon. Houtz and Adkins[187] also showed that the polymerization of styrene was accelerated by the presence of up to 2 per cent of ozonized diisobutylene. Though a polymerized styrene peroxide is simultaneously produced during the oxygen-activated polymerization of liquid styrene, it is doubtful whether this peroxide is the actual catalyst. Staudinger and Lautenschläger[188] have adduced evidence in support of the view that the peroxide is not the actual catalyst but that a primary oxide, formed during autoxidation, is the principal agent.

A number of other catalysts, such as anhydrous metallic halides, aryldiazonium fluoborates[189] and others,[190] promote the polymerization of styrene. Krakau[191] observed that the rate of polymerization of styrene is reduced by the presence of small amounts of elemental bromine, iodine, or sulphur. Pummerer and Kehlen[192] exposed styrene to visible or ultraviolet rays in the presence of a small amount of an aldehyde or ketone to effect polymerization.

Besides polystyrene, a liquid dimer (distyrene) has also been obtained by heating styrene to 170° C. with concentrated hydrochloric acid, or by the action of a mixture of concentrated sulphuric and glacial acetic acids on styrene.[193] Distyrene, which is not depolymerized to styrene by heating, is identical with 1,3-diphenyl-1-butene which has the constitution:

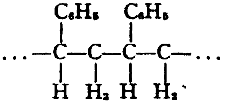
$$C_6H_5.CH{=}CH.\underset{\displaystyle C_6H_5}{\underset{|}{CH}}.CH_3$$

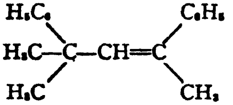
Staudinger[194] represents polystyrene as a long chain of styrene groups formed by end to end combination at the olefin double bond, as follows:



$$\ldots-\underset{\displaystyle H}{\underset{|}{\overset{\displaystyle C_6H_5}{\overset{|}{C}}}}-\underset{\displaystyle H_2}{\underset{|}{C}}-\underset{\displaystyle H}{\underset{|}{\overset{\displaystyle C_6H_5}{\overset{|}{C}}}}-\underset{\displaystyle H_2}{\underset{|}{C}}-\ldots$$

It is therefore a long methylene-chain substituted alternately by phenyl groups. The number of these styrene units in the more highly polymerized forms has been estimated at several thousand.

Of the homologues of styrene, *a-methylstyrene* (formula 1 below) is not readily polymerized by light or heat but is converted by the action of sulphuric acid into a crystalline dimer[195] which probably has the formula:



This dimer can be partly depolymerized to the parent hydrocarbon by heating. In a similar way, *β-methylstyrene* (formula 2) is polymerized by light or by catalysts, such as ferric chloride, to a crystalline saturated dimer.[196]

Of the other aryl-substituted ethylenes, *1,1-diphenylethylene*[197] (formula 3) is remarkably stable, whereas *1,1-diphenyleneethylene* (formula 4) is readily converted to a high molecular weight polymer even in diffused daylight.[198]

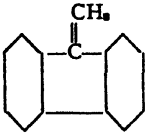
(4)



1,1-diphenyleneethylene

(5)

stilbene

Stilbene (sym.-diphenylethylene) (formula 5 above) is polymerized in benzene solution under the influence of sunlight to yield a dimer which is tetraphenylcyclobutane.[199] This photopolymerization is said to be reversible, the position of the equilibrium $2C_{14}H_{12} \rightleftharpoons C_{28}H_{24}$ depending upon the wave length of the light.

The polymerization products of styrene find application as plastic materials, for example, in the manufacture of cast, molded and lathe-turned articles and as coating materials. They have also been added to lubricating oils to improve their properties and increase their viscosity.[200] Hydrogenated polystyrene or hydrogenated polymerized diolefins can also be used for this purpose. Instead of adding polymerized styrene as such to the oil directly, styrene itself may be added, it then being polymerized and hydrogenated in the oil.

UTILIZATION OF OLEFIN POLYMERS

Large quantities of dimers of the simple monolefins are undoubtedly produced during the refining of cracked gasolines with sulphuric acid. Besides the uses already mentioned, these dimers appear to be quite valuable constituents of motor spirit since Howes and Nash[201] found that diisobutylene and the diamylenes (especially the diamylene prepared from trimethylethylene) possess excellent antidetonating properties.[202] The conversion of olefins to high molecular weight oils capable of being utilized as lubricants, by polymerization under the influence of aluminum chloride or boron trifluoride, is an interesting development in the application of the olefins. An account of industrial developments in the production of lubricants from gaseous and liquid olefins by this method has been presented by Sullivan and Voorhees and their collaborators.[203]

The production of a mixture of liquid paraffins and unsaturated drying oils for use in varnishes by polymerization of gaseous unsaturated hydrocarbons with sulphuric or phosphoric acid, has been effected.[204] A residue obtained by Zilberman, Bolotin and Yakubovich[204a] from the residues of oil cracking, consisting of fractions boiling between 185° and 243° C., was found to reduce the oil-absorption capacity of pigments and could be substituted to the extent of about 75 per cent for linseed oil. This polymerized material had a specific gravity of 0.858, iodine number of 80.7, acid number of 1.9, and saponification number of 28.66.

The liquid polymerization products of olefins may be used as solvents for organic substances such as ethylcellulose, rubber, fats, waxes, and bitumens.[205] For the preparation of varnishes and paints, Chittick[205a] heated for 1 hour at 150° to 260° C., 4 parts by weight of a drying or semi-drying oil (linseed or tung oil) with 6 parts of reduced hydrocarbon polymers obtained by catalytic action of unsaturated residues from petroleum at high temperatures. The mixture was subsequently cooled to 95° C. and 1 part of japan drier and 0.5 part of turpentine or naphtha were added. Robinson[205b] used polymers resulting from washing oil gas with sulphuric acid for the denaturing of alcohol.

The numerous methods for the production of liquid hydrocarbons by the thermal treatment of gaseous or low-boiling olefins are discussed elsewhere (see Chapters 2, 5 and 6).

POLYMERIZATION OF DIOLEFINS

Unsaturated hydrocarbons with two ethylene linkages in the molecule exhibit a great tendency to polymerize under the influence of many comparatively mild reagents. This is particularly true in the case of conjugated dienes like butadiene,

$$CH_2{=}CH{-}CH{=}CH_2$$

and its derivatives, which polymerize readily to high molecular weight, amorphous, rubber-like substances. In polymerizing diolefins, comparatively mild conditions must be employed, since the use of reagents which are successful in polymerizing monolefins, such as aluminum chloride and sulphuric acid, leads to the formation of tars and resins of less value.[206]

Two main types of polymerization may be clearly distinguished in the diolefin series, namely,[207] (1) the allene type in which hydrocarbons of the type $>C{=}C{=}C<$ yield cyclobutane derivatives, and (2) the 1,3-butadiene or isoprene type, which tend to furnish unsaturated cyclohexane hydrocarbons, as well as amorphous polymers of high molecular weight, some of which are rubber-like masses.

ALLENES

When heated in the liquid state at 140° C. under pressure for 3½ days, allene (propadiene, $CH_2{=}C{=}CH_2$) is converted to the extent of about 50 per cent into a mixture of polymers consisting of 5 per cent dimer, 15 per cent trimer, 5 per cent α-tetramer, 22 per cent β-tetramer, 18 per cent pentamer, 10 per cent hexamer, and 25 per cent of a colorless gum-like solid.[208] When pyrolyzed at higher temperatures at atmospheric pressure both allene and methylallene yield large quantities of liquid polymers. A temperature of about 500° C. was found most appropriate for the formation of liquids from allene by pyrolysis in a pyrex tube. Above that temperature considerable cracking occurred with the formation of liquid products.[209] With methylallene, complete decomposition was effected at 500° to 550° C. in 36 seconds and 75 per cent of the hydrocarbon was converted into liquids of a polymeric nature. These were separated as efficiently as possible into fractions each containing one polymer. The lowest fraction boiled at 110° to 115° C. and was apparently a dimer although attempts to prove its structure by oxidation methods were fruitless.

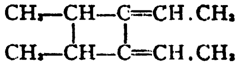
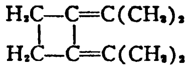
[208] Lebedev and Mereshkovski, *loc. cit.*

Polymerization of the two dimethylallenes and also of trimethylallene and tetramethylallene has been carefully investigated by Lebedev and Mereshkovski,[210] who have shown that dimerization results in the production of cyclobutane derivatives. Polymerization of symmetrical dimethylallene by heating at 150° C. in the absence of catalysts, was complete in 4 to 5 days and the products consisted of 90 per cent of a dimer (boiling point 163° C.) and 5 per cent of an odorless liquid trimer (boiling point 108° to 110° C. at 17 mm. pressure). The dimer was proved to be 1,2-dimethyl-3,4-diethylidene-cyclobutane, of which the graphic formula is:



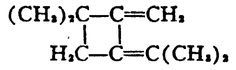
Three isomeric dimers were obtained by Lebedev[211] by heating unsymmetrical dimethylallene in sealed tubes at 100° to 225° C. for 2 to 20 days. The suggested structures of the polymers so produced are shown by the following formulas:

I



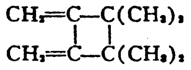
colorless liquid of aromatic odor; b.p. 179°-181° C. at 753 mm.

II



colorless liquid with a kerosene-like odor; b.p. 149°-150° C. at 753 mm.

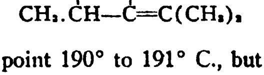
III



colorless liquid of terpene-like odor; b.p. 140°-141° C. at 753 mm.; very readily polymerized.

At 130° C. the relative amounts of the polymers produced from dimethylallene were: 40 per cent of dimer I, 18 per cent of II, 3 per cent of III, 33 per cent of a trimer boiling at 100° C. at 8 mm. and 6 per cent of a petrolatum-like residue.

When trimethylallene was heated in a sealed tube at 150° C. both polymerization and isomerization reactions occurred. The mixture of dimers formed consisted mainly of the hydrocarbon:



a colorless liquid of boiling point 190° to 191° C., but about 10 per cent of higher polymers were also produced.[212] Similarly, tetramethylallene, on heating, condensed to the dimeric form:

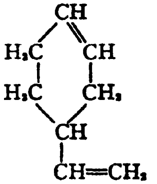
The stability of the methylallenes diminishes with increasing number of methyl groups[213] and the substituted allenes show great tendency to isomerize to the corresponding isomeric acetylene hydrocarbons under the influence of catalysts, such as sodium.

CONJUGATED DIENES

A vast amount of work has been carried out on the conversion of the diolefins into synthetic rubber-like substances. The large number of proposed processes testifies to the great commercial interest in the production of synthetic rubber from these sources. Before presenting a brief summary of this aspect of the polymerization of conjugated dienes, it is well to consider the formation of the simpler liquid polymers of these hydrocarbons. Liquid polymers are frequently formed during the polymerization of 1,3-dienes by heat and other agents, and a study of their properties suggests that many of them are not intermediate products of rubber formation but are formed by polymerization reactions unlike those which result in the formation of rubber-like materials.

It appears that the maximum production of high molecular weight and rubber-like polymers is obtained by carrying out the polymerization at the lowest possible temperatures. Thus, it has been shown that in the case of isoprene and 2,3-dimethylbutadiene, with increasing temperature the proportion of dimers increases and that of the higher polymers diminishes.

The diolefin, 1,3-butadiene, undergoes polymerization to high molecular weight substances when heated to above 90° to 100° C. in an autoclave with or without a catalyst. When heated in a sealed tube at 150° C. for 10 days, butadiene yielded a dimer as well as resinous materials. This dimer, which is a liquid of sharp mustard-like odor and boiling point 129.5° to 130.5° C. at 760 mm., probably has the constitution



since it is hydrogenated to ethylcyclohexane and with bromine forms a tetrabromide.[214] Harries[215] studied the dimer produced from butadiene by heating under pressure and concluded from ozonization experiments that it was identical with 1,5-cyclooctadiene.[216] Vinylcyclohexenes or other oily polymerization products are said to be produced by heating butadiene or its homologues to 400° C. or higher, with or without catalysts.[217]

A kinetic study of the thermal polymerization of butadiene in the vapor phase in pyrex tubes in the temperature range 326° to 436° C. and at pressures of 720 to 1.5 mm. has been made by Vaughan.[218] The reaction was found to be homogeneous and strictly bimolecular over the greater part of its duration. The presence of oxygen in the reacting gas did not accelerate the polymerization rate. The second order velocity constants, k, were related to the temperature, T, by the expression

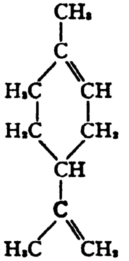
$$\log_{10} k = -5680\left(\frac{1}{T}\right) + 7.673$$

k being expressed in liters per mole per second. The energy of activation is calculated as about 25,000 calories.

Liquid polymerization products are said to be obtained as sole products by heating butadiene above 40° C. under a pressure of 200 atmospheres[219] with aliphatic or aromatic amines or finely divided metals and in the presence of a diluent. A colorless oil may be obtained from butadiene at 150° to 220° C. and a more viscous oil at temperatures above 220° C. The oil may be employed to improve the adhesion of lacquers and binding agents such as glue.

In the polymerization of *isoprene* (2-methyl-1,3-butadiene) at least two dimers appear to be formed, one of which is the well-known hydrocarbon dipentene, having the constitution:



Various divergent opinions concerning the identity of the second dimer have been advanced. By the carefully controlled thermal polymerization of isoprene, Harries[220] obtained a rubber-like substance together with dipentene and a dimer which he regarded as 2,6-dimethyl-1,5,7-octatriene. Similarly, Ostromislensky and Koshelev[221] obtained a hydrocarbon which they called β-myrcene and regarded as an open-chain triene, by heating isoprene at 80° to 90° C. for 3 days. Another dimer, prepared by Aschan,[222] by the autopolymerization of isoprene and called "diprene," corresponded to a m-menthadiene. Wagner-Jauregg[223] indicated that the so-called octatriene of Harries contains only two double bonds and can be catalytically reduced to m-menthane; and also that Ostromislensky's β-myrcene is identical with the m-menthadiene (diprene) of Aschan. The identity of these hydrocarbons with the octatriene of Harries is regarded as established since, like them, it affords carvestrene dihydrochloride on treatment with hydrogen chloride in acetic acid. It appears, therefore, that at least two dimers are formed from isoprene, namely, dipentene and a m-menthadiene of the following constitution (proposed by Lebedev and Mereshkovski[224]):

---

[219] I. G. Farbenindustrie A.-G., British Patent 328,908, 1929; *Brit. Chem. Abs.* B, 1930, 754.

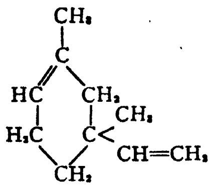
[222] *Ann.*, 1924, 439, 221; *Chem. Abs.*, 1925, 19, 52; *Ber.*, 1924, 57, 1959.
[223] *Ann.*, 1931, 488, 176; *Brit. Chem. Abs.* A, 1931, 1031.
[224] *J. Russ. Phys.-Chem. Soc.*, 1913, 45, 1249.



According to Wagner-Jauregg, this m-menthadiene or β-myrcene is the sole dimer formed by heating isoprene at 80° to 90° C. for several days. Lebedev observed that when isoprene was heated in sealed tubes at 150° C. for 6 to 7 days, both dipentene and the isomeric dimer, which boiled at 160° to 161° C., are formed, together with resinous substances.

Whitby and Crozier[225] found that the polymerization of pure isoprene at temperatures of 10° to 145° C. does not afford a polymerizable dimer such as the β-myrcene of Ostromislensky. The products isolated by these investigators were oily cyclic dimers, which are not intermediate steps in the conversion of isoprene into rubber-like polymers. Dipentene was shown to be present in considerable proportion in these oils, together with one or more oily cyclic dimers. Certain inorganic salts, such as antimony pentachloride or tin tetrachloride polymerize these dimers rapidly in the cold, with the production of polymers which may be isomers of the ordinary synthetic caoutchouc.

Gapon[226] stated his belief that the primary polymerization reactions of diolefins occur by the production of activated molecules which can then react with unactivated molecules but not with other activated molecules. The possible number of dimers produced is therefore a function of the number of activated types capable of being formed. The initial activation step is believed to consist in the breaking of one double bond with the momentary production of tervalent carbon atoms. The rate of polymerization of isoprene in sealed tubes at temperatures of 100°, 110°, 130° and 150° C. in the dark was also studied by Gapon.[227] It was concluded that, in the activation of isoprene, three active forms are produced which, by addition to inactivated isoprene molecules, lead to the formation of dipentene, 1,3-dimethyl-3-vinyl-6-cyclohexene, and two polymers.

The polymerization of isoprene and similar conjugated diolefins under the influence of catalysts takes place very readily at low temperatures and usually results in the production of rubber-like polymers of high molecular weight. A full discussion of the specific action of various polymerizing catalysts is beyond the scope of this work but mention may be made of the following materials which are active in promoting low-temperature polymerization of these hydrocarbons: anhydrous inorganic halides such as aluminum chloride[228]; tin tetrachloride, antimony pentachloride, boron trifluoride[229]; strong acids, metals or oxides,[230] ozonides and peroxides[231] of the alkalies or alkaline earths. In addition to these well-known polymerizing agents, many apparently unrelated materials have been stated to catalyze the polymerization of dienes, for example, alkaline earth alkyls,[232] glycerol, starch, urea, and caoutchouc-like substances.[233]

[230] For example, butadiene is polymerized in the presence of sodium balls of 1.1 mm. diameter by Ebert, Fries and Garbsch (U. S. Patent 1,880,918, Oct. 4, 1932; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1933, **27**, 514). In the polymerization of diolefins by alkali or alkaline earth metals, alkali metal hydrides, or organometallic compounds, additions of dioxan or substances capable of substituting the metallic atoms of organometallic compounds, such as thiophene, hydrocyanic acid, benzyl cyanide and methylacetylene are of advantage, according to Ebert and Fries (U. S. Patent 1,832,450, Nov. 17, 1932; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1932, **26**, 1157; I. G. Farbenindustrie A.-G., French Patent 710,791, 1931; *Chem. Abs.*, 1932, **26**, 1615). See also Ebert, Fries and Reppe, U. S. Patent 1,827,285, Oct. 13, 1931; *Chem. Abs.*, 1932, **26**, 479; French Patents 688,592 and 688,593, 1930; *Chem. Abs.*, 1931, **25**, 710; all patents assigned to I. G. Farbenindustrie A.-G.

The catalytic influences of peroxides, per-acids, and oxidized substances formed during autoxidation of diolefins, on the polymerization of isoprene and its congeners has been known for many years.[234] Conant and Tongberg[235] showed that the rate of polymerization of isoprene under high pressure is greatly increased by the presence of ozonized isoprene. The rate is approximately in accord with a first order reaction probably because of an autocatalytic effect. From experiments on the polymerization of isoprene, dimethylbutadiene, cyclopentadiene, myrcene, and other hydrocarbons in the presence of oxygen at 80° C., Staudinger and Lautenschläger[236] concluded that in all cases autoxidation accelerates polymerization. Though addition of peroxides catalyzes polymerization, the result is not as great as with oxygen, hence the active agent is probably a compound resulting from the autoxidation.

Increase of pressure increases the velocity of the (uncatalyzed) polymerization of isoprene, dimethylbutadiene, and other diolefins, and also reduces the temperature of initial polymerization. The reaction was found by Tammann and Pape[237] to follow the unimolecular law. This suggested that before union the molecules undergo some change and that the speed of the complete process is determined by the rate of this initial reaction.[238]

The other methylated derivatives of butadiene, most important of which are piperylene (1-methylbutadiene) and 2,3-dimethylbutadiene can be polymerized more or less readily to rubber-like polymers. Certain other dienes, such as 1,1-dimethylbutadiene, 1-phenylbutadiene, 1,2,3,4-tetramethylbutadiene, and 1,2-dimethylbutadiene, also possess a great tendency to polymerize but the products are not rubber-like. An increase in the number of methyl substituents in butadiene diminishes the ease of polymerization. Methyl substitution in the terminal carbon atoms, compared with substitution in the middle positions, also exerts an unfavorable influence on the polymerization to high molecular weight products.[239] The introduction of phenyl groups into the butadiene chain favors polymerization to dimers but inhibits further polymerization to rubber-like or resinous polymers.[240]

Very few of the simple polymers of these higher conjugated dienes have been definitely identified. A dimer of 2,3-dimethyl-1,3-butadiene closely resembling dipentene, can be produced by careful polymerization of that diene or by thermal depolymerization of 2,3-dimethylbutadiene rubber.[241] According to Lebedev and Mereshkovski,[242] this dimer, boiling at 85° C. at 13 mm. and at 205° C. at 750 mm., with a density 0.8741, probably possesses the structure:

The diolefins which do not possess a conjugated system of double bonds are much more resistant to polymerization than those of the butadiene type. Thus, diallyl (1,5-hexadiene),

$$CH_2{=}CH.CH_2.CH_2.CH{=}CH_2$$

was completely unchanged by heating for 8 days at 140° to 200° C., but heating for 10 days at 250° C., 40 per cent of the hydrocarbon became converted into polymers and isomerization also occurred. The crude product of the reaction contained about 15 per cent of a liquid dimer (boiling point 97°-98° C. at 20 mm.) and 85 per cent of a colorless insoluble resinous polymer.[243]

Whitby and Gallay[244] prepared a number of dimers of various substituted butadienes by the action of heat on these hydrocarbons. Besides higher polymers the dimers given in Table 113 were obtained:

TABLE 113.—*Dimers of Substituted Butadienes.*

Parent Diolefin	Boiling Point ° C.	Boiling Point of Dimers ° C.
2,3-Dimethylbutadiene	69–70	95 at 17 mm.
1,2-Dimethylbutadiene	80–82	(1) 97–100 at 16 mm.
		(2) 108–110 at 16 mm.
1,1-Dimethylbutadiene	76–77	(1) 94–97 at 16 mm.
		(2) 105–108 at 16 mm.
1,3-Dimethylbutadiene	76–77	90–92 at 16 mm.
1,4-Dimethylbutadiene	—	(1) 90 at 20 mm.
		(2) 96–98 at 20 mm.

Tetramethylbutadiene shows no tendency to polymerize on heating under conditions which readily convert isoprene to rubber-like material, but a dimer may be produced by the action of sulphuric acid.[245] The cyclic conjugated diolefins as a class are very readily polymerized, the usual products being high molecular weight resinous polymers, though the lower polymers are also formed under favorable conditions.

Cyclopentadiene is remarkable for its ease of polymerization and for the large number of polymers which have been prepared, though the question of the constitution of these compounds has aroused considerable controversy. The polymerization of cyclopentadiene to solid polymers proceeds spontaneously on standing at ordinary temperature, particularly in the presence of air or oxygen, but is much more rapid at higher temperatures.[246] Exposure to light has little influence on the reaction.[247] When cyclopentadiene is heated to 135° C., dicyclopentadiene is formed mainly, but by prolonging the heat treatment and by using somewhat higher temperatures, Staudinger and his collaborators[248] have been able to prepare a whole series of polymers which include the dimer, trimer, tetramer, pentamer and also possibly a hexamer.

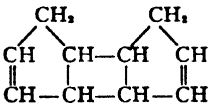
[245] Macallum and Whitby, *Trans. Roy. Soc. Canada*, 1928, 22, 39; *Chem. Abs.*, 1928, 22, 2080; *cf.* Whitby and Gallay, *loc. cit.*

These polymers, the first four of which are crystalline solids, may be separated from one another by fractional distillation *in vacuo*. Each compound possesses two double bonds and the corresponding dihydro- and tetrahydro-derivatives are readily obtained by catalytic hydrogenation. Perhaps the most remarkable feature of this series of polymers is the reversible character of the polymerization process. When heated at atmospheric pressure the polymers are partly dissociated to yield cyclopentadiene and the other (lower) polymers. Dicyclopentadiene yields mainly cyclopentadiene by distilling at atmospheric pressure, but tricyclopentadiene is more stable to heat than either dicyclopentadiene or tetracyclopentadiene. The melting points of these polymers are given in Table 114:

TABLE 114.—*Polymers of Pentadiene.*

Compound	Melting Point ° C.
Dicyclopentadiene	32.5 α-form 19.5 β-form
Tricyclopentadiene	60
Tetracyclopentadiene	188–190
Pentacyclopentadiene	270
Polycyclopentadiene	decomposes above 300

The question of the chemical constitution of these crystalline lower polymers of cyclopentadiene appears to be undecided. If 1,2 addition takes place, the constitution of dicyclopentadiene can be represented by the graphic formula



This formula, first proposed by Kraemer and Spilker,[249] is also supported by Staudinger and Rheiner,[250] who assign to tricyclopentadiene the constitution

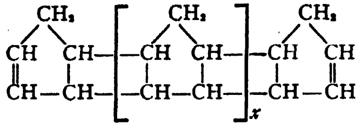
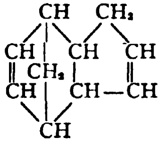
On this basis the general formula for the non-resinous polymers of cyclopentadiene becomes

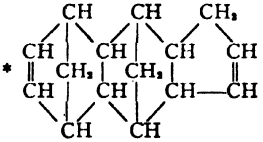


where *x* is a relatively small integer. The depolymerization of these cyclopentadiene polymers is considered to take place by rupture of the cyclobutane ring systems under the influence of heat.

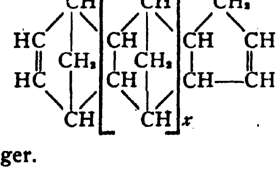
An alternative formula for dicyclopentadiene is that originally proposed by Wieland,[251] namely,



which may be regarded as the result of the addition of a cyclopentadiene molecule activated in the 1,4 position to a second molecule at the 1,2 position. A good deal of evidence in support of this configuration for dicyclopentadiene, and of similar structures for the other polymers, has been put forward by Alder, Stein and Finzenhagen,[252] who found that dicyclopentadiene readily yields an addition compound with phenyl azide and oxidation of its dihydro-derivative affords cyclopentane-1,3-dicarboxylic acid. Later, Alder and Stein [253] showed that tricyclopentadiene and tetracyclopentadiene also form addition compounds with phenyl azide and adduced evidence in support of the contention that tricyclopentadiene is also formed by 1,4- addition of cyclopentadiene to dicyclopentadiene and thus possesses the configuration



Polymerization can continue indefinitely on account of the highly reactive ethylene linkage (marked *) and the general formula of the higher polymers, on the basis of this mode of coupling, can be written as



where *x* is a small integer.

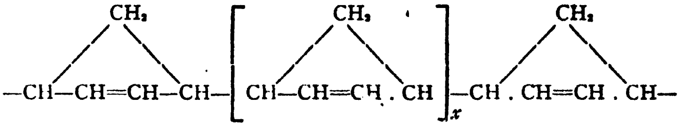
HIGHER POLYMERS OF CYCLOPENTADIENE

Another and different type of condensation occurs when cyclopentadiene is polymerized in the presence of catalysts such as anhydrous metallic halides. There is produced a white amorphous powder of the formula $(C_5H_6)_x$, in which x may vary from 20 to 100. When dried at 50° C. in a high vacuum it swells to a spongy brittle mass which can be powdered. This so-called "cyclopentadiene rubber" takes up oxygen on exposure to air and shows other evidences of being unsaturated. The probable structure of this material is:[254]



The polymerization of cyclopentadiene to this resinous material has been investigated by Staudinger and Bruson.[255] The following substances were found effective as catalysts: the halides of the amphoteric elements such as the tetrahalides of tin and titanium, the tri- and pentahalides of antimony, boron trichloride, arsenic halides, ferric and bismuth halides and also certain strongly negative substances such as sulphuryl chloride, phosphorus pentoxide and phosphorus pentachloride. The reaction is so rapid in the case of tin tetrachloride[256] (the best catalyst found) and of antimony pentachloride and boron trichloride, that it was necessary to use a liquid diluent, such as benzene, chloroform and carbon tetrachloride, and to cool vigorously.

CYCLOHEXADIENE

The work of Hofmann and Damm[257] on *1,3-cyclohexadiene* indicates that this hydrocarbon exhibits considerably less tendency to polymerize than butadiene or its 2- or 3-substituted homologues, thus it is more closely related to 1- and 4-substituted butadienes. Sodium is without influence on this compound, though ferric chloride exerts a pronounced accelerating action on its polymerization. On heating at 200° to 220° C. for several hours the hydrocarbon is largely polymerized with the production of a solid rubber-like polymer ("dihydrobenzene rubber") and a terpenic dimer. Practically no polymerization occurs at temperatures below about 120° C. The dimeric cyclohexadiene differs from the corresponding dimer of cyclopentadiene in that the former cannot be solidified in a freezing mixture and is not decomposed when boiled at atmospheric pressure. To this dimer, which contains two ethylenic linkages and is resinified by concentrated sulphuric and nitric acids, Hofmann and Damm assigned the constitution,

This structure has been confirmed by Alder and Stein[258] by oxidation of the corresponding dihydro-derivatives to cis-hexahydroterephthalic acid.

Cyclohexadiene gives tars immediately when treated with sulphuric acid.[259]

Cyclohexene, when treated with 96 per cent sulphuric acid at 2° to 5° C., yielded 37 per cent of an oil. From this oil Nametkin and Abakumovskaja[260] obtained three fractions, which consisted of (1) a hydrocarbon, $C_{12}H_{22}$, boiling at 216°-219° C. at 739 mm., which gave a small amount of naphthalene on dehydrogenation; (2) a hydrocarbon, $C_{18}H_{32}$, which boiled at 145°-147° C. at 1.5-2 mm.; and (3) a hydrocarbon, $C_{24}H_{20}$, with one unsaturated linkage which was a very viscous liquid and boiled at 200°-203° C. at 1.5-2 mm.

MUTUAL CONDENSATION OF OLEFINS AND DIOLEFINS

Closely allied with the polymerization process proper is the condensation of two different unsaturated hydrocarbons with the production of a more complex molecule. Both types of reaction are essentially the same, and both owe their occurrence to the unsaturated linkages present in the hydrocarbons reacting. The condensation of a conjugated diolefin hydrocarbon with various monolefin hydrocarbons, a reaction which was also noted by Aschan,[261] has been utilized as a source of new synthetic resinous materials. Thomas and Carmody[262] observed that, though the polymerization of pure isoprene in the presence of anhydrous aluminum chloride was slow at ordinary temperature, the addition of an olefin, such as 2-pentene or trimethylethylene, caused a reaction to commence immediately. Two types of polymers were obtained by decomposing the aluminum chloride complex with water: namely, a white granular resin of the formula $(C_5H_8)_x$, insoluble in most organic solvents, together with a light straw-colored resin soluble in many organic solvents and with a carbon-hydrogen ratio which varied with the relative proportions of diolefin and monolefin employed. The insoluble resin is evidently a polymer derived mainly, if not entirely, from the polymerization of the isoprene, whereas the soluble product is probably the result of mutual condensation of diolefin and monolefin. The yield of the soluble polymer is a function of the proportion of monolefin present though its hardness is inversely proportional to that amount. On the other hand, the amount of insoluble polymer is an inverse function of the monolefin present in the diolefin-monolefin mixture. The production of resins for use, for example, in varnish formulation, by the action of aluminum chloride on cooled highly unsaturated cracked distillates containing both diolefin and monolefin constituents, has been carried out by Thomas and Carmody.[263] Thomas and Hochwalt[264] described a process for the production of a non-acid, unsaponifiable resin by subjecting a cracked distillate, which boils below 180° C. and contains 25 to 50 per cent of olefins and diolefins, to the action of aluminum chloride. The product is treated with water and distilled to remove volatile constituents. The residue is dissolved in a hydrocarbon and the resin is then precipitated from the solution by the addition of alcohol and acetone.

Hugh[265] obtained a material resembling rubber or deresinated gutta percha, by polymerizing at 20° to 201° C. a mixture of a diolefin (butadiene, isoprene, or dimethylbutadiene) and an aromatic olefin (styrene, naphthylethylene, divinylbenzene, or their homologues) in the presence of sodium, sodium-amalgam, or other catalyst, and also, if necessary, of an antioxidant such as phenyl-α- or β-naphthylamine. A non-volatile hydrocarbon swelling agent may be added to render the product thermoplastic. These materials are intended for use in the insulation of submarine cables.[266]

THE PRODUCTION OF SYNTHETIC RUBBER

The fact that isoprene, prepared by the destructive distillation of rubber, could be converted to spongy elastic material closely resembling natural rubber was observed by Williams [267] and, 19 years later, by Bouchardat.[268] The latter investigator employed hydrochloric acid as the condensing material. The credit of first actually synthesizing an artificial rubber-like material belongs, however, to Tilden.[269] Tilden found that hydrochloric acid and also nitrosyl chloride were effective in promoting polymerization of synthetic isoprene to rubber-like materials. He noted later that, under the influence of light, polymerization also resulted. Tilden stated that the action of hydrochloric acid on isoprene converts it partially into caoutchouc. The latter seems to be produced most readily from the oily polymer, resulting from the action of heat. This important fact was completely substantiated later by Ostromislensky and Koschelev,[270] who found that the character of the synthetic isoprene rubber was markedly influenced by its mode of polymerization, for, on heating isoprene to 80° to 90° C., it was found to polymerize spontaneously to a dimer called β-myrcene, which then yielded a normal isoprene caoutchouc when polymerized with sodium and barium peroxides at 60° to 70° C., whereas isoprene itself, when treated with these reagents, gave an abnormal caoutchouc product.

The polymerization of 2,3-dimethyl-1,3-butadiene (diisopropenyl), a homologue of isoprene, to a rubber-like product was effected by Kondakov [271] by subjecting this hydrocarbon to the action of alcoholic potash for three days. Kondakov also observed that the polymerization of this unsaturated hydrocarbon occurred spontaneously and was much more rapid than the polymerization of isoprene or butadiene. During the polymerization of this hydrocarbon, either spontaneously or under the influence of alcoholic potash, dimers and trimers were formed also. Like natural Para rubber, Kondakov's rubber can be depolymerized by heat to yield a dimer of 2,3-dimethyl-1,3-butadiene, identical with the product obtained by the careful polymerization of 2,3-dimethyl-1,3-butadiene.

The rapid conversion of unsaturated hydrocarbons to rubber-like substances was also reported by Wallach [272] and Lebedev,[273] with daylight; by Ostromislensky,[274] with ultraviolet radiation; and by Collie,[275] who employed the silent electric discharge.

The rise in the price of natural rubber after 1905, which resulted from the greatly increased demand for this material, stimulated research on the polymerization of dienes to rubber-like materials. In 1911, Harries [276] reported that the polymerization of isoprene to rubber-like substances took place when isoprene was heated in a sealed tube with acetic acid for 8 days at 90° to 100° C., though the yields were variable. Hofmann and Coutelle [277] also observed that pure isoprene or its homologues could be polymerized to caoutchouc in good yield when subjected to heat, with or without catalysts. Perhaps the most important discovery was that of Matthews and Strange [278] (1910), who found that metallic sodium was a very active polymerizing agent. Harries,[276] who appears to have made this same discovery towards the end of 1910, stated that butadiene is converted into synthetic rubber at ordinary temperature in a few hours under the influence of metallic sodium and isoprene is converted at about 60° C. almost quantitatively without the production of dimers or trimers, in from 50 to 100 hours.[279] The sodium is for the greater part quite unchanged. Harries found, however, that the sodium-condensed caoutchouc has a structure differing from that possessed by synthetic rubbers produced by the action of heat or by the aid of acetic acid. Certain other catalytic agents, such as acetic anhydride,[280] perborates, ozonides of isoprene, or other oxygen carriers,[281] sodamide,[282] and sulphur,[283] have also been proposed.

According to Harries,[284] there are three well-known methods of polymerizing butadiene and its simple homologues to rubber-like products, namely, (1) heating alone, or in acetic acid solution, in a sealed tube for a period at 60° to 100° C.; (2) heating, or allowing to stand, in the presence of metallic sodium in an atmosphere of carbon dioxide; and (3) heating in the presence of peroxides, especially benzoyl peroxide.

As regards the quality of the synthetic rubbers produced by the polymerization of the simple butadiene derivatives, it must be clearly borne in mind that though these substances may possess many of the characteristics of natural rubber, they are not identical by any means. Even with the isoprene polymers, the identity with natural rubber is not proved. Harries has attempted to assign structures to natural and synthetic rubbers on the basis of the products obtained by decomposing their ozonides with water.

Briefly, natural rubber or caoutchouc is a transparent tough elastic material, soluble in various organic solvents, and its composition may be expressed by the formula $(C_5H_8)_x$. It is unsaturated in nature and on destructive distillation yields a mixture of hydrocarbons, of which the most important are isoprene and dipentene. When heated with sulphur, or when treated with solutions of sulphur dichloride in carbon disulphide it becomes "vulcanized." This latter important property is also possessed by the synthetic rubbers prepared by the polymerization of diolefins. The synthetic rubbers prepared by the polymerization of dienes under various conditions give rise to ozonides which exhibit different rates of hydrolysis with water and give different decomposition products, According to Harries, 1,3-butadiene, isoprene, and piperylene give rise, on polymerization, to synthetic rubbers which are superior from a practical point of view to those obtained by the polymerization of 2,3-dimethyl-1,3-butadiene, a conclusion also arrived at by Fisher and Chittenden.[285]

[284] "Untersuchungen über die natürlichen und künstlichen Kautschukarten," Julius Springer, Berlin, 1919, 170.

It appears that, though many diolefins have been stated to polymerize to rubber-like substances, the possibilities are in reality quite limited to simple butadiene derivatives, notably butadiene, isoprene, piperylene (1,3-pentadiene), and 2,3-dimethyl-1,3-butadiene. For example, Harries found that both 1,1-dimethyl-1,3-butadiene and 1-phenyl-1,3-butadiene presented difficulties in polymerization to rubber. Macallum and Whitby[286] concluded that, (1) methyl substitution in the terminal carbon atoms of butadiene, compared with such substitution in the middle positions, exerts an unfavorable effect in the ease of polymerization to rubber-like substances, and (2) an increase in the number of methyl substituents in butadiene diminishes the ease of polymerization. In support of the latter statement it was shown that 1,2,3,4-tetramethyl-1,3-butadiene,

$$H_3CCH{=}C(CH_3){-}C(CH_3){=}CHCH_3$$

had little or no tendency to undergo polymerization to a rubber. Recently Fisher and Chittenden[287] prepared 3-methyl-1,3-pentadiene (1,2-dimethyl-1,3-butadiene),

$$CH_3CH{=}C(CH_3){-}CH{=}CH_2$$

and found that this hydrocarbon did not polymerize to an elastic, resilient, rubber-like product. These workers concluded that the polymerization of dienes to rubber-like products does not depend solely upon the presence of the vinyl group.

It must not be supposed that these and other diolefins cannot be made to polymerize. In actual fact many of these substances polymerize with greater ease than butadiene or its simple homologues, but the products are not rubber-like in nature.

Results of theoretical and practical interest were obtained by Ostromislensky[288] on the polymerization of vinyl bromide, a process which resulted in the production of three polymeric substances which he called *caouprene bromides.* On treatment with zinc dust they yielded a substance apparently identical with the butadiene-rubber of Harries. Similarly the bromide of Harries' butadiene-rubber was found to exist in three modifications, identical or isomeric with the caouprene bromide of Ostromislensky.

Since the World War there has been a renewal of interest in the polymerization of diolefins, produced by the pyrolysis of petroleum hydrocarbons, to rubber-like substances and rubber substitutes. Processes for polymerizing isoprene in which this diolefin is treated, for example, with colloidal suspensions or solu-

[287] *Loc. cit.*

[288] *J. Russ. Phys.-Chem. Soc.*, 1912, **44**, 204; *Chem. Soc. Abs.*, 1912, **102** (1), 280; *Chem. Abs.*, 1912, **6**, 1538.

tions of substances such as egg albumin, sodium oleate, or turkey-red oil, in the presence of electrolytes, together with oxygen or compounds which yield oxygen, such as perborates, have been proposed.[289] The rubber so obtained is rolled into sheets, mixed with sulphur, and vulcanized in the ordinary way, and the products are said to be distinguished by high elasticity and strength.

In another method[290] for the production of rubber-like products, the polymerization of diolefins is effected in the presence of an emulsion which has previously been passed through a homogenizer. Polymerization is thereby facilitated and the yield of rubber-like product is improved. Diolefins in the form of creamy or gelatinous mixtures with aqueous solutions (these mixtures containing at least 75 per cent by volume of the hydrocarbons) also may be polymerized to rubber-like products.[291] Additional substances such as oxidizing agents, buffer mixtures, and materials capable of modifying the surface tension of emulsions may be present also. The polymerization of diolefins likewise can be effected in the presence of latex or similar vegetable saps and of oxidizing or emulsifying agents.[292]

The polymerization of butadiene hydrocarbons with the aid of sodium hydride is slower than with metallic sodium, which sometimes induces polymerization with almost explosive violence.[293] With sodium hydride, it is said that a more homogeneous product is obtained. The process is conveniently conducted in the presence of an indifferent solvent such as benzene, with agitation.

Plastic or elastic products of polymerization with exceptional stability on storage, can be made from diolefins such as isoprene or butadiene, by adding a dissolved or emulsified antioxidant to the latex or latex-like products from which the polymerized material is to be separated.[294] The antioxidant may be introduced before or during coagulation of the latex-like suspension and is used in such proportions that 0.5 to 2 per cent is present in the coagulated product. Prior to coagulation, compounding ingredients also may be introduced.

The polymerization of butadiene or its homologues sometimes leads to rubber-like products which are insoluble in benzene and do not readily become plastic when milled. These undesirable features can be removed by treating with an organic nitro-compound, e.g., mono-, di-, or trinitrobenzene, advantageously in the presence of a solvent such as benzene and at temperatures of about 140° to 150° C.[295]

Since the polymerization of diolefins is sometimes extremely violent, it has been proposed[296] to connect a second chamber, containing no polymerizing catalyst, with the actual reaction vessel. If violent reactions do occur, the starting material distils into the second chamber where it may be returned, e.g., by distillation or by gravity, when convenient, into the reaction vessel.

According to Kleiber and Gilardi[297] an elastic mass, capable of being vulcanized and used as a rubber substitute, is obtained by treating petroleum with an oxidizing agent such as nitric acid or sodium peroxide for several days in the presence of soda-lime or sodium acetate.[298] The liquid is neutralized and repeatedly distilled over colophony. The distillate is treated with dilute alkali and allowed to stand, when three layers are formed. The two upper layers are treated with glacial acetic acid or formaldehyde, together with raw rubber as a catalyst. The mixture is heated to 60° C., and a syrupy substance is obtained from which an elastic substance can be precipitated with acetone or alcohol.

On oxidizing petroleum or its residues with sodium peroxide, or for several days with nitric acid, it separates into two layers. Kleiber and Gilardi[299] found one layer to be composed of octanaphthenes, which on treatment with sulphur were transformed to xylenes, whereas the other, a turbid aqueous layer, was converted by oxidation with fuming HNO_3 to cyclohexanes first, and then to adipic acid. The xylenes also are oxidized to adipic acid. Terpenes can then be added and, after heating to about 150° C., isoprene and butadiene are formed. From these, artificial rubber can be obtained.

In a process described by Hultman[300] for the partial polymerization of a mineral oil material, such as "Dubbs pressure distillate," topped Californian crude, or similar oil or fraction, oxides of cerium or tin at a temperature of about 95° C. are used. The products are cooled and treated with carbon monoxide or methane in the presence of nickel, palladium or other catalysts at about 32° C., and then with a halogenating agent such as chlorine, bromine, or boron fluoride. A soft, rubbery product is formed, which is separated from the oily material. The distillation of shale and treatment of the condensate to obtain a crude rubber-like material suitable for admixture with rubber has been considered by Camberu, Langstaff and Stapelfeld.[301]

By passing ethylene or its homologues through a heated mixture of acetone or its homologues with fuming sulphuric acid, Stern[302] also obtained rubber-like substances.

Alkali metals in the presence of a limited amount of water have been suggested as catalysts in the production of synthetic rubber from diolefins.[303] The water is added as water of crystallization, using salts such as hydrated calcium chloride, sodium carbonate, sodium sulphate, or magnesium sulphate. Polymerization of diolefins with alkali or alkaline earth metals in the presence of hydrogen and in the absence of organic oxygen compounds has also been described.[304] Nitrogen, carbon dioxide or other inert gases may be present.

Rubber latex mixtures have been prepared by polymerization of emulsions of vegetable oils, fats, or their derivatives, and unsaturated hydrocarbons in the presence of oxygen or oxygen-splitting compounds.[305] For example, butadiene and oleic acid emulsified in water with turkey-red oil are polymerized with benzoyl peroxide at 60° C.

Vinylcyclohexenes and other oily polymers have been obtained by the polymerization of butadiene and its homologues by heat at about 400° C. in the presence of iron, aluminum, copper, nickel or silica gel as catalysts.[306] Eisele and

Stöhrel[307] have prepared products which can be used in plastics and paints by the polymerization of butadiene or its methyl derivative at 150° to 220° C. under pressure in the presence of a diluent and catalysts such as organic amines or finely divided metals.

Rubber-like plastics have been prepared by polymerizing 2-halogen-1,3-butadienes in the presence of air, oxygen, heat, light, catalysts (benzoyl peroxide, peroxides of sodium, lead or hydrogen, or oxidized turpentine) or under pressure.[308] The polymerization can be controlled by the addition of solvents or inhibitors (phenols, quinones, amines, nitro-compounds, or mercaptans) and the resulting products cured at 50° to 180° C.

Chapter 27

Some Important Reactions of Diolefins

The diolefins are hydrocarbons of the general formula C_nH_{2n-2}, with two ethylene linkages in their molecular structure. They are isomeric with the acetylene series of hydrocarbons. For purposes of classification, the diolefins may be divided into three types which differ in the mutual orientation of the two double bonds and possess somewhat different properties. These three main types are:

(1) The *allenes,* possessing the characteristic structure,

$$>C=C=C<$$

(2) The conjugated dienes (or butadiene type), with the structure,

$$>C=\overset{|}{C}-\overset{|}{C}=C<$$

(3) Other diolefins in which the double bonds are separated from one another by one or more CH_2 groups, among which may be specially mentioned the 1,4- and 1,5-dienes.

Of these three classes the conjugated dienes are by far the most important, both from the point of view of their greater reactivity and power of condensation and because they probably constitute the preponderating diolefin in the products of pyrolysis of hydrocarbons and, therefore, promise to become available commercially in significant quantities.

The gases from both vapor phase and liquid phase cracking processes furnish the principal industrial source of butadiene. For example, Wagner[1] in giving the analysis of a gas from a vapor phase process (Gyro) showed that it contains 1 per cent butadiene. Other analyses of gases from both liquid phase and vapor phase processes indicate that these gases contain from 4.5 to 5.5 per cent collectively of butylenes and butadiene.[2] As the fraction, of which probably about one-seventh is butadiene, can be further separated into butylenes and butadiene by distillation under pressure, the chemical properties and possible utilization of butadiene become of interest to the petroleum technologist.

Flood, Hladky and Edgar[3] pointed out that, of the possible types of unsaturated compounds present in cracked gasolines, the dienes were the most unstable, particularly if the double bonds were not too far apart in the molecule, and that such substances formed gum during storage. The polymerization of the dienes is a well-known phenomenon and part of the sludge formation obtained on treating cracked distillates may be due to the dienes present. From these considerations it is apparent that the chemical properties of the dienes are of importance to the refiner of petroleum products.

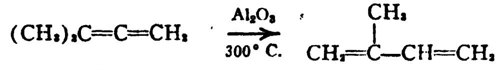
ALLENES

The allene type of diolefins has not been recognized among the products of pyrolysis. This is probably to be ascribed to the ease with which these hydrocarbons isomerize to the corresponding conjugated diolefins. Thus, unsymmetrical-dimethylallene rearranges to isoprene when passed over alumina at 300° C., especially under diminished pressure.[4] The allenes also isomerize to the corresponding acetylene hydrocarbons when allowed to stand in the presence of metallic sodium, a reaction discovered by Favorsky.[5] These two isomerizations may be represented as follows:



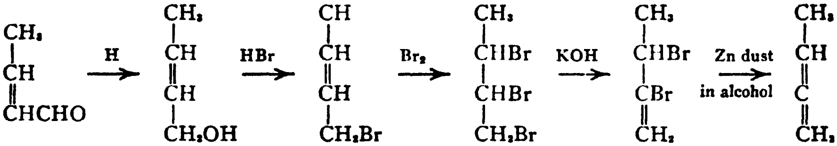
$$(CH_3)_2C{=}C{=}CH_2 \xrightarrow[300^\circ\ C.]{Al_2O_3} CH_2{=}\overset{\overset{\displaystyle CH_3}{|}}{C}{-}CH{=}CH_2$$

unsym.-dimethylallene *isoprene*

$$(CH_3)_2C{=}C{=}CH_2 \xrightarrow{Na} (CH_3)_2CH{-}C{\equiv}CH$$

unsym.-dimethylallene *isopropylacetylene*

The conversion of methylallene into ethylacetylene under the influence of metallic sodium has been described by Jocicz.[6] At high temperatures, however, the reverse reactions occur and the thermal isomerization of methylacetylene to allene at 500° to 650° C. has been observed by Hurd and Meinert.[7] A number of methods are available for the synthesis of the allene hydrocarbons. For laboratory preparation the general method of Bouis[8] seems to possess definite advantages and was the one employed by Hurd and his collaborators in the preparation of pure allene and methylallene. The method is exemplified by the synthesis of methylallene from crotonaldehyde through the following stages:



$$\begin{array}{c}CH_3\\|\\CH\\\|\\CHCHO\end{array} \xrightarrow{H} \begin{array}{c}CH_3\\|\\CH\\\|\\CH\\|\\CH_2OH\end{array} \xrightarrow{HBr} \begin{array}{c}CH\\|\\CH\\\|\\CH\\|\\CH_2Br\end{array} \xrightarrow{Br_2} \begin{array}{c}CH_3\\|\\CHBr\\|\\CHBr\\|\\CH_2Br\end{array} \xrightarrow{KOH} \begin{array}{c}CH_3\\|\\CHBr\\|\\CBr\\\|\\CH_2\end{array} \xrightarrow[\text{in alcohol}]{\text{Zn dust}} \begin{array}{c}CH_3\\|\\CH\\\|\\C\\\|\\CH_2\end{array}$$

In a similar way, allene may be produced by the action of zinc dust on 2,3-dibromo-1-propene, when dissolved in alcohol:[9]

$$CH_2BrCBr{=}CH_2 + Zn \longrightarrow ZnBr_2 + CH_2{=}C{=}CH_2$$

Allene itself is a gas at ordinary temperature (boiling point, —32° C.) and methylallene (1,2-butadiene) is a liquid (boiling point, 19° C.). All the allene hydrocarbons combine readily with bromine (particularly in carbon tetrachloride solution at 0° C.) to yield a dibromide, and ultimately in the presence of excess bromine, to form a tetrabromide. Allene tetrabromide boils at 116° C. at 9 mm. and when pure melts at 10.7° C.[10] Methylallene tetrabromide boils at 97.5° C. at 7 mm. and has a melting point of —2° C.[11]

Subsequently, Bouis[12] developed a general method of making alkylallenes by the action of the appropriate Grignard reagent on acrolein, followed by treatment of the resulting alcohol with phosphorus bromide in pyridine. The pure allyl bromides, $R \cdot CH:CH \cdot CH_2Br$, so formed are brominated at 0° C. to furnish 1,2,3-tribromo-compounds of the type $R \cdot CHBrCHBrCH_2Br$, which are then fused with potash to yield allene dibromides of the formula $RCHBrCBr:CH_2$. Dehalogenation of such dibromides by means of zinc dust and alcohol furnishes the pure allene hydrocarbon. By this series of reactions, Bouis has prepared, *inter alia,* the following allenes: ethylallene, boiling at 45° C.; n-propylallene, boiling at 78° C.; and n-butylallene, boiling at 106° C.

CONJUGATED DIENES

The conjugated diolefins, notably butadiene, isoprene and 2,3-dimethylbutadiene, have been the object of considerable study, almost entirely, however, from the viewpoint of the production of synthetic rubber. A number of methods of manufacture and synthesis, starting with such abundant raw materials as ethanol, acetone, butanol, fusel oil, and phenol has been worked out but, at present, the synthesis of rubber-like materials from such products, though readily realizable in the laboratory, is still economically impracticable (See Chapter 26). The recognition that the simple diolefins (butadiene and isoprene) are present in not inconsiderable quantities in the products of the pyrolysis of oils and petroleum gases, has again stimulated interest in these substances. The application of the diolefin hydrocarbons in the immediate future seems to be in their conversion into chemical products of the type of solvents and perfumes and similar substances, or in the manufacture of synthetic resins. The conjugated diolefins possess high chemical reactivity so that the difficulties reside not in effecting their combination with other materials but rather in controlling such changes. There is no doubt whatever that when the whole chemistry of the addition reactions of the diolefins, a much neglected subject in aliphatic chemistry, has been well explored, many uses in the synthesis of new and valuable industrial organic products will be discovered.

The production of conjugated diolefins by pyrolysis has already been discussed in some detail (Chapter 4) so that only a brief description of other processes of manufacture is necessary at this point.

BUTADIENE

Besides being a constituent of vapor phase cracking gas, butadiene also occurs in the pressure condensate of coal carbonization gases and in the products of pyrolysis of many organic compounds, notably of cyclohexane, butanol,[13] the lower aliphatic alcohols,[14] fusel oil,[15] and of many dichlorinated products.[16]

Butadiene may also be formed by the elimination of two molecules of hydrogen bromide under the influence of hot soda-lime, from the dibromide of 2-butene:

$$CH_3CH{=}CHCH_3 \text{ (from sec.-butyl alcohol)}$$

$$\Big\downarrow Br_2$$

$$CH_3CHBrCHBrCH_3$$

$$\Big\downarrow \text{soda lime}$$

$$CH_2{=}CHCH{=}CH_2 + 2HBr$$

---

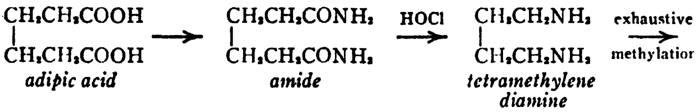
[15] Caventou, *Ann.*, 1863, 127, 93; *Compt. rend.*, 1863, 56, 646, 712.

[16] See Chapter 34 for pyrolysis of chlorinated hydrocarbons.

In the original method, due to Harries,[17] 2,3-dibromobutane was dropped onto soda-lime contained in an iron pot at 600° C. The product thus prepared is not pure and it is necessary to purify it through its tetrabromide, which can be converted to butadiene by zinc and alcohol by the method of Thiele.[18] Jacobson [19] employed a tube furnace and found that better results and less charring were obtained by heating the soda-lime to 530° to 550° C. instead of 600° C. If crotonyl (crotyl) bromide is used as a starting material instead of 2,3-dibromobutane, better yields of butadiene are obtained at lower temperatures (400° to 550° C.).

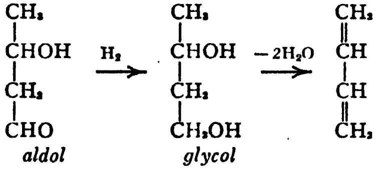
n-Butanol is the starting point of a synthesis of 1,4-butadiene originally suggested by Perkin [20] and later developed as a convenient laboratory method of preparation by Muskat and Northrup.[21] Butanol is converted into its chloride which is chlorinated to yield a mixture of dichlorobutanes. Decomposition of the latter by soda-lime at high temperatures furnishes butadiene. The best yield (about 30 per cent) is obtained in this last stage by passing the 1,4-dichlorobutane fraction over soda-lime at 700° to 730° C.

Another synthesis of butadiene starts with phenol. This is reduced by the Sabatier method to hexahydrophenol which can be oxidized readily (with nitric acid) to adipic acid.[22] Treatment of the amide of this acid with hypochlorite furnishes the diamine and exhaustive methylation of the latter then yields finally, butadiene: [23]



$$\begin{array}{c}CH_2CH_2COOH\\|\\CH_2CH_2COOH\\\textit{adipic acid}\end{array}\longrightarrow\begin{array}{c}CH_2CH_2CONH_2\\|\\CH_2CH_2CONH_2\\\textit{amide}\end{array}\xrightarrow{HOCl}\begin{array}{c}CH_2CH_2NH_2\\|\\CH_2CH_2NH_2\\\textit{tetramethylene}\\\textit{diamine}\end{array}\xrightarrow[\text{methylatior}]{\text{exhaustive}}\begin{array}{c}CH{=}CH_2\\|\\CH{=}CH_2\end{array}$$

One interesting synthesis of butadiene is that in which acetaldehyde (or ethanol) is employed as the raw material. Treatment with dilute alkali converts acetaldehyde into aldol, which may be hydrogenated to 1,3-butylene glycol.[24] Dehydration of this glycol furnishes a good yield of butadiene, thus: [25]



$$\begin{array}{c}CH_3\\|\\CHOH\\|\\CH_2\\|\\CHO\\\textit{aldol}\end{array}\xrightarrow{H_2}\begin{array}{c}CH_3\\|\\CHOH\\|\\CH_2\\|\\CH_2OH\\\textit{glycol}\end{array}\xrightarrow{-2H_2O}\begin{array}{c}CH_2\\\|\\CH\\|\\CH\\\|\\CH_2\end{array}$$

Very good yields of butadiene are obtained by passing 1,3-butylene glycol together with steam over certain dehydrating catalysts. By conducting 80 per cent glycol and 20 per cent steam (at a rate of 100 grams per hour per litre of catalyst) at 270° C. over a catalyst of primary sodium phosphate a yield of 85 to 90 per cent of butadiene is said to result.[26] A dehydration catalyst consisting of phosphoric acid on pumice in conjunction with a pressure of 2 to 20 atmospheres at 250° to 400° C. has been suggested by Mueller-Cunradi and Ober.[26a]

[23] Harries, *Ann.*, 1911, **383**, 179; *Chem. Abs.*, 1911, **5**, 3519.

[24] According to I. G. Farbenindustie A.-G. (British Patent 328,083, 1929) the reduction of aqueous aldol to 1,3-butylene glycol can readily be effected in the presence of reduced copper on silicic acid by hydrogen at 40°-90° C. and 50 to 200 atmospheres pressure.

[25] Ostromislensky, *J. Russ. Phys.-Chem. Soc.*, 1916, **47**, 1947; *J.S.C.I.*, 1916, **35**, 369. German Patent 314,364, 1914; *J.S.C.I.*, 1920, **39**, 83A. Kyriakides, *J.A.C.S.*, 1914, **36**, 980; see Chapter 4.

Other catalysts, such as an oxide or borate with or without activators (copper sulphate or red phosphorus) have also been proposed for this purpose.[27]

A process of Ostromislensky and Kelbasinsky,[28] in which a mixture of acetaldehyde and ethanol is passed first over heated copper and then over heated alumina, probably involves the intermediate formation of aldol, and butylene glycol.

The production of butadiene by passing vinyl bromide through a bath of molten tin has been described by Leyes.[29] The reaction can, presumably, be expressed by the following:

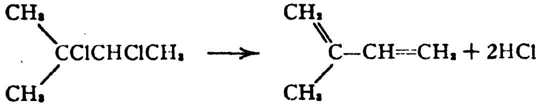
$$2CH_2{=}CHBr + Sn \longrightarrow CH_2{=}CHCH{=}CH_2 + SnBr_2$$

Lebedev [30] suggested the preparation of butadiene by dehydration of the lower aliphatic alcohols over heated catalysts. Butadiene is said to be obtained by passing 95 per cent ethanol over a mixture of aluminum and zinc oxides at 400° C., under a pressure of 0.25 atmospheres. Here again the reaction probably proceeds through the intermediate formation of aldol and butylene glycol.

It is of interest that butadiene was also obtained in a pure condition by the exhaustive methylation of pyrrolidine.[31]

ISOPRENE

Isoprene can be obtained by the pyrolysis of a large number of organic substances, including petroleum oils, rubber, and especially of turpentine.[32] It may be produced, in a manner analogous to the preparation of butadiene, from methyl cyclohexanol (by hydrogenation of cresol). A number of syntheses depend upon the removal of two molecules of hydrogen chloride from the dichloride of trimethylethylene, thus:



$$(CH_3)_2CClCHClCH_3 \longrightarrow (CH_3)(CH_2{=})C{-}CH{=}CH_2 + 2HCl$$

The trimethylethylene necessary for this synthesis may be produced by pyrolysis of monochlorinated pentanes in the presence of barium chloride at 300° to 450° C.[33] or by high temperature dehydration of amyl alcohols. Under these conditions the other amylenes, initially formed, undergo rearrangement to the more stable trimethylethylene.

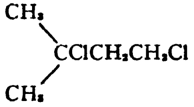
Waterman and van Westen[34] employed this method for the preparation of isoprene possessing a theoretical hydrogen absorption value. Amyl alcohol was dehydrated over alumina at 500° C. and the resulting amylene was brominated at —15° C. The vapors of the dibromide were then passed successively over hot barium chloride and then over potassium hydroxide, and the products condensed in liquid air and fractionated. The isoprene thus obtained absorbed 99.6 per cent of the theoretical quantity of hydrogen.

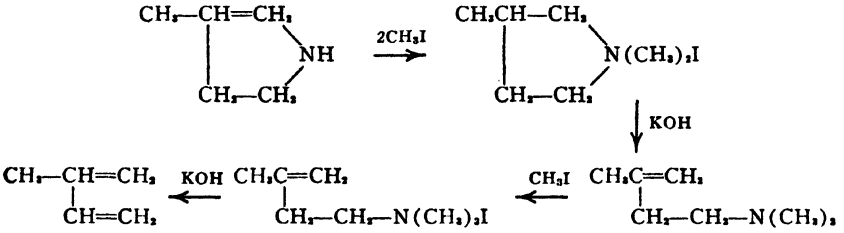
Isoamyl alcohol, the principal constituent of fusel oil, may be used as starting material in the synthesis of isoprene. Chlorination of isoamyl chloride (produced by the action of dry hydrogen chloride on the alcohol) results in the formation of three dichloroisopentanes of which the compound



(boiling point, 15.2° C.)

is the chief product. However, the mixture of isomeric dichlorides may be used for the production of isoprene, the yield being 40 per cent of the theoretical.[35]

Another preparation of isoprene is based upon the exhaustive methylation of methylpyrrolidine,[36] though the process is of no industrial importance. The reactions may be summarized as follows:



The isoprene obtained by many of these processes is always contaminated by impurities. In order to obtain the pure compound it is usually necessary to convert the isoprene into some derivative which can be readily purified and from which the isoprene can be regenerated, e.g., the tetrabromide or sulphone. Farmer and Warren[37] made use of the tertiary alcohol (the so-called "isoprene alcohol") for this purpose. Treatment of crude isoprene at —20° C. with one molecule of pure hydrobromic acid furnishes the 4-bromo-2-methyl-2-butene which can be readily purified by fractionation. This monohydrobromide is converted by the action of 5 per cent aqueous potassium carbonate solution into "isoprene alcohol", or 2-methyl-4-butene-2-ol[38] which can be catalytically dehydrated, by refluxing with aniline hydrobromide and a trace of hydrobromic acid, to yield pure isoprene.[39] The production of isoprene alcohol from the 1,4-hydrobromide of isoprene is an example of simultaneous hydrolysis and isomerization. The process can be summarized in the following manner:

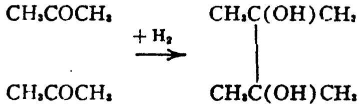
A laboratory method of preparing chemically, pure isoprene from 3-bromo-2-methyl-1-propene has been described by Merejkowsky.[40]

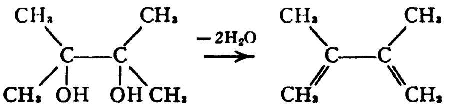
HIGHER DIOLEFINS

The preparation of 2,3-dimethylbutadiene was carried out in Germany during the War, the starting material being acetone. On reduction of acetone by alkaline reagents, particularly amalgams[41] both condensation and reduction occur and the product is pinacone:



$$\begin{array}{c} CH_3COCH_3 \\ \\ CH_3COCH_3 \end{array} \xrightarrow{+H_2} \begin{array}{c} CH_3C(OH)CH_3 \\ | \\ CH_3C(OH)CH_3 \end{array}$$

Pinacone can be dehydrated smoothly in the presence of alumina at about 400° C. to give a good yield of 2,3-dimethylbutadiene.[42] The reaction may be represented as follows:



The production of dimethylbutadiene by the action of heated bases, such as dimethylaniline, on pinacone chlorohydrin[43] and also by the elimination of hydrogen chloride from tetramethylethylene dichloride[44] have also been suggested.

Piperylene (1-methyl-1,3-butadiene or 1,3-pentadiene) may be produced by the dehydration of 2-pentene-4-ol over alumina or kaolin[45] at 400° C. This unsaturated alcohol is formed by the methylation of crotonaldehyde[46] (with methyl magnesium iodide) which in turn can be synthesized from acetaldehyde:[47]

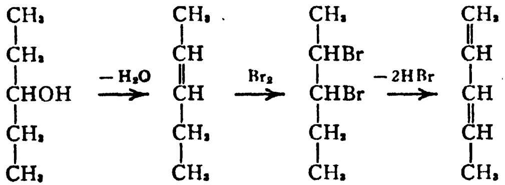
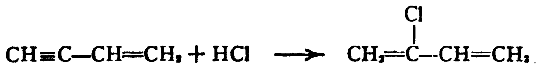
A convenient laboratory method[48] for the preparation of piperylene consists in dehydrating diethylcarbinol[49] with a 50 per cent aqueous solution of sulphuric acid at 100° C. to yield 2-pentene, which is brominated at —20° C. in hexane solution to furnish the dibromide (boiling point, 178° C.). The dibromide loses two molecules of hydrogen bromide to yield piperylene when passed through soda-lime at 500° C.:



Of the cyclic conjugated dienes, cyclopentadiene is of interest since it is one of the products of high temperature pyrolysis of hydrocarbons[50] and has been isolated from the forerunnings of crude benzol (from coal carbonization[51]). 1,3-Cyclohexadiene may be produced by the decomposition of cyclohexene dihalides.[52]

2-CHLOROBUTADIENE

The 2-chloro-derivative of butadiene is obtained by the direct combination of vinylacetylene and concentrated hydrochloric acid in the presence of a mixture of cuprous chloride and ammonium chloride.[53] The addition reaction occurs according to the equation:



$$CH{\equiv}C{-}CH{=}CH_2 + HCl \longrightarrow CH_2{=}\overset{\overset{\displaystyle Cl}{|}}{C}{-}CH{=}CH_2$$

This substance, also called chloroprene in order to show its analogy in structure and in chemical behavior to isoprene, is a colorless liquid with an ethereal odor somewhat resembling ethyl bromide and possesses a boiling point of 59.4° C. at 760 mm. and has a specific gravity of 0.9583 at 20° C.

The action of aqueous hydrochloric acid on vinylacetylene results intially in 1,4 addition, the product being 4-chloro-1,2-butadiene. This readily isomerizes to chloroprene.[54] With cuprous chloride present in the reaction mixture the isomerization is much more rapid and no 4-chloro-1,2-butadiene appears to be formed. Larger proportions of hydrochloric acid in the mixture cause the reaction to yield 2,4-dichloro-2-butene.

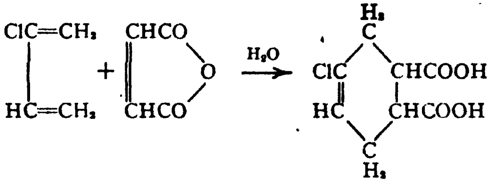
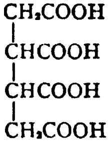
[53] Carothers, Williams, Collins and Kirby, *J.A.C.S.*, 1931, 53, 4203. The production of vinylacetylene by the polymerization of acetylene in the presence of hydrochloric acid and cuprous chloride is described by Nieuwland, Calcott, Downing and Carter, *J.A.C.S.*, 1931, 53, 4197; see also Chapter 28.

The chlorine atom in chloroprene is very firmly bound, for only traces of the chloride ion appear on boiling it with alcoholic silver nitrate, alcoholic sodium hydroxide, or pyridine. It reacts with maleic anhydride and yields, after hydrolysis, a white crystalline product which is apparently 4-chloro-1,2,5,6-tetrahydrophthalic acid.



The chlorine atom in this chlorohydrophthalic acid is very firmly bound, being also resistant to the action of boiling alkalies. Oxidation of this compound with boiling nitric acid, however, yields butane-1,2,3,4-tetracarboxylic acid:



$$\begin{array}{l} CH_2COOH \\ | \\ CHCOOH \\ | \\ CHCOOH \\ | \\ CH_2COOH \end{array}$$

Perhaps the most interesting derivatives of chloroprene, however, are its polymerization products. When allowed to stand for about 10 days in a closed vessel containing a little air, chloroprene changes into a transparent, resilient, non-plastic, elastic mass resembling vulcanized rubber. This product is designated μ-polychloroprene. It has a density of about 1.23 at 20° C., tensile strength of about 140 kg. per sq. cm., and an elongation at break of about 800 per cent. It swells strongly, but does not dissolve in carbon tetrachloride, carbon disulphide, benzene and other organic solvents. Its tendency to imbibe gasoline or lubricating oil is very slight compared with that of natural rubber.[54a]

The polymer formed during the early stages of the reaction just described, which can be isolated by precipitation with alcohol or by distilling off the unchanged chloroprene, is designated α-polychloroprene. Unlike μ-polychloroprene, it is soft, plastic, completely soluble in benzene, and resembles unvulcanized rubber. On standing it is transformed into the μ-polychloroprene.

Aqueous emulsions of chloroprene can be transformed into a polymer resembling μ-polychloroprene and the resulting product which remains suspended constitutes a synthetic latex. The size of the particles is smaller than those of natural latex, hence the particles penetrate porous material more readily. Other polymers which have been isolated are a volatile (β-) polymer, a granular (ω-) polymer, and a balata-like polymer. The rubber-like product is known as

The simple conjugated diolefins are highly refractive, easily volatile liquids having a pungent odor. Many of them are unstable, and, on standing in the presence of air or sunlight, tend to undergo polymerization and autoxidation. On a laboratory scale, they can usually be separated from a mixture with other hydrocarbons by conversion into their tetrabromides which, in most cases, are readily crystallizable solids. Their tetrabromides are reducible to the parent diolefin by the zinc-copper couple of Gladstone and Tribe.[56] Various methods have been proposed for the separation of diolefins from other hydrocarbons. Among these may be mentioned the following: selective solution in certain organic solvents, such as ethylene glycol mono- or di-acetates, furfural, or bases such as aniline;[57] and absorption in aqueous solutions of certain salts of the metals of Groups I and II of the periodic system. Monolefins are also absorbed by such solutions but advantage may be taken of the fact that diolefins and the salts form precipitates which can be separated by filtration. Thus, with solutions of cuprous chloride, butadiene gives a solid double compound which is precipitated from the solution, whereas the double compounds of the monolefins remain in solution.[58] The diolefins may be recovered from such double compounds by heating or by reducing the pressure. A material which can be used for separating conjugated diolefins from mixtures is anhydrous sulphur dioxide, which readily combines with such hydrocarbons in the presence of a small proportion of a phenol, amine, or copper salt to furnish monomeric sulphones. The latter are resolved into their parent materials by heating to temperatures of about 120° C.[59] Butadiene may be separated from its mixture with more reactive monolefins (such as isobutylene) by taking advantage of the fact that the butadiene is less readily absorbed by sulphuric acid than these monolefins.[60] The separation of substantially pure butadiene from a liquid mixture containing butylene by distillation at about 45° C. under 5 atmospheres pressure has also been effected.[61] Since many materials favor the polymerization of diolefins, the distillation of these hydrocarbons on a large scale demands equipment constructed of non-catalytic metals. For distilling butadiene hydrocarbons under pressure the use of plant constructed of magnesium, copper, manganese, zinc, tin, cadmium, cobalt, nickel, lead, aluminum, precious metals or stainless steel alloys has been recommended.[62]

---

[55] *Ind. Eng. Chem., News Ed.,* Nov. 10, 1931. The production of synthetic rubber by the polymerization of butadiene hydrocarbons has already been discussed in Chapter 26. Other polymerizations of acetylene hydrocarbons are mentioned in Chapter 28. See also Ellis, "Synthetic Resins and Their Plastics," Chemical Catalog Co., Inc., New York. [57] I. G. Farbenindustrie A.-G., British Patent 319.025, 1928; *Brit. Chem. Abs.* **B**, 1930, 50.

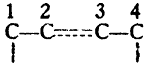
All the conjugated dienes exhibit a high chemical reactivity which renders them capable of undergoing a large number of addition reactions with all kinds of chemical reagents. However, diolefins with a conjugated system of double bonds behave in a peculiar manner on addition of two atoms of a univalent atom or group of atoms. It might be expected, for example, that butadiene would combine with two bromine atoms to yield the 1,2-dibromide exclusively, thus:

$$CH_2Br.CHBr.CH{=}CH_2$$

As a matter of fact, however, it is the 1,4-dibromide which is produced to a preponderating extent. To explain the formation of 1,4 addition products of conjugated diolefins, Thiele[63] assumed that the whole of the affinity of the double bond is not employed but that a part, called the "residual affinity", remains free at atoms 1 and 4, the remainder being satisfied between atoms 2 and 3. Thiele's conception of the valency distribution in conjugated systems may be represented by the scheme:



$$\begin{array}{cccc}1&2&3&4\\ C-&C\overset{\cdots\cdots}{=\!=}&C-&C\\ \vdots&&&\vdots\end{array}$$

in which the dotted lines denote partial valencies.

There is thus established a partial double bond between carbon atoms 2 and 3, but this is less active than the "residual affinities" on carbon atoms 1 and 4. When butadiene reacts with bromine the 1,4 addition product is first formed, thus satisfying the "residual affinities" and establishing a double bond between carbon atoms 2 and 3. In the presence of an excess of bromine the tetra- addition product having a normal structure is formed.

The impression has prevailed that all conjugated diolefins furnish 1,4 addition compounds exclusively. This is by no means the case, however, for it has been shown that the addition of two atoms of bromine to the simple conjugated diolefins results in the formation of both 1,4 and 1,2 addition compounds, though the latter are usually formed to a much less extent. The proportion of the two isomers formed depends greatly upon the solvent employed, higher proportions of 1,2-addition products being formed in non-polar solvents than in polar or readily polarizable solvents.[64] Constitutional influences also exert an effect on the proportion of the two isomers formed and 1-phenylbutadiene appears to yield 3,4-dibromide almost exclusively, irrespective of conditions.[65]

Though the diolefins resemble the monolefins in their general tendency to form addition products with numerous reagents, the former hydrocarbons are very much more reactive and their power of polymerization much more highly developed. Certain inorganic reagents, which combine smoothly with the simple monolefins to furnish well-defined addition compounds, react with conjugated diolefins with almost explosive violence to form polymers and tarry materials. Thus, for example, concentrated sulphuric acid reacts with many conjugated dienes to form tars with reduction of the acid while more dilute acids tend to form high molecular weight resins. This is particularly true of the action of sulphuric acid on the cyclic 1,3-diolefins such as cyclopentadiene and 1,3-cyclohexadiene. The production of tarry matters in the refining of cracked distillates with sulphuric acid is sometimes ascribed to the presence of conjugated diolefins and similar reactive hydrocarbons. The conjugated diolefins also exhibit a very much greater power of autoxidation and peroxide formation than the monolefins and are probably largely responsible for gum formation in cracked gasolines. (See Chapter 40.)

In the following brief account of the reactions of the simpler conjugated diolefins with various organic and inorganic reagents, an attempt has been made to summarize such reactions as are likely to be of industrial interest either from the viewpoint of the refiner or from that of the chemist. In particular, the great chemical reactivity of the simple butadiene derivatives appears to be the gateway to a wide field of possibilities in the utilization of these abundant hydrocarbons for industrial organic syntheses. In the following account, attention will be concentrated upon butadiene, the simplest and most abundant hydrocarbon of the series.

Although it is desirable to discuss the conjugated diolefins as a single class of hydrocarbons, it must be borne in mind that generalizations about a series cannot take into account the variations among the individual members. It must not be imagined that all the conjugated diolefins possess a similar degree of reactivity either to different or to the same chemical reagents. The conjugated dienes exhibit wide individual variations in their reactivities. In general, the order of diminishing chemical reactivity is: conjugated cyclic diolefins, butadiene homologues, butadiene.

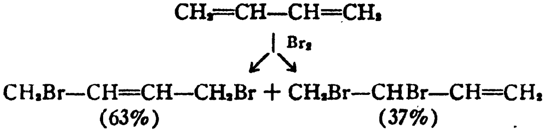
REACTIONS OF CONJUGATED DIOLEFINS WITH BROMINE AND CHLORINE

As previously stated, the addition of halogens to the conjugated dienes proceeds in two stages, first a dihalogen addition product being formed and then, in presence of excess halogen, a tetrahalogen compound. Farmer, Lawrence and Thorpe[66] found that addition of the requisite quantity of bromine to butadiene in chloroform solution at —15° C. resulted in the production of the 1,4-dibromide together with about 37 per cent of the 1,2-product, as indicated:

---

[64] Ingold and Smith, *J.C.S.*, 1931, 2752.

[65] Muskat and Huggins, *J.A.C.S.*, 1929, 51, 2496.



$$\begin{array}{c} CH_2{=}CH{-}CH{=}CH_2 \\ \downarrow Br_2 \\ \underset{(63\%)}{CH_2Br{-}CH{=}CH{-}CH_2Br} + \underset{(37\%)}{CH_2Br{-}CHBr{-}CH{=}CH_2} \end{array}$$

Griner[67] had previously observed that the addition of bromine to a chloroform solution of butadiene (at —21° C.) resulted in the formation of a liquid dibromide. He further found that this dibromide on being heated to 100° C. changed into the solid isomer, melting at 53° to 54° C., which was considered to be the *trans*-1,4-dibromobutadiene. A small quantity of a liquid dibromide which remained, boiling at 70° C. at 2 mm., was considered to be the *cis*-1,4-dibromobutadiene. This *cis* form of the dibromide was not detected by Farmer, Lawrence and Thorpe,[68] and its existence has been contested also by Thiele.[69]

In a similar way the addition of two atoms of chlorine to butadiene in solution results in the formation of both 1,4- and 1,2-products.[70] Combination of butadiene with one molecule of iodine monochloride in methylene dichloride solution at —35° C. results[71] in the production mainly of the 1,4-compound together with about 22 per cent of the 1,2-isomer, $CH_2ICHClCH{=}CH_2$.

Addition of two atoms of bromine to isoprene in chloroform solution at 0° C. yields two isomeric dibromides[72] but, according to Staudinger and his collaborators, the main product is always the 1,4-compound.[73]

Of the other conjugated diolefins, the 2,3-, 1,4-, and 1,3-dimethylbutadienes yield mixtures of dibromides with a preponderating content of the 1,4-product.[74] On the other hand, 1-phenylbutadiene furnishes,[75] under widely different temperature conditions and in different solvents, only the 3,4-dichloride, $C_6H_5CH{=}CH{=}CHCl{-}CH_2Cl$.

Cyclopentadiene forms both 1,2- and 1,4-dibromides, the latter in larger amount. Farmer and Scott[76] stated that the proportion of the 1,4-compound is increased by changing the solvent from hexane to chloroform. The 1,4-dibromide of cyclopentadiene exists in two stereoisomeric forms, one a liquid (b.p., 53° to 54° C. at 2 mm.) and the other a crystalline solid (m.p., 45° to 46° C.).[77] Bromination is conveniently effected in chloroform solution at —10° to —15° C.

The tetrahalides of the conjugated diolefins are readily prepared by adding an excess of halogen to a solution of the diolefins cooled to 0° C. or below. They frequently exist in two stereoisomeric forms. They may be utilized in the purification of diolefins. From the diolefin tetrahalide, the diolefin may be regenerated by reduction with zinc in alcohol.[78] 1,2,3,4-Tetrabromobutane is a typical member of the series of diolefin tetrahalides. It exists in two forms, one melting at 118° C. and boiling at 260° to 270° C., and another melting at 39° C. and boiling at 180° to 181° C., both forms being produced (in approximately equal amount) by the action of excess bromine on butadiene (in carbon tetrachloride solution at 0° C.).[79] Jacobson[80] obtained butadiene tetrabromide by passing a slow stream of crude butadiene through bromine cooled in an ice-bath. The butadiene tetrabromide (melting point, 116° to 117° C.) was contaminated with quantities of other bromobutanes, including 1,1,4,4-tetrabromobutane and the isomeric butadiene tetrabromide (melting point, 38° C.). When treated with sodium ethoxide in cold alcoholic solution butadiene tetrabromide loses two molecules of hydrobromic acid and is converted into 2,3-dibromobutadiene, $CH_2=CBr-CBr=CH_2$, (boiling point, 44° C. at 10 mm., and melting point, —21.5° C.). Heated with excess of alcoholic potash at 150° to 160° C. either of the butadiene tetrabromides gives a small yield of the hydrocarbon, diacetylene, $CH\equiv C-C\equiv CH$, a colorless gas condensible to a liquid (boiling point, 10° C.; d^{5}0.7107; and n, 1.4198).[81]

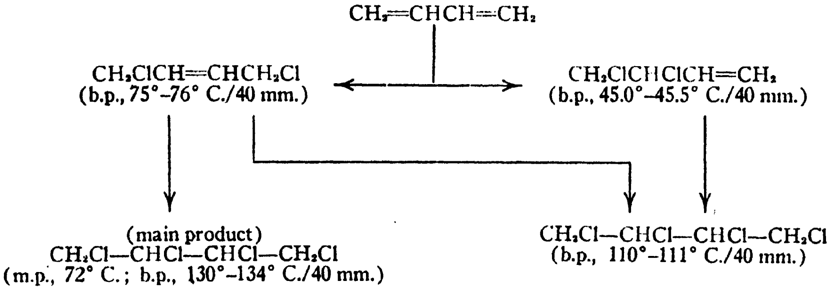
The tetrachlorides of the butadiene hydrocarbons are readily obtained by treatment with chlorine in a solvent. Two stereoisomeric butadiene tetrachlorides result from treatment of butadiene with chlorine in chloroform, carbon disulphide or petroleum solution, one form boiling at 110° to 111° C. at 40 mm., and the other melting at 72° C. and boiling at 130° to 134° C. at 40 mm. The latter variety is the main product of the continued chlorination of 1,4-dichloro-2-butene, whereas the lower-boiling stereoisomer forms on the further addition of chlorine to 3,4-dichloro-1-butene. The chlorine addition reactions of butadiene can accordingly be represented by the scheme:[82]



$CH_2=CHCH=CH_2$
$CH_2ClCH=CHCH_2Cl$
(b.p., 75°-76° C./40 mm.)
$CH_2ClCHClCH=CH_2$
(b.p., 45.0°-45.5° C./40 mm.)
(main product)
$CH_2Cl-CHCl-CHCl-CH_2Cl$
(m.p., 72° C.; b.p., 130°-134° C./40 mm.)
$CH_2Cl-CHCl-CHCl-CH_2Cl$
(b.p., 110°-111° C./40 mm.)

According to Sorokin and Belikov,[83] butadiene tetrachloride (m.p., 70° C.; b.p., 118° to 122° C.), which can be prepared by passing butadiene through carbon tetrachloride saturated with chlorine at 15° to 16° C., may be employed in the estimation of butadiene in mixtures of unsaturated gases. The yield of tetrachloride is said to be within 2.5 to 5.0 per cent of the theoretical.

The tetrahalides of butadiene homologues are very similar to those of butadiene. Piperylene tetrabromide exists in two stereoisomeric forms, a crystalline solid melting at 114.5° C. and a liquid boiling at 115° to 118° C. at 4 mm.[84] Isoprene tetrabromide (b.p., 153° to 155° C. at 12 mm.) on treatment with sodium ethoxide yields a dibromoisoprene, boiling at 78° to 83° C. at 12 mm.[85]

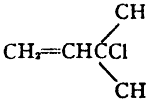
REACTIONS OF CONJUGATED DIOLEFINS WITH HALOGEN ACIDS

Conjugated diolefins combine readily with halogen acids, either anhydrous or in very concentrated solution, to furnish both mono- and di-hydrohalides, the latter being the products obtained in the presence of excess of reagent. These reactions usually proceed very smoothly and without appreciable polymerization. The main result of the addition of one molecule of hydrogen halide to conjugated dienes appears to be always the 1,4-product but certain negatively substituted dienes (such as 1-phenylbutadiene and 1-bromobutadiene) yield only 3,4-addition compounds.

The addition of hydrogen halides to butadiene has apparently been very little studied. Combination of hydrogen bromide with butadiene in glacial acetic acid solution has been said[86] to give an 85 per cent yield of crotonyl (crotyl) bromide:

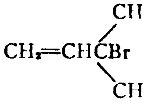
$$CH_2{=}CH{-}CH{=}CH_2 \xrightarrow{HBr} CH_3.CH{=}CH.CH_2Br$$

Somewhat contradictory statements have been made with regard to the addition of one molecule of hydrogen halides to isoprene. According to the earlier investigators both hydrogen chloride[87] and hydrogen bromide[88] combine with the formation of



$CH_2{=}CHC(CH_3)(CH_3)Cl$

and



$CH_2{=}CHC(CH_3)(CH_3)Br$

respectively.

The addition of one molecule of hydrogen bromide to crude isoprene cooled to —20° C. was studied by Claisen, Kremers, Roth and Tietze.[89] They concluded that the initial product of the reaction was the above tertiary bromide, i.e., 3-bromo-3-methyl-1-butene, but that this compound can isomerize under certain conditions to yield the 1,4-addition compound, 2-methyl-4-bromo-2-butene. Addition of hydrogen bromide to ice-cold isoprene with avoidance of excess of hydrogen bromide was found to yield a material boiling largely below 50° C. at 40 mm., particularly if the distillation was carried out immediately after the addition reaction. If, however, the reaction product was not distilled within a few hours, and especially if excess hydrogen bromide was present, it was observed that the reaction product boiled at 50° to 51° C. at 40 mm. and consisted largely of the primary bromide, 2-methyl-4-bromo-2-butene. Staudinger, Kreis and Schilt[90] found that treatment of 100 grams of isoprene in acetic acid solution with 122 grams of bromine for 2 days at 0° C. led to the production of 74 per cent of the 1,4-hydrobromide, $CH_3C(CH_3){=}CHCH_2Br$, the constitution of which was proved by oxidation. A possible explanation of the discrepancy between the results of various workers is that both types of monohydrohalide are formed, the relative proportion of the isomers depending upon the conditions. The monohydrochloride of isoprene, obtained by Aschan[91] by treating isoprene with hydrogen chloride in the presence of a little water in the cold, was a liquid (boiling point, 107° to 110° C. and d^{20}_{4} 0.9335) possessing a smell similar to that of allyl chloride. It was readily oxidized with permanganate and added a second molecule of dry hydrogen chloride with the formation of the dihydrohalide.

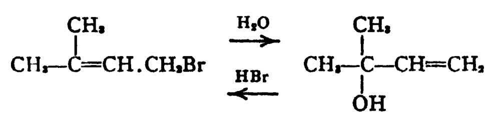
[89] *J. prakt. Chem.*, 1922, (2) 105, 65; *Chem. Soc. Abs.*, 1923, 124 (1), 1050.

[90] *Helv. Chim. Acta*, 1922, 5, 743; *Chem. Abs.*, 1923, 17, 2974.

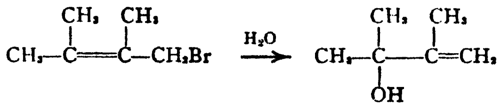
The 1,4-monohydrobromide of isoprene is unusually easily hydrolyzed by water, being converted into a tertiary alcohol, the so-called "isoprene alcohol" of Mokijewski.[92] Although this conversion involves simultaneous hydrolysis and shifting of the double bond, the tertiary alcohol is evidently produced directly and not through the intermediate formation of the corresponding primary alcohol (3-methyl-2-butene-1-ol) since the latter shows no tendency to isomerize.[93] Claisen and his collaborators[94] studied this hydrolysis and concluded that it could be carried to completion by the use of sodium carbonate solution. The reaction is reversible since the isoprene alcohol is converted into the primary bromide by the action of hydrobromic acid, and can, accordingly, be represented as follows:



$$CH_3-\overset{\overset{\displaystyle CH_3}{|}}{C}=CH.CH_2Br \underset{HBr}{\overset{H_2O}{\rightleftarrows}} CH_3-\underset{\underset{\displaystyle OH}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}-CH=CH_2$$

1,4-hydrobromide *"isoprene alcohol"*

This hydrolytic conversion is also displayed by the 1,4-hydrobromide of 2,3-dimethylbutadiene (the principal product of the action of hydrogen bromide on that hydrocarbon), which is hydrolyzed to a tertiary (and not, as might be expected, a primary) alcohol by the action of aqueous sodium carbonate. The tertiary alcohol, namely 1,1,2-trimethylallyl alcohol, is formed as follows:



$$CH_3-\overset{\overset{\displaystyle CH_3}{|}}{C}=\overset{\overset{\displaystyle CH_3}{|}}{C}-CH_2Br \xrightarrow{H_2O} CH_3-\underset{\underset{\displaystyle OH}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}-\overset{\overset{\displaystyle CH_3}{|}}{C}=CH_2$$

The dihydrohalides of isoprene are readily prepared either from the diene or from its monohydrohalide. Thus, treatment of isoprene with two molecular proportions of hydrogen bromide in glacial acetic acid solution[95] furnishes the dihydrobromide of the constitution $(CH_3)_2CBrCH_2\text{-}CH_2Br$.

The dihydrochloride was obtained by Aschan[96] in 94 per cent yield by treating the monohydrochloride with concentrated hydrochloric acid saturated with dry hydrogen chloride. The reaction proceeded smoothly without polymerization and the product, 2,4-dichloro-2-methylbutane, $(CH_3)_2CCl\text{-}CH_2\text{-}CH_2Cl$, has a boiling point of 52° to 53° C. at 12 mm., 145° to 146° C. at 760 mm. Ostromislensky[97] proposed a method of estimating isoprene in mixtures containing amylenes and butylenes, which consists in converting the isoprene into the above di-hydrochloride by shaking with fuming hydrochloric acid for 6 hours and separating this substance from admixed secondary and tertiary amyl and butyl chlorides by fractionation.

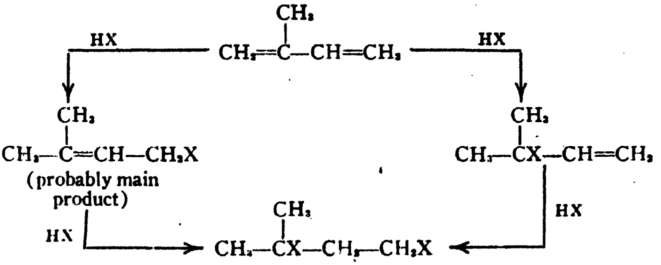
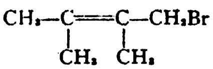
The addition of hydrogen halides to isoprene may be represented as follows:

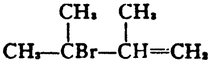


Of the other simple homologues of butadiene, 2,3-dimethylbutadiene adds on hydrogen bromide in two stages and the monohydrobromide consists mainly of the 1,4-compound:[98]



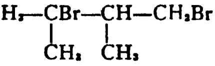
$$CH_3{-}\underset{CH_3}{C}{=}\underset{CH_3}{C}{-}CH_2Br$$

According to Claisen and his collaborators,[99] the main product of the addition of one molecule of hydrogen bromide is the above 1,4-hydrobromide, a lacrimatory oil boiling at 51° to 54° C. at 20 mm., but there is evidence that the tertiary bromide



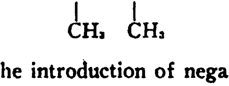
$$CH_3{-}\overset{CH_3}{C}Br{-}\overset{CH_3}{C}H{=}CH_2$$

is formed initially and then undergoes isomerization, since the reaction product has a much lower boiling point (27° to 50° C. under 20 mm.) if distilled immediately after its formation. The dihydrobromide consists of the 2,4-dibromo-compound,



$$CH_3{-}\underset{CH_3}{C}Br{-}\underset{CH_3}{C}H{-}CH_2Br$$

though, according to Bergmann,[100] it is also accompanied by about 30 per cent of the isomeric 2,3-dibromo-compound (described by Thiele[101]) with the structure



$$CH_3{-}\underset{CH_3}{C}Br{-}\underset{CH_3}{C}Br{-}CH_3$$

The marked influence of the introduction of negative groups into the butadiene molecule on the mode of addition of halogens, is well illustrated by the combination of 1-phenylbutadiene[102] and 1-bromobutadiene[103] with hydrogen bromide. In both cases 3,4-addition products are formed in accordance with the scheme:

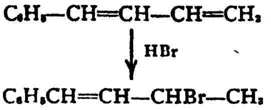
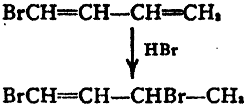
[102] Riiber, *Ber.*, 1911, 44, 2977.
[103] Ingold and Smith, *J.C.S.*, 1931, 2752.



$$C_6H_5{-}CH{=}CH{-}CH{=}CH_2 \xrightarrow{HBr} C_6H_5CH{=}CH{-}CHBr{-}CH_3$$

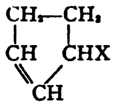


$$BrCH{=}CH{-}CH{=}CH_2 \xrightarrow{HBr} BrCH{=}CH{-}CHBr{-}CH_3$$

Similarly, it was later observed[104] that 2-chlorobutadiene combines readily with aqueous hydrochloric acid in the presence of cuprous chloride as catalyst with the production of 1,3-dichlor-1-butene, thus:

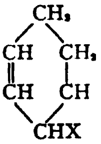
$$CH_2{=}CCl{-}CH{=}CH_2 \xrightarrow{HCl} CH_3{-}CCl{=}CHCH_2Cl$$

The cyclic diolefins, cyclopentadiene[105] and 1,3-cyclohexadiene[106] combine readily with one molecule of hydrogen halide to yield products having the constitutions



(X = halogen atom)

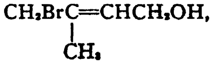
and



The hydrochloride of cyclopentadiene (b.p., 50° C. at 40 mm.) is not further acted upon even by an excess of hydrogen chloride though it combines readily with chlorine to furnish 1,2,3-trichlorocyclopentane (b.p., 196° C.).[105]

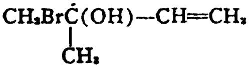
Halohydrins of the Diolefins

With hypochlorous acid or bromine water the conjugated dienes react with the production of both mono- and di-halohydrins. The dichlorohydrin of isoprene was isolated as a crystalline solid melting at 82° C. by Mokijewski.[107] The action of bromine water on isoprene and 1-phenylbutadiene has been shown by Ingold and Smith[108] to yield monobromohydrins of these hydrocarbons. When treated with bromine water in the cold, isoprene gave a mixture of bromohydrins, which was shown to contain about 47 per cent of the compound:



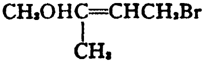
$$CH_2BrC(CH_3){=}CHCH_2OH,$$

about 16 per cent of



$$CH_2BrC(OH)(CH_3){-}CH{=}CH_2$$

together with a small amount of



$$CH_2OHC(CH_3){=}CHCH_2Br$$

Evidently 1,4-addition products also predominate.

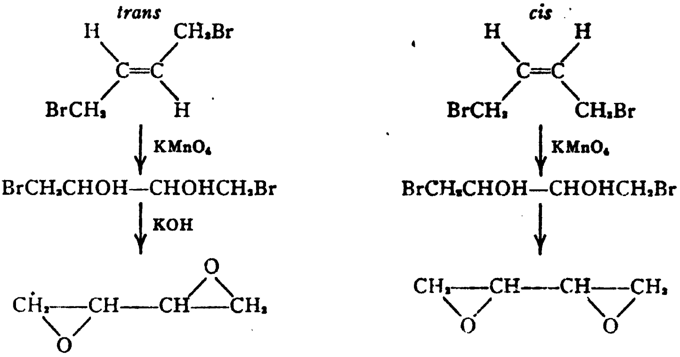
[108] *J.C.S.*, 1931, 2752.

By the action of bromine water on 1-phenylbutadiene an oily monobromohydrin of the structure $C_6H_5CH{=}CHCHOHCH_2Br$ was obtained, further illustrating the effect of negative groupings on the orientation of addition compounds.

Griner[109] reported obtaining two stereoisomeric butadiene dibromohydrins by mild oxidation with 1 per cent potassium permanganate solution of the cis and trans forms of butadiene 1,4-dibromide. The action of anhydrous caustic alkali converts these bromohydrins into two stereoisomeric oxides. The reactions may be summarized as follows:



m.p., 4° C.; b.p., 59°-60° C. at 30 mm. m.p., −15° C.; b.p., 49° C. at 20 mm.

Reaction of Conjugated Diolefins with Sulphuric Acid

The conjugated dienes exhibit wide variations in their behavior towards sulphuric acid. The more reactive members such as the cyclic dienes, cyclopentadiene and 1,3-cyclohexadiene, react with concentrated acid almost explosively forming tars and sulphur dioxide, whereas dilute acids exert a resinifying action.[110] Butadiene itself, however, is much more resistant to the action of sulphuric acid, being absorbed in 83 per cent acid at about the same rate as propylene.[111] Indeed, the relatively slow rate of absorption of butadienes in sulphuric acid of lower concentrations has been proposed as a basis for the separation of this diolefin from admixed isobutylene and similarly reactive monolefins.[112] In general, the products of the reaction of diolefins with sulphuric acid are tars of ill-defined nature. The observation of Wagner-Jauregg[113] that geranyl acetate results from the action of a mixture of glacial acetic acid and sulphuric acid on isoprene suggests that this is a fruitful field of research.

A more detailed examination of the products of this reaction was made later.[114] A mixture of 450 grams of isoprene, 1500 cc. of glacial acetic acid and 5 grams of concentrated sulphuric acid were allowed to react at room temperature for 3 days. The reaction product, which contained only a small amount of a rubber-like polymer, was hydrolyzed and distilled, yielding 101 grams of a mixture of materials boiling at 72° to 160° C. under 12 mm. pressure. From this mixture, primary alcohols were extracted with phthalic anhydride, tertiary alcohols were removed as borates, leaving a mixture of hydrocarbons. The primary alcohol fraction contained geraniol, cyclogeraniol, and a mixture of sesquiterpené alcohols of the formula $C_{15}H_{26}O$, containing three ethylene linkages in the molecule and boiling mainly at 114° to 126° C. at 0.7 mm. The tertiary alcohol fraction contained *dl*-linalool, *dl*-α-terpineol and sesquiterpene alcohols (also of the composition $C_{15}H_{26}O$) boiling at 108° to 122° C. at 0.43 mm., and the hydrocarbon fraction contained, among other substances, a monocyclic triethylenic hydrocarbon boiling at 120° to 125° C. at 12 mm. This latter compound was converted by boiling 98 per cent formic acid into a dicyclic hydrocarbon of the caryophyllene series.

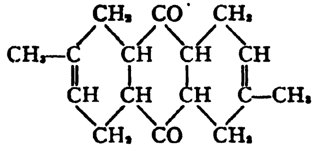
When shaken with dilute sulphuric acid in the presence of carbon dioxide for 5 days at room temperature, isoprene yields a mixture of hydrocarbons, alcohols, and cyclic ethers (oxides), 1,4-cineol and a small proportion of 1,8-cineol. Evidently, therefore, the action of even dilute sulphuric acid on isoprene is complex, resulting in the formation of a wide variety of products.

Condensation Reactions of Conjugated Diolefins

The fact that the simple monolefins react very readily with aromatic hydrocarbons to form alkylated derivatives[115] suggests the possibility that diolefins also would undergo this condensation. Albrecht[116] described several addition products of cyclopentadiene with quinones (cyclopentadiene quinone, the dicyclopentadiene quinone, the cyclopentadiene chloranil and the cyclopentadiene naphthoquinone) without, however, determining their constitution.

Later, von Euler and Josephson[117] found that isoprene could be condensed with benzoquinone by heating in a sealed tube at 120° to 180° C. for 5 to 6 hours to yield a white crystalline substance melting at 234° C., to which they assigned the provisional formula



since it yielded a tetrabromide with bromine in warm acetic acid and a dioxime with alkaline hydroxylamine.

More than twenty years after the original studies of Albrecht, Diels[118] investigated the chemical constitution of these products and discussed the production of these addition products from the diene hydrocarbons. Tetrahydroanthraquinone was obtained from butadiene and α-naphthoquinone,

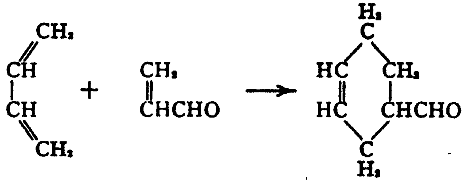
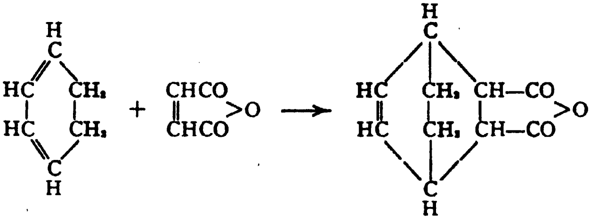
while butadiene and acrolein yielded the tetrahydrobenzaldehyde,

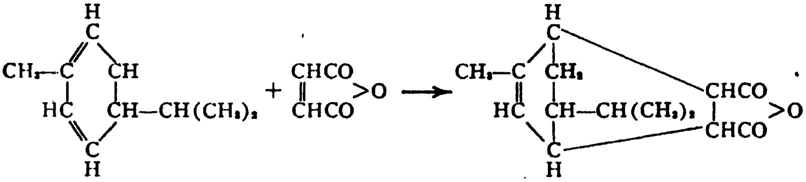


The condensation of butadiene with benzoquinone or its substitution products yielded similar products.[119]

1,2-Dihydrobenzene and maleic anhydride form the endodimethylene tetrahydrophthalic anhydride



and α-phellandrene reacts with maleic anhydride to yield the compound $C_{14}H_{18}O_3$:

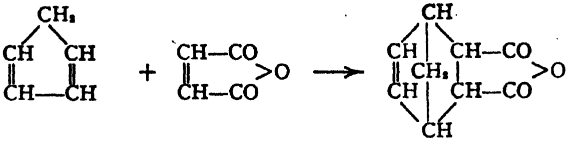


It appears from the subsequent work of Alder and his collaborators[120] that these reaction products of maleic anhydride and conjugated dienes can undergo further condensation with the same or other conjugated diolefins to form still more complex molecules containing one double bond. This cumulative condensation (which is analogous to the stepwise polymerization of cyclopentadiene) is exemplified by the combination of butadiene at 140° to 150° C. under pressure (in the presence of benzene as solvent) with 3,6-endomethylene tetrahydrophthalic anhydride. This material is obtained by condensing cyclopentadiene with maleic anhydride, so that the whole synthesis may be expressed graphically as follows:

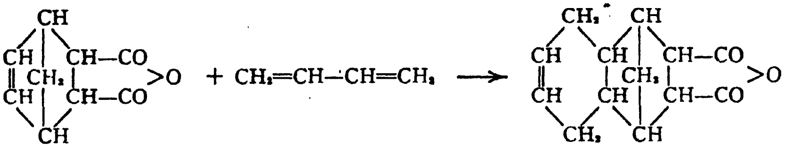
---

[119] Diels and Alder, German Patent 521.621, 1927; *Chem. Abs.*, 1931, **25**, 3363; British Patent 300,130, 1928; *Brit. Chem. Abs.* **B**, 1930, 549; both patents assigned to I. G. Farbenindustrie A.-G.

[120] Alder and Stein, with Reese and Grassmann, *Ann.*, 1932, **496**, 204; *Brit. Chem. Abs.* **A**, 1932, 938; *Chem. Zentr.*, 1932, **2**, 2048.



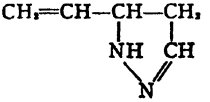
cyclopentadiene *maleic anhydride* *3,6-endomethylene tetrahydrophthalic anhydride*



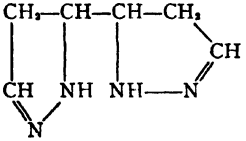
In the same way, 3,6-endomethylene tetrahydrophthalic anhydride can be condensed with isoprene, 1,4-diphenylbutadiene or cyclopentadiene.

The reaction of other diolefins with various unsaturated compounds, such as citraconic and itaconic acid anhydrides, acrylic acid, acrolein and cyclohexanone have also been effected, good yields of condensation products being obtained.[121] Diels and his collaborators[122] also described the production of cyclic nitrogen compounds by the so-called diene-synthesis, for example, that of endomethylene piperidazine from cyclopentadiene and ethyl azodicarboxylate.

According to Müller and Roser,[123] butadiene reacts with diazomethane in absolute ether solution, at —20° C., to yield 5-vinylpyrazoline and then 5,5′-bipyrazoline:



5-vinylpyrazoline



5,5′-bipyrazoline

Similar products are said to be obtained from butadiene and methyldiazomethane and diazoacetic ester.

The importance of the diene-synthesis is indicated by a number of developments. In one process[124] butadiene or other diolefin hydrocarbon is condensed with an aromatic hydrocarbon under slight pressure in the presence of an alkali or alkaline earth metal as a catalyst at somewhat raised temperature. By heating 1 part of butadiene with 3 to 4 parts of toluene at 80° to 90° C. with sodium in an autoclave a colorless liquid hydrocarbon (b.p., 203° to 204° C.) is obtained[125] which is said to have the formula $CH_3CH{=}CHCH_2CH_2C_6H_5$. Isoprene in toluene, when heated in the presence of sodium at 160° C. for 1 hour, yields 5 (or 3)-phenyl-3(or 5)-methyl-2-pentene (b. p., 218° to 222° C.).[126] Under similar conditions, 2,3-dimethylbutadiene yields 5-phenyl-2,3-dimethyl-2-pentene, a liquid boiling at 235° to 238° C., and butadiene and tetrahydronaphthalene condense to a butenyltetrahydronaphthalene boiling at 270° to 272° C,

---

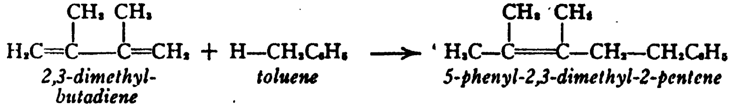
[125] Hofmann and Michael, German Patent 557,514, 1928; *Chem. Abs.*, 1933, 27, 514; Swiss Patent 144,850, 1928; *Chem. Zentr.*, 1931, 2, 1055; *cf.* British Patent 315,312, 1929; patents assigned to I. G. Farbenindustrie A.-G.

It appears that direct combination occurs between aromatic hydrocarbons and conjugated diolefins so that 1,4-addition products of the latter are frequently formed. The combination of 2,3-dimethylbutadiene with toluene may thus be represented:



$$H_2C{=}\overset{CH_3}{\overset{|}{C}}-\overset{CH_3}{\overset{|}{C}}{=}CH_2 + H-CH_2C_6H_5 \longrightarrow H_3C-\overset{CH_3}{\overset{|}{C}}{=}\overset{CH_3}{\overset{|}{C}}-CH_2-CH_2C_6H_5$$

2,3-dimethylbutadiene *toluene* *5-phenyl-2,3-dimethyl-2-pentene*

The condensation of quinones with butadiene hydrocarbons appears to be a promising method for the production of anthraquinone and related compounds. Thus, benzoquinone reacts with two molecules of butadiene or its homologues, under the influence of acid or alkaline reagents or by heating, with the production of tetrahydroanthraquinones, which can be oxidized by air in the presence of catalysts if necessary, to yield the corresponding anthraquinones. The condensation product of 1 mole of benzoquinone and 2 moles of isoprene consists of two isomers, one of which is oxidized to 2,6-dimethylanthraquinone by air.[127]

An 80 per cent yield of anthraquinone of excellent purity is said to be formed by the condensation of naphthoquinone with butadiene at 140° C. under pressure in the presence of nitrobenzene. Similarly, 6-methylquinizarin, 6,7-dimethylquinizarin, and 2,3,6,7-tetramethylquinizarin may be prepared.[128]

Diels and Alder [129] produced tetrahydroquinizarins by reaction of naphthazarin or its homologues with conjugated dienes. For example, tetrahydroquinizarin (melting point, 150° to 151° C.) is obtained by heating naphthazarin with butadiene at 50° to 60° C. under pressure in the presence of glacial acetic acid.

A further application of the condensation of the dienes with maleic acid or anhydride is the purification of crude coke-oven benzol.[130] The crude benzol after refluxing with 1 to 3 per cent of the acid or anhydride is distilled. Impurities such as cyclopentadiene, butadiene, and heterocyclic compounds (pyridine) are thus removed. Methylene tetrahydrophthalic anhydride is obtained from the residue and this can be esterified with a polyhydroxy alcohol to yield a resin.[131] The esters of the condensation product from butadiene and maleic anhydride are plasticizers for cellulose esters, according to Brooks and Cardarelli.[131a] Their boiling points are: butyl ester, 186° to 192° C. at 18 mm.; ethyl ester, 133° to 137° C. at 5 mm.; prcpyl ester, 140° to 141° C. at 5 mm.; and secondary-amyl ester, 163° to 165° C. at 5 mm.

The condensation of conjugated diolefins with acid chlorides under the influence of Friedel-Crafts condensing agents takes place vigorously but does not appear to follow the same course as the reaction between monolefins and acid chlorides which results in the ultimate production of vinyl alkyl ketones. According to Wieland and Hasegawa,[182] 1,4-diphenylbutadiene reacts with acetyl chloride in benzene solution and in the presence of aluminum chloride to furnish a white crystalline solid melting at 262° C., corresponding to $C_{30}H_{33}O_2Cl$. Condensation of the same diolefin with benzoyl chloride under similar conditions yields a white crystalline solid which melts at 203° C. and corresponds to $C_{36}H_{30}O$. The constitution of these products is at present unknown but they are probably formed by condensation of benzene as well as of acid chloride with the diolefin accompanied by elimination of hydrogen chloride.

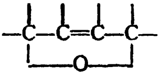
MISCELLANEOUS REACTIONS OF CONJUGATED DIOLEFINS

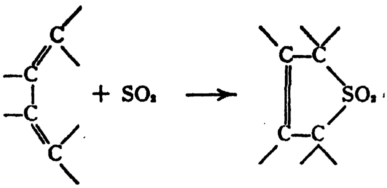
The action of oxygen on conjugated diolefins is very important from the viewpoint of petroleum technology since the gums produced in cracked gasolines on standing are probably oxidized products of such hydrocarbons. The question is dealt with more fully in Chapter 40. The general character of the autoxidation of unsaturated hydrocarbons was clarified by the work of Engler and Weissberg,[183] who demonstrated that the initial products of autoxidation of several monolefins were peroxides containing two atoms of oxygen per molecule. Kogerman[184] recently adduced evidence to show that during the autoxidation of the conjugated diolefins addition of 1 atom of oxygen to each diolefin molecule takes place, the products having some resemblance to the gums of cracked gasolines. Probably addition of oxygen takes place at the 1,4 position with production of substances of the type



The whole subject of autoxidation is very intimately connected with the subject of polymerization since it has been shown that peroxides are highly active catalysts for polymerization of diolefins, styrenes, and analogous bodies.

Diolefins readily form ozonides with ozone. These products play an important rôle in the elucidation of the constitution of diolefins and their derivatives. The conjugated diolefins react very energetically with ozone to furnish monozonides but the diozonides are formed only slowly.

The combination of conjugated diolefin hydrocarbons with anhydrous sulphur dioxide (or in some cases with aqueous solutions of sulphur dioxide or sulphites) is a characteristic reaction which can be used not only for the separation and purification of such hydrocarbons but also for their analytical identification. Monomolecular sulphones, which can be split into their components by heating above about 120° C., are formed according to the general reaction:



---

[182] *Ber.*, 1931, 64B, 2516.

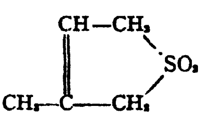
[183] *Ber.*, 1898, 31, 3050.

[184] *Trans. 2nd World Power Conference*, 1930, 8, 33; *Chem. Abs.*, 1931, 25, 5549.

Many of these monomolecular sulphones are well-defined crystalline substances.[134a] It will be noted that this reaction with sulphur dioxide affords yet another example of 1,4 addition to a conjugated system of double bonds. Under certain circumstances polymerized sulphone-like substances are formed instead of the simple monomolecular products.

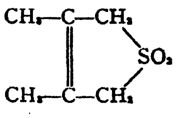
De Bruin,[135] who appears to be one of the first investigators in this field, found that when isoprene was mixed with an equal volume of liquid sulphur dioxide and allowed to stand for 1 to 2 days, a crystalline substance separated which melted without decomposition at 62.5° C. and had the formula $C_5H_8SO_2$. This could be recrystallized from ether and dissolved unchanged in benzene.

On warming a solution of 10 grams of isoprene in 100 cc. of diethyl ether saturated with sulphur dioxide for 5 hours in the water bath, Eigenberger[136] obtained a 60 per cent yield of a monomeric sulphone melting at 63° to 63.5° C. This substance, which was decomposed by heating to 120° to 135° C., readily yielded a dibromide melting at 127° C. when treated with bromine in carbon tetrachloride solution. From a study of various derivatives, Eigenberger assigned to this substance the formula,



Subsequently, he found that this sulphone was converted by the action of aqueous or alcoholic alkali in the presence of radiation from a quartz lamp into an isomeric sulphone, also monomolecular, which melted at 79° C. and was less soluble in ether.[137] The conversion did not take place in the presence of radiation alone and alkali appeared to be essential. On catalytic hydrogenation, the lower melting isomer was found to yield a dihydro-derivative melting at 0.2° C., whereas the higher melting sulphone yielded a dihydro-derivative melting at 0.5° C., showing that the isomerism was the result of a different spatial arrangement of groups around the double bond. To the lower melting isomer Eigenberger[138] assigned a cis-configuration, the other isomer being accordingly assigned a trans-structure. It is interesting to note that the dibromoisoprene sulphone can be readily reduced by zinc and ethyl alcohol to yield 90 per cent of the cis-isomer.

Backer and Bottema[139] obtained a similar monomeric sulphone by treating 2,3-dimethylbutadiene with two molecular proportions of ammonium bisulphite in saturated aqueous solution at 120° C. The product, having the formula



melted at 135° C. and could also be obtained by treating the hydrocarbon with a solution of sulphur dioxide in ether at 100° C. or with sulphurous acid at room temperature. The sulphone could be brominated in benzene solution to yield a dibromide which was readily hydrolyzed by boiling water to a glycol of the formula

---

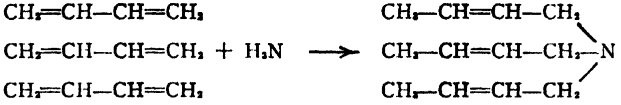
melting at 175° C.

Staudinger[140] developed a process for the manufacture of monomolecular sulphones from butadiene hydrocarbons and liquid sulphur dioxide involving the use of 0.5 to 1 per cent of a stabilizing agent or anti-catalyst, which is said to obviate in part the formation of polymerized sulphones. Such stabilizers may consist of polyvalent or other phenols (e.g., hydroquinone, pyrocatechol, and pyrogallol), amines, and metallic copper or its salts. The sulphur dioxide may be employed either in the anhydrous liquid condition or in a solvent such as benzene.

According to Schmidt, Fries and Kollek,[141] conjugated diolefins react with ammonia and amines in the presence of an alkali metal or of alumina, magnesia, or barium chloride, to form unsaturated organic bases which can be used in the vulcanization of rubber and as insecticides. For example, a solution of sodium in liquid ammonia is allowed to react with butadiene at —80° C. for 10 days and then at —15° C. for 5 days more, when the products are found to consist of tributenylamine and higher bases. By conducting a gaseous mixture of vinyl acetate and monomethylamine over bauxite at 300° C. a mixture of unsaturated bases is produced. Assuming 1,4 addition to take place, the condensation of ammonia and butadiene may perhaps be represented as follows:



tributenylamine

Conjugated diolefins may be directly ethylated by reaction of an ethereal solution of 2 moles of ethyl bromide, or 1 mole of ethyl sulphate, with a mixture of 2 moles of potassium and 1 mole of the diolefin. Midgley and Henne[142] observed that ethylation of isoprene by this method gave a comparatively poor yield of 4-methyl-4-octene, $CH_3CH_2CH_2—C(CH_3)=CHCH_2CH_2CH_3$.

Lebedev and Yakubchik[143] made a study of the hydrogenation of twelve typical butadiene hydrocarbons in the presence of platinum black (Willstätter) in alcohol and concluded that three different reactions may be postulated, namely:

(1) Hydrogenation in two consecutive stages, in the first of which 1,4 addition of hydrogen atoms takes place and in the second, addition to the resulting 2,3-bond, which occurs at a different reaction velocity. Conjugated diolefins of the general formula

---

[140] German Patent 506,839, 1929; *Chem. Abs.*, 1931, **25**, 522; French Patent 698,857, 1930; *Chem. Abs.*, 1931, **25**, 3360; British Patent 361,341, 1930; *Brit. Chem. Abs.* **B**, 1932, 301.

in which R^1, R^2, R^3, and R^4 are alkyl groups (e.g., diisobutenyl), are hydrogenated in this manner.

(2) The first two hydrogen atoms add to the diene molecule in all three possible positions (i.e., 1,2; 3,4; and 1,4) and further hydrogenation takes place simultaneously with the formation of fully saturated molecules. This reaction, which is exhibited by butadiene, isoprene, piperylene and diisopropenyl, is of a complicated nature.

(3) The possible immediate addition of two hydrogen molecules at such a high velocity that the intermediate monolefin has but a transitory existence. Though this is theoretically possible, no examples of this reaction were observed.

The condensation of isoprene with amylene, pinene, trimethylethylene, isopinene, dipentene and sylvestrene in the presence of aluminum chloride has been noted by Aschan.[144] Recently, Thomas and Carmody[145] found that, though pure isoprene does not immediately condense under the influence of aluminum chloride, the presence of a small amount of a monolefin such as 2-pentene immediately initiates a violent reaction. From the reaction of isoprene with monolefins in the presence of aluminum chloride, Thomas and Carmody have been able to obtain synthetic resins of promise. The procedure has already been discussed more fully in Chapter 6.[146]

CONDENSATION REACTIONS OF CYCLOPENTADIENE

Cyclopentadiene, one of the most highly reactive of the conjugated diolefins, deserves special mention because of its great power of condensation with a large number of organic substances, some of which have already been mentioned. Its condensation with itself to yield the dimer, dicyclopentadiene, occurs spontaneously at ordinary temperature[147] and is apparently catalyzed by autoxidation products, though not by light.[148] Condensation to a tetramer and heavier polymers also occurs.[149]

Cyclopentadiene is resinified by dilute acids and alkalies and strong sulphuric acid reacts with it explosively. The great reactivity of the CH_2 group of the hydrocarbon has been ascribed by Thiele[150] to the presence of the contiguous unsaturated linkages. One hydrogen atom of the CH_2 group is replaceable by potassium. The hydrocarbon reacts with methyl magnesium iodide according to the equation:

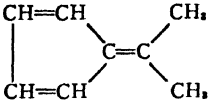
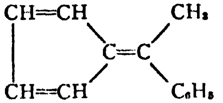
The CH_2 group of the cyclopentadiene ring condenses, under the influence of sodium ethylate, with a large variety of ketones and aldehydes to form the highly colored hydrocarbons of the fulvene series:[151]

With acetone



With acetophenone



Cyclopentadiene condenses with unsaturated nitriles at 150° to 160° C. under pressure to yield cyclic nitriles. The product of the condensation of cyclopentadiene and crotononitrile is said to be a dicyclic nitrile boiling at 87° to 88.5° C. at 12 mm.[152]

Analytical Reactions of Conjugated Dienes

The analytical methods for the determination of unsaturated hydrocarbons by bromine or iodine addition values are unsuitable for the estimation of diolefins since these hydrocarbons behave under the conditions of those determinations as monolefins and add only two, instead of four, halogen atoms. Thus the McIlhiney bromine value of a pure sample of isoprene was found to be 234.7 instead of the theoretical 469.5 for two double bonds.[153] On the other hand, Dobrjanski[154] made use of the bromide-bromate reagent of Francis for estimating butadiene in gas mixtures containing monolefins and stated that tetrabromides were formed from the diolefins and dibromides from the monolefins. It has been shown,[155] however, that the diolefins readily add four atoms of hydrogen on catalytic hydrogenation at low temperatures and that this hydrogen addition value may be utilized to ascertain the purity of isoprene and other diolefins such as isoprene.

For the analytical determination and identification of the diolefins in hydrocarbon mixtures, the halogen derivatives have been most frequently employed, more especially the tetrabromides. The tetrabromide of butadiene was used to identify that hydrocarbon in a complex mixture of hydrocarbons of "oil gas" by Armstrong and Miller[156] and subsequently by Schütz[157] in the case of low-temperature carbonization gas. A determination of butadiene in the gas from low-temperature carbonization processes by conversion into the tetrabromide has been described by Manning, King and Sinnatt.[158] The method consisted in passing a known volume of the hydrocarbon mixture through bromine and water. When the scrubbing was complete the mixed bromides were freed from excess bromine by washing with dilute caustic soda, and were then distilled into 3 fractions as follows:

(1) Below 80° C. at 20 mm. (ethylene, propylene and butylene dibromides);
(2) 80° to 130° C. at 20 mm. (some butylene dibromide and bromine derivatives of higher olefins);
(3) Residue.

The residue from the distillation (containing acetylene tetrabromide and butadiene tetrabromides) was extracted with hot alcohol. The filtered solution was cooled to 0° C., and the solid crystalline butadiene tetrabromide (m.p., 118° C.) which separated was rapidly filtered, dried, and weighed. Experiments with pure butadiene showed that the two forms of the tetrabromide were produced in about equal amounts, so that to obtain the total tetrabromide present the weight of the higher melting form, obtained as described above, must be doubled. The higher melting tetrabromide, though soluble in hot alcohol, separates almost completely from that solvent at 0° C.

According to Sorokin and Belikov,[159] a more accurate method of determining butadiene in gas mixtures is to separate it in the form of its tetrachloride by passing the gas through a saturated solution of chlorine in carbon tetrachloride. The butadiene tetrachloride (b.p., 118° to 122° C.) is separated from other dichlorides by fractionation and weighed.

The analytical estimation or identification of diolefins in the form of their tetrabromides has the obvious advantage that it permits the regeneration of the diolefins by reduction with zinc and alcohol. A limitation of this method, however, is that many of the diolefins, particularly isoprene, cyclopentadiene, and the dimethylbutadienes, form liquid tetrabromides. Nevertheless, both piperylene and butadiene furnish easily crystallizable tetrabromides, useful for identification purposes.

As previously mentioned, to estimate isoprene in a mixture of butenes, pentenes and benzene, Ostromislensky[160] converted the former hydrocarbon into its dihydrochloride by shaking it with concentrated hydrochloric acid for 6 hours. The products of reaction were carefully washed, dried, and then fractionated, the fraction boiling at 130° to 140° C. being fairly pure isoprene dihydrochloride (2,4-dichloro-2-methylbutane). The applicability of this method is probably limited to mixtures containing comparatively high concentrations of isoprene.

Perhaps the most promising method for the positive identification and possibly the estimation of conjugated diolefins is that based upon the previously discussed combination of these hydrocarbons with maleic anhydride.[161] The importance of this reaction, from the analytical standpoint, is that the reaction products are easily crystallized and have characteristic melting points, so that they are of unusual value for purposes of identification. The products of the reaction between conjugated diolefins and maleic anhydride are acid anhydrides, some of which can be hydrolyzed to the corresponding acid by boiling water. The ease of formation of these condensation products with maleic anhydride varies considerably. The cyclic diolefins, 1,3-cyclopentadiene and 1,3-cyclohexadiene, react energetically with maleic anhydride at 0° C. to give almost quantitative yields. Butadiene, isoprene and piperylene react slowly with maleic anhydride in the cold and some polymerization of the two latter hydrocarbons occurs. With butadiene, heating under pressure to about 100° C. is apparently necessary to complete reaction. According to Farmer and Warren,[162] a 95 per cent yield of the addition product of piperylene and maleic anhydride is obtained by allowing the mixed reactants, dissolved in benzene, to stand at 0° C. for 5 days. If higher temperatures are employed, pronounced polymerization occurs. Under similar conditions, 1,2-dimethylbutadiene furnishes a 96 per cent yield of the condensation product but 1,1-dimethylbutadiene yields only polymerized products even at low temperatures. The melting points of some of these reaction products of maleic anhydride are given in Table 116.[163]

1,3-Cyclopentadiene	164–165	177–179
1,3-Cyclohexadiene	147	—

The maleic anhydride condensation provides a satisfactory method for the identification of a number of conjugated diolefins in mixtures. The method has been used by Birch and Scott[164] for the identification of conjugated diolefins (butadiene, isoprene, piperylene and cyclopentadiene) in the lower fractions of vapor-phase cracked gasoline. Unfortunately, its applicability as a quantitative method of estimation appears to be limited, except perhaps in the case of conjugated cyclic diolefins which react readily and quantitatively with this reagent. However, Bassett and Williams[165] applied the condensation with maleic anhydride to the quantitative estimation of isoprene in the products of distillation of rubber, using a procedure essentially similar to that of Farmer and Warren. The method was more satisfactory than other proposed modes of estimation, which were found to yield low results.

It has previously been shown[166] that under controlled conditions, conjugated diolefins can combine with sulphur dioxide to yield well-defined crystalline monomolecular sulphones. It would appear that such sulphones might be of value in the identification of conjugated diolefins in hydrocarbon mixtures. The sulphones can be reconverted into their parent substances by heating to temperatures above about 120° C. Lebedev and Yakubchik[167] proposed a method of estimating isoprene, based upon the formation of a sulphone on treatment with sulphur dioxide, but Bassett and Williams[168] find that this method yields results which are too low.

OTHER DIOLEFINS

The 1,4- and 1,5-diolefins do not appear to be formed to any appreciable degree during the pyrolysis of petroleum hydrocarbons. They are of importance, however, in the chemistry of the essential oils and perfumes. A number of the 1,4-diolefins have been studied by Shoemaker and Boord.[169] The 1,5-diolefins are of interest because of their conversion by the action of 70 per cent sulphuric acid into an oxide, the anhydride of the 2,5-glycol, which contains a 5-membered heterocyclic ring.[170]

When 1,5-hexadiene (diallyl) is treated with 100 per cent sulphuric acid at —15° C. to +4° C. the production of diallyl ether is not noticeable, the two main products being a crystalline neutral cyclic monoester and a diester. These substances are easily hydrolyzed to the 2,5-glycol, which is unstable in the presence of acids and tends to dehydrate, thus forming diallyl oxide.[171]

Chapter 28

Important Reactions of Acetylene. Production of Acetaldehyde and Vinyl Esters

The hydrocarbon acetylene is the simplest member of a series of hydrocarbons, called the acetylenes or alkynes, possessing the general formula C_nH_{2n-2} and characterized by a triple-bonded carbon linkage. Acetylene itself is $HC{\equiv}CH$, while two series of homologues exist, in which either one, or both, of the hydrogen atoms of the acetylene molecule are replaced by alkyl groups.

Because of the extraordinary breadth of reactivity of acetylene,[1] it stands forth as one of the most promising hydrocarbons to be considered as a source of chemical products. Since it can be obtained from natural gas or cracked petroleum gases by pyrolysis (discussed in Chapters 4 and 9) or oxidation (Chapter 39), as well as from calcium carbide manufactured from coal and lime, its importance in this regard is assured and bids fair to create for this hydrocarbon a status in the aliphatic as important as that occupied by benzene in the aromatic series.

MANUFACTURE OF ACETYLENE

The acetylene of commerce has been obtained chiefly by the hydrolysis of calcium carbide, a compound produced in immense quantities by heating lime and carbon (e.g., coke) together to a very high temperature in the electric furnace. On treatment with water, calcium carbide is decomposed according to the equation:

$$CaC_2 + H_2O \longrightarrow Ca(OH)_2 + C_2H_2$$

a reaction discovered by Wöhler in 1862.[1a] Some 30 years after this discovery, the commercial production of calcium carbide in the electric furnace was begun and since that time the carbide industry has grown in magnitude and importance. As the manufacture of calcium carbide on a large scale demands a cheap and plentiful supply of electrical energy, carbide factories are entirely located in districts where water power can be utilized for the generation of the necessary electrical power.

Acetylene is produced to a greater or less extent by the decomposition of a large number of metallic carbides by water or by dilute mineral acids. The carbides of calcium, barium, strontium, or of lithium, sodium, potassium, caesium and rubidium, having the formulas $M^{II}C_2$ or $M^I_2C_2$, are all decomposable by water to yield acetylene in a more or less pure condition. Certain other carbides, such as carbides of manganese, iron, cerium, and thorium, furnish mixtures of saturated and unsaturated hydrocarbons (including acetylene), while aluminum and beryllium carbides furnish almost pure methane on decomposition by water.[2] The production of acetylene-forming carbides by heating metallic oxides in methane at high temperatures has been described by Fischer and Bangert.[3]

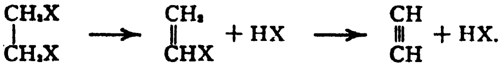
---

[1] The properties of acetylene are reviewed by Miloslavskii and Glizmanenko (*Avtogennoe Delo*, 1932, No. 4, 17; No. 6. 3; *Chem. Abs.*, 1932, 26, 5544).

[1a] *Ann.*, 1862, 124, 220.

Of considerable scientific interest is the direct synthesis of acetylene by the passage of hydrogen between the poles of a carbon electric arc.[4] The electrical decomposition (by means of either low- or high-tension arcs) of many hydrocarbons, a subject discussed in Chapter 9, similarly yields considerable quantities of acetylene together with other hydrocarbons. During recent years much interest has been aroused in the commercial production of acetylene by the high-temperature pyrolysis of methane and other saturated hydrocarbons. It appears that very high temperatures (above 1000° C. and up to 3000° C.) in conjunction with very short periods of heating are the conditions most favorable to good yields of acetylene. Acetylene may also be produced by the incomplete combustion of hydrocarbons such as methane or natural gas, with air or oxygen at high temperatures. The formation of acetylene by all these high-temperature methods is connected with the fact that acetylene has increased stability with rising temperature as shown by thermodynamic calculations. Though it is very doubtful if acetylene ever becomes perfectly stable with respect to its elements even at the highest temperatures, it appears that an equilibrium of the type $2C\ (gas) + H_2 \rightleftarrows C_2H_2$ is set up, in which the point of equilibrium tends more towards the acetylene side of the equation as the temperature is increased.

Very pure acetylene may be produced by the decomposition of copper acetylide (made by passing crude acetylene into an ammoniacal cuprous salt solution) with potassium cyanide.[5] If mineral acids are used to decompose this acetylide, relatively small yields of acetylene are formed and considerable amounts of by-products result. Acetylene may be obtained from a large number of halogenated hydrocarbons. Thus, acetylene tetrachloride or tetrabromide are readily reduced to acetylene by treatment with metallic zinc,[6] while iodoform and bromoform also yield this hydrocarbon by the action of metallic copper or zinc or of the zinc-copper couple[7] of Gladstone and Tribe. The ethylene dihalides can be converted into acetylene either by the action of hot alcoholic potash[8] or by pyrolysis at moderately high temperatures. In each case a vinyl halide is formed as an intermediate compound and the reactions may be represented as follows:



$$\begin{matrix} CH_2X \\ | \\ CH_2X \end{matrix} \longrightarrow \begin{matrix} CH_2 \\ \| \\ CHX \end{matrix} + HX \longrightarrow \begin{matrix} CH \\ \| | \\ CH \end{matrix} + HX.$$

A number of other methods of preparation are known, including the electrolysis of unsaturated carboxylic acids, but these are of little practical interest.

The carbide process is possibly the most widely used, although the electrical decomposition and the thermal decomposition of gaseous hydrocarbons to produce acetylene are being developed on a commercial scale. The electrical decomposition of higher boiling petroleum fractions, such as fuel oil, also leads to the formation of acetylene together with ethylene and other unsaturated hydrocarbons. In localities where cheap supplies of electrical energy and natural gas are available, the production of acetylene and hydrogen together with carbon black, ethylene and other by-products should be economical.

PURIFICATION AND SEPARATION OF ACETYLENE

The purity of acetylene obtained by interaction of calcium carbide and water depends mainly on the purity of the carbide used. The impurities actually present in acetylene, so generated, consist mainly of phosphine, hydrogen sulphide, ammonia, and very small amounts of silicon hydrides. The actual proportion of these impurities is usually relatively very small but their objectionable nature renders their removal imperative for a number of purposes. Scrubbing with water is usually sufficient to reduce the quantities of all impurities, except phosphine, below the limit necessary for safe application. Phosphine is removed by oxidation (to phosphoric acid) with reagents such as bleaching powder, or acid solutions of chromic acid. Acid solutions of cuprous salts, with which phosphine and sulphuretted hydrogen readily combine to yield copper phosphide or sulphide, have also been employed.

For the separation of acetylene from the gaseous mixture obtained by high-temperature pyrolysis or electrical disintegration of hydrocarbons, a number of methods have been proposed, some of which have already been discussed in Chapters 4 and 9. Hull[9] recovered acetylene from gas mixtures by scrubbing them in stages with a sulphuric acid solution of mercuric sulphate under successively higher pressures. Solvents[10] for recovering acetylene are esters or ethers boiling above 100° C., particularly an ester, ether, or ester-ether of a polyhydric alcohol, such as glycol monoformate, glycol mono- and dialkyl ethers, esters of monoalkyl ethers of ethylene glycol, glycerol mono- and diacetates, glycerol ethers, esters of glycerol mono- or dialkyl ethers, phthalate esters of glycol ethers, and ethyl lactate. Liquefied sulphur dioxide, ammonia, carbon dioxide, and methyl and ethyl chlorides have also been suggested for the extraction of acetylene.[10a]

A method for purification of acetylene in the presence of other unsaturated hydrocarbons such as diacetylene, ethylene, allene, butylene, isoprene, butadiene and cyanogen compounds has been developed.[11] The cyanogen compounds are removed by washing with solutions of ferrous sulphate, sodium or potassium hydroxide and the gases are then passed over activated carbon or silica gel to remove other impurities. The gas is then ready for conversion into acetaldehyde by absorption in sulphuric acid in the presence of mercury or in other ways. In another process the acetylene is frozen out between a temperature of —30° and —81° C.[11a]

PHYSICAL PROPERTIES OF ACETYLENE

Pure acetylene is a colorless gas having a pleasant ethereal odor. At low temperatures it solidifies to a white crystalline mass, m.p. —81.5° C. and sublimation point —83.6° C.[12] Liquid acetylene boils at —88.5° C. according to McIntosh and Maass,[12] but other workers give the following temperatures: —82.4° C.[13] and —84.0° C.[14] Its critical constants are as follows: critical temperature 37.05° C.; critical pressure 68.0 atmospheres, and critical volume 83 cc.

Acetylene is a very highly endothermic compound, its heat of formation from its elements at constant pressure and volume being about —50 kg. cals. For this reason it has a great tendency to decompose, and compression of gaseous acetylene beyond a certain pressure results in violent explosions. According to the determinations of Rimarski,[15] pure acetylene undergoes explosive decomposition at pressures in excess of atmospheric varying from 1.1-1.3 atmospheres, 0.80-0.85 atmosphere, and 0.50-0.55 atmosphere in tubular containers of 3.8 cm., 6.6 cm., and 25 cm. bore, respectively. When acetylene is diluted with other gases such as hydrogen or hydrocarbons the tendency to explode is very greatly diminished and such gas mixtures may be compressed to fairly high pressures without danger of explosion. Thus a mixture of oil-gas and 20 to 40 per cent acetylene is reported not to be explosive under 7 atmospheres pressure.

Since acetylene cannot, like other gases, be stored in cylinders under high pressure, some safe method of storage in concentrated form had to be adopted. Claude and Hess[16] in 1896 proposed to overcome the difficulty by making use of the very high solubility of acetylene in acetone, which dissolves 24 volumes of acetylene at 15° C. and 1 atmosphere, but it was found that the danger of explosion, though greatly minimized by such solution, was not entirely obviated. The problem was finally solved by Janet and Fouche,[17] who showed that when acetylene is dissolved in acetone previously adsorbed by a porous material of the right kind under 10 atmospheres pressure, then pressures up to 150 lbs. per sq. in. may be applied with safety.

The solubility of acetylene in many liquids is very considerable, especially in organic liquids of the ketone class. It is soluble in water to the extent of about 1 volume per volume of water at 12° C.[18] Alcohol and acetic acid dissolve 6 volumes of the gas and chloroform and benzene 4 volumes, per volume of solvent. Its very great solubility in acetone has previously been noted. Acetaldehyde has also been suggested since it dissolves half its own weight of gas.[18] According to Roffey[19] acetylene may be stored in cylinders containing solid absorbent material impregnated with solvents consisting of a relatively non-volatile ether, ester, or ether-ester of a polyhydric alcohol, or mixtures of these. Before storing, the acetylene is preferably dried by passing over calcium chloride before and after compression.

Pure acetylene has little action on metals but crude acetylene readily attacks copper with the formation of the explosive acetylide. Since nickel and tin are both resistant to the action of this gas, coatings of these metals are recommended where exposure to acetylene is contemplated.

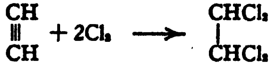
CHEMICAL PROPERTIES OF ACETYLENE

Acetylene is a hydrocarbon possessing very great chemical reactivity and power of condensation. From a thermodynamic standpoint this high reactivity is the result of its relatively great internal energy content. The acetylene molecule may, perhaps, be compared to a high explosive which only needs some slight impetus (in the form of a catalyst or an energy excitation) to enable it to release its store of chemical energy.

As a typical unsaturated hydrocarbon, acetylene readily undergoes a vast number of *addition* reactions not only with halogens, halogen acids and organic acids, but also, under proper conditions, with water, alcohols, ammonia and numerous organic compounds. It also combines with a great number of inorganic substances, notably with hydrogen sulphide, hydrogen cyanide, sulphuric acid, and many metallic salts.

Its addition reaction with chlorine, considered in detail later, is typical of the acetylene hydrocarbons as a class. Four atoms of chlorine are ultimately added to yield acetylene tetrachloride, thus:



$$CH{\equiv}CH + 2Cl_2 \longrightarrow CHCl_2{-}CHCl_2$$

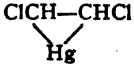
On hydrogenation, acetylene yields first ethylene and finally ethane. The condensations of acetylene with water, chlorine, halogen acids and organic acids are of industrial importance.

Some of the characteristic reactions of acetylene are those with the salts of silver, copper and mercury. When acetylene is passed into an ammoniacal solution of a silver or cuprous salt, the so-called acetylides of these metals are formed. Silver acetylide is a yellowish precipitate of the composition $C_2Ag_2.H_2O$, while cuprous acetylide is a brick-red precipitate of the formula $Cu_2C_2.H_2O$, which may be dehydrated to Cu_2C_2 by gently warming. All the acetylides are highly unstable and explode with violence on heating, or, when dry, under the influence of slight mechanical agitation. The formation of explosive metallic derivatives is characteristic of hydrocarbons containing a hydrogen atom linked to a triple-bonded carbon atom, i.e., containing the group $—C{\equiv}CH$. These include not only acetylene and the monoalkylacetylenes but also diacetylene $HC{\equiv}C—C{\equiv}H$, and its monoalkyl derivatives.

The products obtained by treating mercury salts with acetylene are of importance because these compounds are employed industrially in the preparation of acetaldehyde from acetylene. They may be briefly summarized by the following cases.

Passage of acetylene through aqueous solutions of *mercuric* salts leads to the production of white precipitates which on warming with water, or on treatment with acids, furnish good yields of acetaldehyde. Thus mercuric acetate solutions give a slimy non-explosive white precipitate of the composition $3C_2Hg.2Hg(OH)_2$; while a saturated solution of mercuric chloride in alcohol furnishes a white, crystalline addition product, m.p. 113° C., of the formula $HgCl_2.C_2H_2$ and possible constitutions [20]

$ClHgCH{=}CHCl$ or



---

[20] Chapman and Jenkins, *J.C.S.*, 1919, 115, 847.

Aqueous solutions of mercuric chloride yield an amorphous, white precipitate of the formula $C_2Hg.HgCl_2$ (also possibly $(HgCl)_3.C.CHO$) which, on heating in aqueous suspension, furnishes a practically quantitative yield of acetaldehyde.[21] It appears certain that these addition products with mercuric salts, in non-alkaline solutions, are the intermediates in the synthesis of acetaldehyde by the liquid-phase process. On passing acetylene into alkaline solutions of mercuric salts (e.g., Nessler solution), a white, very explosive *mercuric acetylide* of the formula C_2Hg is formed.[22] Treatment of this substance with acids regenerates acetylene.

Mercurous acetylide, a gray explosive precipitate of the formula $C_2Hg_2.H_2O$, is made by passing acetylene through an aqueous solution of mercurous acetate in the dark.[23]

From solutions of gold, palladium and osmium, acetylene precipitates the metals either in the free state or as double compounds but the gas does not appear to react with the salts of iron, nickel, cobalt, lead, cadmium, platinum, iridium, rhodium, zinc, arsenic, or tin.

INDUSTRIAL UTILIZATION OF ACETYLENE

In the early stages of the carbide industry the chief interest lay in the utilization of the acetylene, produced therefrom, for illuminating purposes. Although even today considerable quantities of carbide are employed for acetylene lighting, the main applications of acetylene gas are, first, in autogenous welding (by means of the oxy-acetylene flame) and, second, as a raw material for the manufacture of a wide variety of organic chemicals, which include numerous halogen compounds as well as acetaldehyde, acetic acid, acetone and vinyl derivatives. The progress in the field of the chemical utilization of acetylene since 1910 has been exceptionally rapid.

Later, attention was directed to the possible utilization of acetylene as a raw material for the manufacture of synthetic rubber-like substances. In the following pages an account is given of some of the more important reactions of acetylene.

POLYMERIZATION OF ACETYLENE

Berthelot and Gaudechon[24] observed that ultraviolet rays from a mercury arc caused partial polymerization of acetylene to a yellow solid; neither decomposition nor benzene formation was noted. Acetylene polymerizes[24a] under the influence of high temperatures and leads to a complex mixture of aromatic hydrocarbons, of which benzene may constitute, under some conditions, a very considerable proportion. The subject of the pyrolysis of acetylene has been discussed in Chapters 2, 4, 5 and 9, and need only be referred to briefly here. The pyrolytic process necessitates the use of temperatures of about 600° C. or higher and catalysts tend to cause the formation of methane, hydrogen, and carbon. Under such conditions benzene, derived from acetylene according to the reaction, $3C_2H_2 \rightarrow C_6H_6$, is by no means the main product and usually a whole series of aromatic hydrocarbons, both mono- and polynuclear, are simultaneously formed. According to the work of Berl and Hofmann,[25] 87 per cent of aromatic condensation products are obtained by heating acetylene at 600° to 700° C. in the presence of a beechwood charcoal contact material. With excess steam at 740° C. yields as high as 98.8 per cent were attained.

[24a] The polymerization and decomposition of acetylene and its homologues has been reviewed by Egloff, Lowry, and Schaad (*J. Phys. Chem.*, 1932, 36, 1457; *Chem. Abs.*, 1932, 26, 3479).

Other investigators obtained a 50 per cent yield of benzene by polymerizing acetylene at 700° C. using selenium or tellurium as a catalyst.[26] It is said that the polymerization may be carried out at 300° to 500° C. under 10 to 200 atmospheres in the presence of a heavy oil (e.g., transformer oil) and iron and magnesium bromide and yields liquids, for the most part aromatics, nearly quantitatively.[27]

Bahr [28] studied the polymerization of acetylene at moderate temperatures in the presence of various catalysts. Using ferrous sulphide a black-brown tar was formed at 300° C.; with deposition of carbon at 430° C. With 50 per cent nickel and 50 per cent tin a water-clear condensate, which later turned green or brown, was produced; carbon deposited at about 430° C. Using tinned iron turnings a small amount of liquid was produced at 250° C., but with stannous chloride and pumice no reaction was observed up to 500° C.

In the presence of zinc chloride at 420° to 430° C., Lozovoj [28a] obtained gaseous products consisting of 32 per cent acetylene, 2 per cent isoolefins, 10 per cent normal olefins, 12 per cent hydrogen, and 41 per cent saturated paraffin hydrocarbons. The unsaturated hydrocarbons identified were ethylene, propylene, 1-propinine, allene and butadiene. The liquid products contained a small proportion of olefins, benzene, toluene and naphthalene but no paraffins or naphthenes.

Fischer, Peters and Koch [28b] passed water gas containing 10 per cent acetylene over a copper-iron alkali catalyst at 250° C., 40 to 70 per cent of the acetylene being thus converted to benzine and oil. With a catalyst of copper and iron in proportions greater than 10 to 1, respectively, cuprene was formed. One per cent of nickel added to the catalyst produced 50 to 55 per cent of benzine and oil in the ratio of 3 to 1, respectively. Iron alone gave no results below 340° C., but above this temperature 35 to 40 per cent oil was formed accompanied by carbon. With cobalt, methane was quantitatively produced. Two parts of iron and 1 of nickel raised the proportion of benzine in the yield to 85 per cent, the total yield at 250° C. being 30 to 35 per cent of the acetylene used. Likewise coal gas was catalytically polymerized. One cubic meter passed first through an electric discharge and then over a heated catalyst gave 85 grams of oil, of which 75 per cent was light oil. In all cases 90 per cent of the benzine boiled between 50° and 150° C. and contained 60 per cent unsaturated compounds.

The low-temperature polymerization of acetylene has been studied very little. The action of the silent electric discharge on acetylene at low temperatures was found by Mignonac and Vanier de Saint-Aunay [29] to result in the production of dipropargyl and other highly reactive diacetylene hydrocarbons.

Nieuwland, Calcott, Downing and Carter [30] described a method of controlling the polymerization of acetylene at low temperatures by making use of the condensing action of a concentrated aqueous solution of cuprous chloride and ammonium chloride. The products consist of monovinylacetylene, divinylacetylene and a tetramer of acetylene. On introducing pure gaseous acetylene under slight pressure into a 2-liter flask containing a cooled solution of 100 grams of cuprous chloride, 390 grams of ammonium chloride, 100 grams of precipitated copper powder, 30 grams of 37 per cent hydrochloric acid, and 425 grams of water, more than 100 grams of acetylene are absorbed. During the absorption the catalyst may be allowed to warm up to 40° to 50° C. without detriment to the recovery of the products. The solution becomes light yellow in color and insoluble addition products are formed. On allowing the mixture to stand at room temperature for 5 to 7 days, polymerization of the combined or dissolved acetylene takes place. Acetylene polymers may be distilled by heating the catalyst solution to 100° to 110° C. until only water distils over. The distillate separates into two layers; the lower aqueous layer is returned to the catalyst mixture which is recharged with more acetylene; and the oily layer, consisting of a mixture of divinylacetylene and a tetramer, C_8H_8, together with small amounts of chlorine-containing products, is dried and distilled *in vacuo* on a water bath. Divinylacetylene is distilled at 200 mm. pressure and the tetramer at 20 mm., the temperature in each case being nearly 100° C. The yield of divinylacetylene is 70 to 80 per cent, and that of the tetramer 10 per cent, of the acetylene absorbed while the loss amounts to 10 to 20 per cent.[81] By a modification of the above process substantial amounts of monovinylacetylene may be obtained.

Polymerization of acetylene under these carefully controlled conditions, therefore, leads to the formation of varying proportions of highly unsaturated hydrocarbons containing one triple bond together with one or more double bonds. The chemical and physical properties of these polymers are as follows:

Monovinylacetylene, $CH_2{=}CH{-}C{\equiv}CH$, is a colorless liquid of sweet odor, boiling point 5° C. and $d_0^t = 0.7095\text{-}0.00114\ t$. On hydrogenation it yields butadiene[82] and n-butane. Hydration of the triple bond using a catalyst (mercuric sulphate or acetate, cadmium sulphate or acetate, or silver phosphate) in sulphuric acid furnishes the unsaturated ketone, $CH_2{=}CHCOCH_3$.[83] Monovinylacetylene forms a white silver salt and a yellow copper salt with ammoniacal solutions of these metals.

On treatment with hydrochloric acid in the presence of cuprous, auric, calcium, magnesium, mercuric or mercurous chloride, monovinylacetylene gives rise to 2-chlorobutadiene, boiling point 60° C.; 2,4-dichlorobutylene, boiling point 128° C.; and chloromethylallene, boiling point 86° to 88° C.[84] Similarly with concentrated hydrobromic acid, 2-bromobutadiene, boiling point 42° to 43° C. at 165 mm.; and 2,4-dibromo-2-butene, boiling point 168° to 169° C., are produced.[85]

Both 2-chlorobutadiene and 2-bromobutadiene may be polymerized to rubber-like substances.[36]

When vinylacetylene is polymerized under pressure by heating either with or without catalysts (benzoyl peroxide or sodium perborate), it forms viscous drying oils and finally hard resinous solids.[37]

Divinylacetylene, $CH_2=CH—C\equiv C—CH=CH_2$, is a colorless liquid of unusual alliaceous odor, boiling point 83.5° C. at 760 mm. and d^{20}_{4} 0.7851. As previously mentioned, it may be prepared from acetylene in the presence of an aqueous acid solution of cuprous chloride and an ammonium salt.[38] It is an extremely explosive substance and readily absorbs oxygen from the air to yield a highly explosive peroxide. Its structure is deduced from its being hydrogenated to n-hexane and brominated to a mixture of stereoisomeric, 1,2,3,4,5,6-hexabromo-3-hexenes (melting point 81° and 114° C.).

Divinyl acetylene may be partially hydrogenated to less saturated products[39]; it is said that if the partial hydrogenation is carried out under nonoxidizing conditions a more stable product is obtained.[40] The halogenation of divinylacetylene leads to products which may be used as drying oils or plastics.[41] Two substances isolated from the chlorination are 1,2,3,4,5,6-hexachlorohexene-3, and 3,4-dichlorohexatriene,1,3,5.[42]

Coffman and Carothers[42a] obtained a 25 per cent yield of 1,4-dichloro-2,3,5-hexatriene on passing chlorine into a solution of divinylacetylene in carbon tetrachloride at —56° C. for 5 hours. At —50° C. the yield was 19 per cent and at 0° C., 20 per cent. Other products consisted of a liquid dichloride and tetrachloride and a crystalline hexachloride.

By heating in an inert atmosphere, divinylacetylene may be polymerized first to a viscous liquid and finally to a hard brittle resin insoluble in all known solvents.[43] The intermediate liquid products are synthetic drying oils[44] possessing high stability but drying by oxidation and polymerization to hard films. These resinous films are stated to be highly resistant not only to solvents but also toward acids.[45] Coating compositions are also obtained from the reaction of divinylacetylene and sulphur chloride.[46]

A synthetic rubber may be obtained from emulsions of divinylacetylene or its liquid or gaseous polymers.[47] The emulsion is prepared by adding 30 parts of divinylacetylene to 100 parts of a solution containing 1 per cent gelatin and 1 per cent of sludge acids obtained in the treatment of petroleum distillates with sulphuric acid.[48] The mixture is agitated and a milky emulsion which has slight tendency to separate, results. Such an emulsion having a particle size of about 1 μ and containing a resin extracted from guayule rubber by acetone, resembles latex and on coagulation forms a synthetic rubber.

The so-called "tetramer," a colorless liquid resembling divinylacetylene, has d^{20} 0.830 and n^{20}_{D} 1.576. It apparently boils at 156° C. with violent decomposition and boils with polymerization at 40° C. at 20 mm., 50° C. at 30 mm., and at 82° C. at 100 mm.[49] Its probable structure is $CH_2{=}CH{-}C{\equiv}C{-}CH{=}CH{-}CH{=}CH_2$.

The low-temperature polymerization of acetylene, therefore, results initially in the production of straight-chain highly unsaturated hydrocarbons containing one triple bond and one or more double bonds.

CUPRENE

A product of the pyrolysis of acetylene [50] is the voluminous yellow-brown solid polymer known as *cuprene* or *carbene*. This material, which appears to correspond with the formula $(CH)_x$, was first prepared by Erdman and Köthner [51] by passing acetylene over copper or copper oxide at temperatures below 250° C. Later investigations of this substance were undertaken by Alexander,[52] Gooch and Baldwin,[53] Sabatier and Senderens,[54] and especially by Kaufmann and Schneider.[55] In view of the facts that cuprene, on being heated with zinc at elevated temperatures, yielded aromatic hydrocarbons, was oxidized by fuming nitric acid to mellitic and benzoic acids, and also to naphthalene derivatives, and on bromination at 100° to 130° C. in the presence of ferric bromide furnished, among other products, hexabromohexahydrotriphenylene, it can hardly be doubted that this curious material is of aromatic nature though its precise structure is unknown.

Cuprene is now manufactured on a considerable scale but the details of the process have so far remained veiled in secrecy. It is known, however, that copper or cupriferous bronze powders have been used as catalysts at temperatures of 200° to 260° C. and under pressure, together with the combined action of dark electric discharges.[55a] A special arrangement to prevent the voluminous polymerization products from clogging up the reaction chamber is advantageous. The addition of 5 to 15 per cent of nitrogen to the acetylene has been found to yield homogeneous products of lighter color.[56] With undiluted acetylene, there is a tendency for coking to occur, resulting in the formation of dark products of lower hydrogen content. A greenish blue, neutral, strongly unsaturated tarry liquid, called "cuprene tar" is simultaneously formed in amounts of 5.5 to 7.0 per cent as well as 13 to 17 per cent of waste gases. This tar has been investigated by Schläpfer and Stadler.[57] Under proper conditions the yield of cuprene is 25 per cent. In another proposed method for the preparation of a highly adsorbent material (cuprene), acetylene at 200° to 400° C. is passed over copper, nickel.

iron, or oxides of these metals to which has been added less than 1 per cent of magnesium powder.[58]

Acetylene mixed with an indifferent gas may be conducted into stearic acid heated to 250° to 300° C. to which has been added copper bronze.[59] The cuprene made by this process is a fine powder and of a light or dark brown color. Addition of air or oxygen to the acetylene has also been proposed.[59a]

Because of its chemical inertness and its highly voluminous structure, cuprene presents industrial possibilities. Its applications as a filler in the manufacture of acid-resisting and electric insulating materials, plastic masses,[59b] electrodes and explosives, as a cork substitute [59c] in the linoleum industry and as an adsorbing agent for illuminants and fuels or volatile substances [59d] have been discussed by Herzog.[60] Sulphurized cuprene, containing 11 per cent of sulphur, is prepared by refluxing cuprene with sulphur monochloride in the presence of benzene. When working under 10 atmospheres pressure at 180° to 200° C. a product containing 13.6 per cent of sulphur and 4 per cent of chlorine is obtained which may be employed in the rubber industry.

HALOGEN DERIVATIVES OF ACETYLENE

A number of halogen derivatives of both substitution, addition, and substituted-addition types are known and some of these products, especially those containing chlorine, are of industrial importance. Only the chlorine derivatives will be considered in the following brief account.[60a]

Though chlorine is without action on pure acetylene in the dark, addition occurs smoothly in diffused daylight with the ultimate formation of the tetrachloride $C_2H_2Cl_4$, the dichloride being an intermediate product. In practice, however, direct combination of acetylene and chlorine to yield the tetrachloride may be accompanied by violent explosions, particularly in presence of traces of impurities. For this reason, catalysts are often employed to control the reaction. If desired, however, the reaction can be stopped at the intermediate dichloride stage by adjustment of operating conditions.[61] Thus, trans-1,2-dichloroethylene is the main product when a mixture of chlorine and excess of acetylene is led at high space velocities over active carbon at temperatures below 100° C., the optimum temperature being about 40° C.[62]

Acetylene tetrachloride (tetrachloroethane, $Cl_2HCCHCl_2$) is by far the most important of the industrial halogen derivatives of acetylene and serves as a starting material for the synthesis of a number of solvents, notably of trichloroethylene and its derivatives. As previously stated, it is prepared by the direct combination of acetylene and chlorine in the presence of catalysts, which serve to obviate the danger of explosions. A number of catalysts have been proposed including iodine monochloride,[63] aluminum chloride,[64] ferric chloride,[65] iron filings and bone charcoal,[66] and antimony pentachloride,[67] but the last substance appears to be most generally employed.[67a] The reacting gases are introduced either simultaneously or alternately into a solution of antimony pentachloride in acetylene tetrachloride at a slightly elevated temperature. According to Igi,[68] the optimum temperature for absorption in antimony pentachloride is 80° to 100° C.[68a] for chlorine and 60° to 80° C. for acetylene. In the preparation of acetylene tetrachloride the acetylene is passed in first at the lower temperature. Various intermediate compounds such as antimony chloroacetylide and antimony trichloride are probably formed. Acetylene tetrachloride has been formed in 93 per cent yield by passing 1 volume of acetylene and 2 volumes of chlorine through a tube at 205° C. carrying a water-cooled tube at 110° C.[68b] Fukagawa [69] states that an iron-silicon-aluminum alloy is a catalyst.

Acetylene tetrachloride is a colorless liquid of boiling point 145.5° C. and d_4^{15} 1.6011. It is a solvent for fats, varnishes and cellulose acetate, but its use has been greatly restricted by its very marked toxic properties and its ease of decomposition in the presence of moisture. As a solvent, it has been largely displaced by a number of its derivatives which are equally satisfactory for most purposes, are much less toxic, and exhibit greater stability.[69a] One of the most important of these derivatives is the substance trichloroethylene, $CHCl{=}CCl_2$. This is manufactured on a large scale by heating acetylene tetrachloride with an alkali, such as lime [70] or ammonia,[71] whereby an almost theoretical yield is obtained. MacMillan [72] prepares trichloroethylene by heating acetylene tetrachloride with lime, water, and sodium carbonate at about 100° C. Guyot [73] prefers aqueous ammonia at 140° to 170° C. as the dechlorinating agent. Other proposed methods of converting acetylene tetrachloride into trichloroethylene include the catalytic decomposition of the former substance in the presence of heated copper or barium chlorides [74] or of thorium dioxide at 390° C.[75] Trichloroethylene may also be obtained by passing acetylene tetrachloride vapor mixed with steam or xylene vapor over a catalyst at 450° to 500° C.[75a] The catalyst is prepared by shaking moistened pumice with finely powdered copper phosphate.

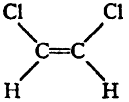
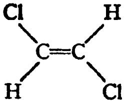
Trichloroethylene is a colorless liquid of boiling point 87° C. at 760 mm. and d^{15}_{4} 1.471, possessing solvent power[76] for fats, waxes, resins, rubber and other organic compounds as well as for sulphur and phosphorus. It is utilized in the extraction of fats and in dry cleaning[76a] and as a dehydrating agent (by azeotropic distillation) in the production of absolute alcohol.[76b] It may be used as a raw material for the production of pentachloroethane,[76c] dichloroethylene, dichlorovinyl ether, chloroacetic acid, and glycollic acid. According to Dangelmajer,[77] 10 per cent of an aliphatic petroleum fraction of boiling range 40° to 232° C. stabilizes trichloroethylene. Hexylresorcinol[77a] has also been suggested for this purpose.

1,2-Dichloroethylene, or acetylene dichloride, exists in two geometrically isomeric forms,

(*cis*)



(*trans*)



which have the following physical properties:

	cis-Dichloroethylene	trans-Dichloroethylene
b.p. ° C. at 760 mm.	59.8°	48.8°
m.p. ° C.	—80.5°	—50°
d^{15}_{4}	1.289	1.265

These isomeric compounds may be produced from acetylene tetrachloride by heating with water and zinc at 100° C. or with iron and water at 150° to 200° C. in an autoclave.[77b] A vapor-phase process in which the mixed vapors of the tetrachloride and steam are passed over a heated iron catalyst at ordinary pressure, has also been described.[78] Dichloroethylene is said to be produced when 1,1,2-trichloroethane[78a] is passed at about 500° C. over a heated surface which is coated with a salt of copper, iron or an alkaline earth metal.[79] It may also be

made directly from acetylene and chlorine[80]; various catalysts, cupric chloride,[81] activated carbon,[82] nickel deposited on active carbon[83] and silica gel[83a] have been suggested.

Dichloroethylene resembles trichloroethylene in chemical properties. It is said to be a good solvent for rubber,[84] and the lower boiling form has been proposed as a refrigerant for ice machines.[85] Clarke and Othmer[85a] suggested the application of dichloroethylene for the removal of water from acetic acid. Its use for the manufacture of chloroacetyl chloride has been proposed.[86] When hydrogen chloride is passed into a mixture of 1,1,2-trichloroethylene and aluminum chloride at 50° C., pentachlorobutadienes, hexachlorobenzene, 1,1,2,2- and 1,1,1,2-tetrachloroethane in proportions of 1 to 5, are obtained.[86a] Similarly, dichloroethylene yields 1,1,2-trichloroethane and a pentachlorobutane.

Asymmetrical-dichloroethylene is formed[87] when 1,1,1- or 1.1,2-trichloroethane is slowly heated to 70° to 80° C. with excess of lime; the yield of 1,1-dichloroethylene is approximately 90 per cent.

Mono- and dichloroacetylene are highly unstable, volatile liquids which as yet have no industrial applications. The manufacture of dihalogen substituted acetylenes may be carried out by passing acetylene into an ice-cooled alkaline solution of a hypochlorite or hypobromite.[88] In this way, dichloroacetylene and dibromoacetylene,

$ClC{\equiv}CCl$ and $BrC{\equiv}CBr$
b.p. + 32° C. b.p. 76°-77° C.
m.p. −64° to −68° C.

may be obtained very readily. Acetylene and bromine combined to the extent of 60 per cent when passed over pumice at 160° to 170° C.[88a] The product consisted of a mixture of halogenated compounds, from which a separation of dibromoethylene is complicated. The melting point determination indicated a yield of 29 per cent ethylene bromide although the viscosity indicated a yield of 45 per cent.

THE HYDRATION OF ACETYLENE TO ACETALDEHYDE

The direct hydration of acetylene to yield acetaldehyde according to the equation $C_2H_2 + H_2O \rightarrow CH_3CHO$, is perhaps the most important of the chemical reactions of that hydrocarbon. Acetaldehyde is a widely used chemical intermediate and is utilized in the production of n-butanol, acetic acid, ethyl acetate, and numerous other products. On reduction with hydrogen in the presence of a catalyst, acetaldehyde yields ethanol so that the synthesis of that alcohol from acetylene is readily accomplished.

The direct hydration of acetylene to acetaldehyde is an exothermic reaction which can be conducted in either the liquid or the gaseous phase. On an industrial scale the hydration is effected by passing a stream of acetylene through dilute sulphuric acid in the presence of a catalyst. The catalyst usually consists of a mercuric salt, such as mercuric sulphate, dissolved in the acid. It is beyond the scope of this work to discuss in detail the voluminous literature of the subject. One process,[89] however, for the conversion of acetylene into acetaldehyde is as follows: A vigorous current of acetylene, about 60 cubic feet per minute, is passed through a well-agitated liquid bath consisting of 1000 gallons of 6 per cent sulphuric acid, to which has been added 23 pounds of mercuric oxide. The reaction proceeds at ordinary pressure with heat evolution so that cooling may be necessary to control the temperature which is kept at 60°-65° C. The excess acetylene carries away the acetaldehyde produced, which is recovered by cooling the exit gases, and rectifying. Owing to a slow but continuous reduction of the mercuric salt to metallic mercury it is necessary to add fresh mercuric oxide from time to time. The metallic mercury is reoxidized electrolytically. The yield of acetaldehyde is as high as 98 per cent of the acetylene consumed. Other processes use more concentrated sulphuric acid (15 to 25 per cent) at 65° to 80° C. It is said that the reduction of the catalytic mercuric salts to mercury may be inhibited by the addition of oxidants, such as ferric salts or chromic acid.[90]

Attention has been directed toward the vapor-phase catalytic hydration of acetylene. At temperatures up to about 350° C. the thermodynamic tendency appears to be for the hydration process to proceed almost completely. One of the obvious difficulties of such vapor-phase processes is the extraordinary reactivity of acetaldehyde itself in the presence of numerous contact materials, rendering it very liable to be converted into crotonaldehyde or esters. Several procedures have been developed by Horsley[91] for the vapor-phase hydration of acetylene, such as by passing this hydrocarbon admixed with an excess of steam over (1) zinc oxide activated with molybdic acid or a molybdate at 325° C., (2) a compound of bismuth at 200° to 350° C., (3) cadmium metaphosphate at 300° to 400° C. at high space velocities, and (4) a compound of boron trioxide and phosphoric acid at 200° to 400° C. When using cadmium metaphosphate there is a tendency for crotonaldehyde to be produced, and the amount of this compound formed is dependent upon the proportions of cadmium oxide and phosphoric oxide in the catalyst. Catalysts used by other investigators are, anhydrous aluminum oxide activated with heavy metals of groups I or VIII of the periodic table,[92] anhydrous oxides, sulphides or carbides of tungsten,[93] zinc chloride,[94] and various phosphate catalysts.[94a]

Closely related to the hydration of acetylene to acetaldehyde are the various processes advanced for the direct synthesis of acetic acid, metal acetates and acetone[94b] from acetylene.[94c] The formation of acetic acid probably follows that of acetaldehyde by oxidation and acetone may be synthesized from acetic acid according to the reaction:

$$2CH_3COOH \longrightarrow (CH_3)_2CO + H_2O + CO_2$$

Alkali metal acetates are produced from acetylene in alkaline solution and the reaction is said to proceed as follows:

$$NaOH + C_2H_2 + H_2O = CH_3COONa + H_2$$

Acetic acid and acetaldehyde may be made by conducting acetylene, saturated with steam at 100° to 200° C. with added oxygen over a mercury catalyst, e.g., mercuric orthophosphate or mercuric vanadate, or a mixture of mercuric sulphate and silver or tin vanadate.[95] In another procedure, a mixture of acetylene, steam and oxygen is first passed through mercury heated to 300° C. and then over a hydration catalyst which may be mercuric phosphate mixed with heavy metal salts or oxides.[96] Nitrogen oxides have also been used in the synthesis of acetic acid from acetylene presumably to catalyze the oxidation of acetaldehyde to acetic acid.[97] Still another method calls for the passage of an acetylene-steam mixture through molten zinc chloride at 300° to 450° C.[98] Catalysts, such as barium sulphate and zinc oxide or a mixture of zinc oxide, chromium oxide, barium oxide and potassium hydroxide may be used.

Acetone may be synthesized by passing acetylene and steam at 350° to 500° C. over zinc oxide.[99] Other catalysts are manganese dioxide and manganese acetate,[100] ferric oxide[101] or heavy metal oxides.[102] An 89 per cent yield of acetone is formed when a mixture of acetylene, steam and ethyl alcohol vapor is passed at 470° C. over a catalyst consisting of oxidized iron sponge containing 3 per cent of manganese dioxide.[102a] Dreyfus[102b] forms aliphatic ketones from acetylene and steam by using a catalyst prepared by heating a mixture of one or more alkaline earth oxides and one or more oxides of heavy metals or silicon dioxide.

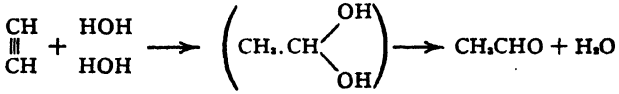
Strosacker and Stephenson[103] produce sodium acetate from acetylene by continuously supplying acetylene and steam at a temperature above 200° C. to a mixture of pulverized sodium hydroxide and sodium acetate. Mugdan and Wimmer[104] lead acetylene and steam above 200° C. through a melt of alkali hydroxide. The melting point of the hydroxide is reduced by addition of alkali acetate or water. Vinyl chloride can be reacted similarly with sodium hydroxide at 100° to 500° C. under pressure to form sodium acetate, according to Strosacker and Pelton.[104a]

Alkali metal acetylides are made by treating molten metals with acetylene.[104b] The fused metal may be diluted with an inert solid diluent such as sodium chloride.

CONDENSATION OF ACETYLENE WITH HYDROXY-COMPOUNDS

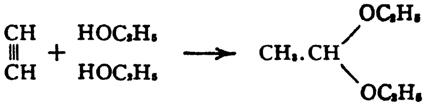
Acetylene may be condensed with alcohols, and hydroxy-compounds, in the presence of catalysts, to furnish di-ethers of the hypothetical ethylidene glycol (acetals). The reaction is strictly analogous to the addition of water to acetylene, which may be assumed to proceed through the intermediate formation of ethylidene glycol, the hydrated form of acetaldehyde. The analogy is illustrated by the following reactions:

(1) *With water:*



$$\begin{matrix}CH\\ |||\\ CH\end{matrix} + \begin{matrix}HOH\\ \\ HOH\end{matrix} \longrightarrow \left(CH_3.CH\begin{matrix}OH\\ \\ OH\end{matrix}\right) \longrightarrow CH_3CHO + H_2O$$

(2) *With ethanol:*



$$\begin{matrix}CH\\ |||\\ CH\end{matrix} + \begin{matrix}HOC_2H_5\\ \\ HOC_2H_5\end{matrix} \longrightarrow CH_3.CH\begin{matrix}OC_2H_5\\ \\ OC_2H_5\end{matrix}$$

diethyl acetal

Acetals may be conveniently prepared by passing acetylene into an alcohol, such as ethanol, in the presence of a mercuric salt.[105] The reaction is not limited to simple aliphatic monohydric alcohols and appears to possess commercial possibilities. For example, the acetal of the monoethyl ether of diethylene glycol can be made by leading acetylene into an ethanol solution of that ether in the presence of mercuric oxide and fluoboric acid.[106]

It may be noted that the combination of alcohols with acetylene probably proceeds with the intermediate formation of vinyl ethers of the general type $CH_2{=}CHOC_nH_{2n+1}$, which then combine with another molecule of alcohol. Vinyl ethers may be condensed with alcohols to yield acetals in the presence of a trace of sulphuric acid at temperatures not above 30° C.[107]

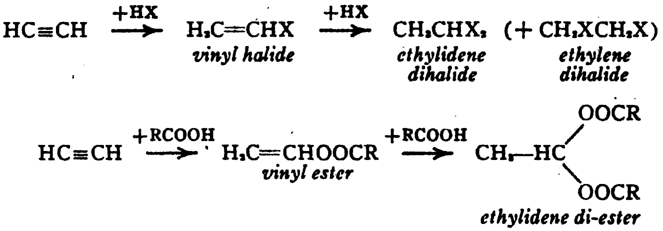
Condensation of Acetylene with Hydrogen Halides and Organic Acids

Both halogen acids and organic acids may be condensed with acetylene with the addition first of one and then of two molecules of acid to the hydrocarbon molecule. The first stage in the reaction gives rise to vinyl esters, and the second step, to ethylidene di-esters. In the case of the halogen acids it appears that though addition usually takes place in such a way that ethylidene derivatives are formed predominantly, under certain conditions, particularly in the case of hydrogen bromide, a certain amount of ethylene dihalides are also obtained.[108] On the other hand, addition of two molecules of an organic acid to the acetylene molecule seems to produce only ethylidene di-esters. These reactions are represented by the following scheme:



$$HC{\equiv}CH \xrightarrow{+HX} \underset{\textit{vinyl halide}}{H_2C{=}CHX} \xrightarrow{+HX} \underset{\textit{ethylidene dihalide}}{CH_3CHX_2} \quad (+\ \underset{\textit{ethylene dihalide}}{CH_2XCH_2X})$$

$$HC{\equiv}CH \xrightarrow{+RCOOH} \underset{\textit{vinyl ester}}{H_2C{=}CHOOCR} \xrightarrow{+RCOOH} \underset{\textit{ethylidene di-ester}}{CH_3{-}HC\begin{matrix} \diagup OOCR \\ \diagdown OOCR \end{matrix}}$$

It is interesting to note that the interaction of acetylene with fuming sulphuric acid mainly results in the production of acetaldehydedisulphonic acid[109] of the formula $(SO_3H)_2CHCHO$. Atterbury and Macalpine[110] produced ethyl alcohol by passing equal volumes of acetylene and hydrogen into hot concentrated sulphuric acid and then diluting the acid with water. Vinylsulphuric acid is said to be formed by forcing acetylene under pressure into concentrated sulphuric acid containing mercuric sulphate at temperatures below 0° C.[111]

Vinyl Esters. The vinyl esters are remarkable for their ease of polymerization to amorphous and resinous substances under the influence of heat, actinic light or oxidizing agents. Under proper conditions clear and colorless masses, either non-inflammable or difficultly so, may be obtained which can be molded and machined. The industrial application of these resinous polymers of vinyl esters has been hindered mainly by the absence of economical methods of manufacturing such esters. The esters which have been suggested for the production of resinous materials are the *chloride, acetate,* and *chloroacetates.*[112]

Vinyl halides may be obtained by the action of concentrated aqueous hydrogen halides on calcium carbide at 60° to 95° C. in the presence of a catalyst consisting, for example, of a mixture of mercury and copper salts. However, the catalytic vapor-phase combination of dry hydrogen halides with acetylene appears to be the most convenient mode for the production of these halides. It has been reported that vinyl chloride may be obtained in quantitative yield by passing a mixture of hydrogen chloride and acetylene at 180° C. over a contact mass of pumice impregnated with mercuric chloride.[113] Vinyl halides can also be made by vapor-phase combination at elevated temperatures in the presence of compounds of elements of groups II and V of the periodic system or of mixtures of such compounds.[114] In another process the catalyst for vapor-phase combination of hydrogen halides and acetylene at 100° to 300° C. is carbon which has been previously activated by preheating in the presence of the hydrogen halide at a higher temperature (200° to 600° C.) than that used for reaction.[115] The production of vinyl chloride from acetylene and hydrochloric acid is said by Nieuwland[116] and also by Perkins[117] to proceed in the presence of a mixture of cuprous chloride and ammonium chloride. Acetylene and hydrogen chloride also formed vinyl chloride when passed through a tube heated to 300° C. carrying a water-cooled tube at 80° C.[117a]

[112] For an account of vinyl resins, see Ellis, "Synthetic Resins and Their Plastics," Chemical Catalog Co., Inc., New York, 1923.

It has also been proposed to make vinyl chloride and bromide by warming ethylene dichloride[118] or dibromide[119] respectively with alkali in methanol solution. Baxter, Edwards and Winter[119a] made vinyl chloride, together with acetylene, by heating ethylene dichloride in the presence of steam as a diluent between a temperature of 800° and 1000° C. The production of acetylene is favored by the presence of diluents, reduced pressure, or increased heating periods.

On chlorination, vinyl chloride yields 1,1,2-trichloroethane,[120] which may also be obtained directly from acetylene by interaction with a mixture of chlorine and hydrogen chloride in the presence of contact materials.[121]

Vinyl chloride may be reacted with hydrogen chloride in the presence of aluminum chloride to form ethylidene chloride (1,1-dichloroethane).[121a] When a vinyl halide, oxide or sulphide is passed over heavy metals such as iron, copper, lead, tin, bismuth, antimony, cadmium or zinc at a temperature below 400° C., 1,3-butadiene is said to result.[121b]

Staudinger, Brunner and Feisst[122] investigated the reactions of polymers of polyvinyl bromide. On reducing fractions soluble and insoluble in benzene with hydriodic acid and red phosphorus at 160° C. and then distilling with soda-lime, two impure hydrocarbons were obtained which corresponded to the formulas $C_{40}H_{82}$ and $C_{55}H_{112}$, melting at 70°-75° C. and 88°-94° C., respectively.

VINYL ACETATE

The combination of acetylene with organic acids, such as acetic acid, proceeds in the presence of catalysts consisting usually of mercury salts, to yield first vinyl ester, and, if the reaction is prolonged, finally ethylidene diesters. Of the vinyl esters, the acetate is of technical importance, on account of its ease of production, the comparative cheapness of the raw materials employed in its synthesis and its ease of polymerization to light-colored resinous substances. Its production on a technical scale is described by Skirrow and Morrison[123] who maintain that the addition of acetylene to organic acids is extremely sensitive to the state and nature of the catalyst and to the temperature employed. The catalyst suggested for this process consists of a precipitate produced by the addition of sulphur trioxide (or fuming sulphuric acid) to an acetic acid solution of mercuric oxide. If acetylene is introduced into acetic acid containing this catalyst, combination occurs smoothly at 20° to 60° C. with the production of vinyl acetate, though, at higher temperatures, ethylidene diacetate becomes the major product. It is suggested that acetylene be passed at a rapid rate through the reaction mixture so that the escaping excess acetylene entrains most of the vinyl acetate (together with some acetic acid and a trace of diacetate) which is condensed. For example, 20 parts of mercuric oxide are dissolved in 2000 parts of glacial acetic acid and to this solution is added, at 85° C., 276 parts of a precipitate formed by reacting 34 parts of sulphur trioxide with 242 parts of glacial acetic acid at 20° C. The mixture is brought to about 25° C. and a great excess of acetylene gas is passed through, the temperature being allowed to rise to 35° C. with an average temperature of about 34° C. The gas and entrained vapors are cooled and the condensate obtained is fractionated to yield vinyl acetate. At the end of 10 to 12 hours, the rate of acetylene absorption diminishes owing to reduction of the catalyst, and at this time the yield of vinyl acetate is about 70 per cent based on the acetic acid combined and 78 per cent based on the acetylene consumed. The amount is said to be 115 parts of vinyl acetate per part of mercuric oxide used.

A modification of the above process in which acetylene is led into acetic acid at 5°-25° C. in the presence of a mercury compound, sulphacetic acid, and acetic anhydride, to yield vinyl acetate has been suggested.[124] Dykstra and Sly[125] produced vinyl esters by passage of acetylene into a hot mixture of an organic acid and an aliphatic hydrocarbon distillate. According to Herrmann, Deutsch and Baum[126] vinyl esters may be produced by vapor-phase combination of acetylene and an organic acid in the presence of a heated catalyst, such as zinc acetate or activated carbon, the reacting gases having a vapor velocity of 350 liters per hour per liter of reaction space. Acetylene and acetic acid also combine to form vinyl acetate and ethylidene diacetate when passed through a tube heated to 200° C. containing a water-cooled tube at 20° C.[126a]

Vinyl esters may be smoothly halogenated at 0° C. to yield 1,2-dihalogen esters. Chlorination of vinyl acetate results in the production of 1,2-dichloroethyl acetate.[127] Acid anhydrides result on reacting vinyl esters with carboxylic acids. For example, vinyl acetate and acetic acid[127a] react in the presence of catalysts such as sulphuric, phosphoric, benzenesulphonic, sulphoacetic acid and sulphur chloride to form acetic anhydride and ethylidene diacetate.

VINYL ETHERS

Divinyl ether, $CH_2{=}CHOCH{=}CH_2$, a very interesting unsaturated ether partly polymerizable by benzoyl peroxide, is a liquid of boiling point 28.3° ± 0.2° C. at 760 mm. It has been prepared in a pure state by Ruigh and Major[128] by heating $\beta\beta'$-dichlorodiethyl ether with potash at 200° to 240° C. Aromatic vinyl ethers may be prepared either from vinyl halides[129] or ethylene dihalides by interaction with phenols in alkaline media. Thus an 80 per cent yield of vinyl phenyl ether, boiling point 155°-156° C., is obtained by heating ethylene dichloride with caustic soda, phenol, and alcohol in an autoclave at 180° to 200° C.[130] Vinyl and other unsaturated ethers may also be produced by passing the vapor of an aliphatic or aromatic acetal over a catalyst.[130a] The catalyst may consist of silver, gold, platinum or palladium mixed with metals of groups I to IV and VI to VIII of the periodic system or their oxides, phosphates or silicates. Alkyl vinyl ethers have also been prepared by Chalmers[130b] by heating alkyl 2-bromoethyl ethers with sodium hydroxide.

ETHYLIDENE ESTERS

As previously stated, the ethylidene diesters of the general formula CH_3CHX_2, where X represents an acidic group, are the ultimate products of the reaction between acetylene and organic acids. Of these diesters, ethylidene diacetate, $CH_3CH(OOCCH_3)_2$, a liquid of boiling point 170° C., is by far the most important. Technical interest in this ester is almost entirely centered around its ready decomposition under the influence of heat, which results in the formation of acetic anhydride, together with acetaldehyde, a reaction which has been known for many years. According to one method, acetic anhydride is conveniently made from this ester by rapidly heating it to 300° to 450° C.[131]

The methods of producing ethylidene diacetate usually involve the introduction of acetylene into warm acetic acid containing a mercury catalyst.[132] The same catalysts are used as for making vinyl esters. The essential difference in the processes for making the two types of compounds is that ethylidene diesters require a higher temperature. A process of Skirrow and Morrison[133] involves the passage of acetylene into acetic acid, maintained at about 80° C., and containing a catalyst of a mercuric salt of sulphacetic acid. For example, 10 parts of mercuric oxide are dissolved in 2000 parts of glacial acetic acid and to this is added, at 85° C., 276 parts of a precipitate formed by reacting 30 parts of sulphur trioxide with 246 parts of glacial acetic acid at about 20° C. After precipitation of the catalyst, the mixture is brought to a temperature of 60° to 70° C. and an excess of acetylene is passed through, the temperature being allowed to rise to 80° C. The main product is ethylidene diacetate, which, together with a little vinyl acetate and some free acid, is carried over by the escaping excess of acetylene. After 1 to 3 hours, depending upon the scale of operations and the cooling capacity, the rate of acetylene absorption diminishes owing to the large percentage conversion of the acid and to the reduction of the catalyst.

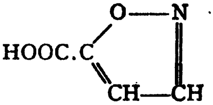
A method of purification of crude ethylidene diacetate by agitation with an aqueous salt solution of density greater than that of the ester, followed by stratification and separation, has been developed.[134]

MISCELLANEOUS REACTIONS OF ACETYLENE

When passed slowly into fuming *nitric acid,* acetylene combines to form a solid acid of the formula, $C_4H_3O_3N$, melting at 149° C., which was described by Baschieri[134a] and Testoni and Mascarelli.[134b] It was later subjected to a careful examination by Quilico and Freri,[135] who concluded, from its properties and chemical reactions, that the substance was an isoxazole-*a*-carboxylic acid of the formula,



With *hypochlorous acid,* acetylene combines to yield dichloroacetaldehyde,[136] or $CHCl_2CHO$.

Acetylene may be condensed with *ammonia* or *amines* at elevated temperatures in the presence of catalysts to yield a number of compounds, among which nitriles and pyridine bases may be specially mentioned. The preparation of acetonitrile by condensing acetylene with ammonia has been the subject of a number of investigations.[137] Acetylene can be converted into pyridine bases without the formation of acetonitrile by passing a mixture of ammonia and acetylene, over a heated catalyst of zinc sulphate, zinc chloride, cadmium chloride or other inorganic salt capable of combining with ammonia.[138] Acetonitrile and other nitriles[139] may be produced without simultaneous formation of pyridine bases, by condensing acetylene with ammonia or amines at high temperatures in the presence of compounds of metals of groups II to VII of the periodic system, not reducible under the working conditions, and employing a gas velocity not exceeding 50 liters of acetylene per hour per liter of catalyst. Good catalysts are mixtures of metallic oxides not reducible at 450° C. or single non-reducible compounds of zinc, aluminum, zirconium, thorium, tin, vanadium, bismuth, molybdenum and tungsten, supported on silica or alumina gel. The nitriles yield acetic acid on saponification, ammonium salts being obtained as by-products.[139a] When saponified with alcohols at 50° to 250° C. in the vapor phase, esters are formed.[139b] Rötger[140] prepared products containing 80 per cent pyridine bases consisting predominantly of picolines, which can be used for the protection of plants, by passing ammonia and acetylene over silica gel and finely divided cadmium at 320° C. Another process[141] consists in condensing acetylene with ammonia or amines together with steam in the presence of condensing catalysts at 250° to 500° C. and followed by mixing the reaction products with hydrogen and passing them over a hydrogenating catalyst at 180° to 250° C. Thus, a mixture of acetylene, ammonia, and hydrogen is passed at 350° C. over a catalyst of zinc oxide and thorium oxide on silica gel and then at 150° C. over finely divided nickel on silica gel to yield piperidine and monoethylamine. The treatment of aniline, acetylene, and hydrogen to furnish tetrahydroquinoline, and also of acetylene, hydrogen, methane and ammonia to obtain ethylamine and acetonitrile, has been suggested by Nicodemus.[142]

Vinyl cyanide is formed when acetylene and hydrogen cyanide are led over a catalyst consisting of, for example, a mixture of barium cyanide and active carbon, according to Baum and Herrmann.[142a]

Thiophene and similar sulphur-containing compounds are made by the reaction of acetylene with sulphur, metallic sulphides or hydrogen sulphide. They may be produced, for example, by conducting acetylene over pyrites heated to 280°-310° C.[143] The catalytic combination of acetylene and hydrogen sulphide in the vapor phase to yield thiophene has been described. A mixture of acetylene and hydrogen sulphide and a heated catalyst of nickel hydroxide mixed with a silicate cement or partially reduced bauxite is used.[144]

both nitrogen and sulphur has been accomplished.[145] Such materials so obtained may be employed as denaturants for alcohols and as flotation agents. The liquid condensation products are made by passing a mixture of acetylene and ammonia over iron pyrites at 350° to 450° C. and consist of mixtures of nitriles, pyridine and other nitrogen bases and organic sulphur compounds such as ethyl mercaptan, thiophene as well as mustard oils containing the characteristic grouping –NCS. For example, a mixture of equal parts of acetylene, ammonia, and steam is passed over granular pyrites at 350° C. The condensate consists of two layers: an aqueous layer containing acetonitrile, water-soluble pyridine bases, sulphur compounds, and ammonia; and an oily layer, made up of about 20 per cent of thiophene, up to 30 per cent of pyridine bases, besides nitriles, mercaptans, and high-boiling sulphur compounds of unknown nature. A fraction, boiling below 200° C., of the oily layer may be used as a denaturant for ethyl alcohol, the amount required being about 5 cc. per liter of alcohol.

Bergmann and Bondi[146] studied the action of phosphorus pentachloride on acetylene derivatives. Phenylacetylene, on treatment with phosphorus pentachloride and subsequent hydrolysis, is converted to β-chloro-β-phenylvinylphosphinic acid, which may be changed by potassium hydroxide into phenylacetylenylphosphinic acid.

On treatment with potassium mercuri-iodide or with mercuric acetate, vinylacetylene yields divinylethynyl-mercury, a crystalline solid melting at 144° to 145° C. Reactions of the compounds formed on treating vinylacetylenes with mercury salts have been studied by Carothers, Jacobson and Berchet.[147]

Chapter 29

Halogenation of Methane. Properties and Uses of Halogen Derivatives

The behavior of saturated hydrocarbons, i.e., paraffins and cycloparaffins, toward halogens is fundamentally different from that of unsaturated hydrocarbons. Whereas halogens combine additively with unsaturated hydrocarbons to form more saturated derivatives, they substitute or replace hydrogen of saturated hydrocarbons. The hydrogen atoms thus displaced are eliminated as hydrogen halide. The progressive substitution of hydrogen atoms of completely saturated hydrocarbons by chlorine may be expressed by the following general series of reactions:

$$C_nH_{2n+2} + Cl_2 \longrightarrow C_nH_{2n+1}Cl + HCl,$$
$$C_nH_{2n+1}Cl + Cl_2 \longrightarrow C_nH_{2n}Cl_2 + HCl; \text{ etc.}$$

The order of decreasing reactivity of halogens with paraffin hydrocarbons is fluorine, chlorine, bromine and iodine, i.e., the higher the molecular weight the smaller the tendency to substitute a hydrogen atom of the hydrocarbon. Fluorine often reacts with explosive violence but iodine does not appear to react at all. On account of the comparative cheapness of chlorine, the chlorination of hydrocarbons has been much more extensively studied than the action of the other halogen elements. Many of the chlorohydrocarbons formed from the paraffins are of industrial value as solvents, while the monochlorinated products, the alkyl chlorides, have received much attention because of their use in the manufacture of alcohols.

The Chlorination of Methane

Both the abundance of methane and the comparative cheapness of chlorine favor the commercial application of the chlorination of methane for the production of one or other of the chloro-derivatives. The extensive amount of work on this subject indicates the great interest in this problem. The products of the chlorination usually consist of all of the four possible chlorination products and in general it is not possible to control the reaction so as to produce one substance only.

Because of the very highly exothermic nature of the chlorination reactions, the successful control of the process is often a matter of difficulty even on a laboratory scale. Furthermore, there is always a danger of chlorination proceeding extremely violently and even with explosive force. When this occurs high reaction temperatures are attained and the main products are carbon and hydrogen chloride, formed according to the reaction:

$$CH_4 + 2Cl_2 \longrightarrow C + 4HCl.$$

High temperature chlorination of methane and other hydrocarbons can, in fact, be utilized for the production of lampblack or carbon black together with hydrogen chloride.[1]

The actual heats of reaction of the various chlorination processes cannot be calculated with certainty, owing to the unreliability of the thermal data, but the approximate figures for the gaseous reactions at 400° C. are as follows:[2]

$$\begin{aligned}
CH_4 + Cl_2 &\longrightarrow CH_3Cl + HCl + 33\text{ Cal.}\\
CH_4 + 2Cl_2 &\longrightarrow CH_2Cl_2 + 2HCl + 60\text{ Cal.}\\
CH_4 + 3Cl_2 &\longrightarrow CHCl_3 + 3HCl + 94\text{ Cal.}\\
CH_4 + 4Cl_2 &\longrightarrow CCl_4 + 4HCl + 137\text{ Cal.}
\end{aligned}$$

Although there is no rigorous parallelism between the heats of reaction and reaction velocity, nevertheless as there is a slight increase in the heat of reaction with progressive chlorination, it may be expected that the chlorination reaction will tend to go to completion, i.e., to produce carbon tetrachloride, unless some temperature control is maintained. In fact Jones, Allison and Meighan[2] in their work on the chlorination of natural gas stated:

> "If the temperature of the reaction chamber rises above 500° C., the reaction proceeds according to the formulas: $CH_4 + 2Cl_2 = C + 4HCl$, and $C_2H_6 + 3Cl_2 = 2C + 6HCl$. This reaction is explosive in character and gives no hydrocarbon chlorides. The heat control of the reaction is the important phase of the problem that must be solved before the work can be placed upon a plant basis."

Furthermore, active catalysts will evidently favor the formation of polychlorinated derivatives. Also thermodynamic calculations indicate the chlorination reaction possesses a great tendency to proceed even at comparatively low temperatures. These deductions are in accord with the observed facts.

The methods which have been used for effecting the chlorination of methane have been of diverse character. In general, chlorination has been brought about by exposing a mixture of methane and chlorine to the action of actinic light, heat, catalysts, and other activating influences such as the silent electric discharge. The greatest difficulties arise in controlling the process to avoid both explosion and the formation of all but the desired chlorinated product. Proper control of concentrations, temperature, and activating influence minimizes, though it does not entirely overcome, the latter difficulty while danger of explosion may be obviated to some extent by dilution of the hydrocarbon with inert gases, such as carbon dioxide, nitrogen, steam, hydrogen chloride, or chlorinated substances and also by accurate regulation of the quantities of chlorine admitted to reaction. Chlorination in inert liquid diluents has been utilized.[3]

Chlorination of methane may also be effected by means of certain reagents which give rise to chlorine in the reaction mixture, such as, for example, sulphuryl chloride, phosgene or antimony pentachloride, while hydrogen chloride has been proposed as a source of nascent chlorine.

It is convenient to subdivide the work on the chlorination of methane into the following main headings, namely, (1) thermal, (2) catalytic, (3) photochemical, and (4) other modes of chlorination.

[2] Jones, Allison and Meighan, *U. S. Bureau Mines, Tech. Paper* 225, 1921.

[3] Reviews of the chemistry of the chlorination of methane have been published by Wegscheider (*Z. Elektrochem.*, 1922, **28**, 99) and by Egloff, Schaad and Lowry (*Chem. Reviews*, 1931, **8**, 1).

THERMAL CHLORINATION

Like all other chemical processes, chlorination of methane is greatly accelerated by heat alone and may become exceedingly violent if suitable precautions are not taken to moderate the reaction. According to Jones, Allison and Meighan,[4] the reaction in the dark between chlorine and natural gas begins at a temperature slightly below 250° C. and at this lower temperature the chlorine reacts with the ethane present in such gas in preference to the methane. At 250° C. the chlorination was only partial, but at 300° C., and higher, the maximum amount of chlorine was used and the reaction took place smoothly without carbon deposition. In the presence of light, however, and particularly of light from the electric arc, chlorination takes place very readily at much lower temperatures and, within certain concentrations of reactants, may become explosive.

Pease and Walz[5] measured the rate of thermal chlorination of methane in the neighborhood of 250° C. using a cylindrical catalyst tube of Pyrex glass. At this temperature it was found quite safe to work with mixtures containing an excess of chlorine and which are subject to explosion at higher temperatures. Under the conditions employed by Pease and Walz the only reactions occurring were straightforward chlorinations to methyl chloride, methylene dichloride, chloroform, and carbon tetrachloride. With excess of methane ($3CH_4 : 1Cl_2$) and small conversion of chlorine (e.g., 25 per cent), methyl chloride is the main product of the thermal chlorination. The observation was made that the reaction under these conditions is powerfully inhibited by traces of oxygen, which suggests that a chain mechanism is involved.

The chlorination of methane, and also of other paraffin hydrocarbons, is undoubtedly a stepwise reaction in which the mono-chloro-compound first produced is progressively chlorinated to higher chlorinated products. The thermodynamic tendency appears to be toward complete chlorination over a wide temperature range. The stepwise nature of the chlorination process of methane is amply proved by the work of a large number of observers, particularly of Bedford.[6] Furthermore, methyl chloride may be readily chlorinated either to methylene dichloride, chloroform, or carbon tetrachloride or to a mixture of these substances by thermal chlorination in the presence or absence of catalysts.[7] In connection with the mechanism of the methane chlorination, Martin and Fuchs[8] have calculated the following equation:

$$y_m = \frac{\lfloor\underline{n}}{\lfloor\underline{m}\;\lfloor\underline{n-m}}\,(100-x)\left[\left(\frac{100}{100-x}\right)^{\frac{1}{n}}-1\right]^m$$

The theoretical and practical results are, however, only in agreement in certain cases. This general formula gives the percentage of initial substance (e.g., methane), represented by y_m, converted into the m^{th} product of a reaction of n bimolecular stages, in terms of the total percentage of initial substance consumed (x). For example, in the chlorination of methane, the percentage of methane converted to dichloromethane is obtained by substituting 4 for n, 2 for m, and the total percentage of methane consumed in the entire chlorination for x in the equation.[8a]

[8] *Z. Elektrochem.*, 1921, **27**, 150.

The purely thermal chlorination of methane at very high temperatures has been examined experimentally by Mason and Wheeler.[9] The use of very high space velocities (as high as 30,000 reciprocal minutes at 1400° C.) in conjunction with high temperatures results in a cutting short of the chlorination process and consequently in a relatively large production of methyl chloride in preference to higher chlorinated products. Thus for example by passing a mixture of 1 volume of chlorine and 7 volumes of methane through an alumina-silica refractory reaction tube heated to 1200° C. and at a space velocity of 23,800 reciprocal minutes, the yields of products calculated on the chlorine input were: methyl chloride 39.2 per cent, methylene dichloride 13.4 per cent, chloroform 20 per cent, and carbon tetrachloride 2.0 per cent. In later experiments somewhat lower temperatures (800° to 900° C.) and lower space velocities were used and it was found advantageous to pack the reaction tube with refractory material. Passage of a mixture of 9.2 volumes of methane and 1.0 volume of chlorine at a space velocity of 9000 reciprocal minutes through the packed refractory tube at 900° C. resulted in the formation of the following yields of products (calculated on the chlorine input): methyl chloride 36.3 per cent, methylene dichloride 6.46 per cent, and chloroform 2.35 per cent, with practically no carbon tetrachloride. It is evident, therefore, that this method of chlorination, consisting essentially in the use of high temperatures in conjunction with high space velocities (i.e., short heating periods) is very efficient for the production of methyl chloride with the coincident production of only small amounts of higher chlorinated products. It is very interesting to note that the results of Mason and Wheeler for the high temperature chlorination of both methane and methyl chloride were in quite good agreement with the theoretical predictions of Martin and Fuchs. Some of the experimental results of Mason and Wheeler are given in Table 117:

TABLE 117.—*High Temperature Chlorination of Methane* (*Mason and Wheeler*).

Experiment	1	2	3	4	5	6
Temperature ° C.	900	900	900	900	900	900

CHLORINATION WITH CATALYSTS

In general, catalysts tend to accelerate the chlorination of methane and appear to favor the formation of higher chlorinated products than methyl chloride.

[8a] In the above equation $\underline{|n}$ represents factorial n, i.e., when $n = 4$, $\underline{|4}$ is $4 \times 3 \times 2 \times 1$. It is to be understood that $\underline{|0}$ is taken to be unity. The number of bimolecular stages (n) is the number of replaceable hydrogens in the molecule.

[9] *J.C.S.*, 1931, 2282.

A variety of catalysts has been used and these include metallic chlorides (such as ferric chloride, silver chloride, partially reduced cupric chloride, aluminum chloride, manganous chloride, antimony pentachloride, molybdenum pentachloride, coke impregnated with the chlorides of platinum, zinc, cadmium, tin, and lead) as well as various adsorbent materials, such as activated charcoal, and animal charcoal admixed with finely divided calcium oxide. These catalysts have been used in conjunction with temperatures up to 300° C. and above, and since chlorination can proceed at these temperatures without the aid of catalysts, the results obtained cannot always be solely attributed to the effect of these catalysts.

The effect of various solid materials in promoting the combination of chlorine and methane was investigated by Phillips,[10] who passed a mixture of chlorine and natural gas through heated tubes packed with sand, asbestos, and bone black. He found that the tendency was to form methyl chloride and carbon tetrachloride with very little of the intermediate products. When the temperature became too high, carbon was deposited.

The chlorination of natural gas in the presence of pumice, alone and impregnated with cupric and managanous chlorides, was examined by Tolloczko and Kling.[11] In order to eliminate the possibility of an explosion, which was very prone to occur in sunlight and also at higher temperatures, chlorination was carried out with an excess of one of the reactants and at as low a temperature as possible. Using pumice as a catalyst at 400° C. and an excess of chlorine, the products of the chlorination consisted mainly of carbon tetrachloride together with various chloro-hydrocarbons derived from ethane. Poor yields were obtained when an excess of the hydrocarbon gas was employed. A catalyst of pumice impregnated with cupric chloride was more efficacious than a pumice catalyst soaked with manganous chloride, and could be used at a lower temperature. Passage of a mixture of chlorine and natural gas over the former catalyst at 300° C. led to the production of methyl chloride, methylene dichloride and a little ethyl chloride as well as of chloroform, carbon tetrachloride, tetrachloroethylene, acetylene tetrachloride, and, in the fraction boiling above 165° C., dichloroethane.

An experimental investigation of the chlorination of nearly pure methane (containing only small amounts of oxygen and nitrogen and no olefins) in the presence of antimony pentachloride and ferric chloride at 360° to 400° C. has been reported by Pfeifer, Mauthner and Reitlinger.[12] The dried hydrocarbon was mixed with chlorine and passed through a heated quartz reaction tube containing the catalyst, while the gaseous products of the reaction were passed through two spiral condensers, the first of which was water-cooled and the second maintained at —35° to —45° C. by means of alcohol and solid carbon dioxide. The distillate in the first receiver contained dichloromethane, chloroform, and carbon tetrachloride, while that in the second receiver was mostly methyl chloride. The best results were obtained by using ferric chloride as a catalyst. With this catalyst and using a methane-chlorine volume ratio of 2:1, 85 per cent of the chlorine was converted and the product consisted of 30 per cent of methyl chloride (calculated on chlorine) as well as about equal amounts of dichloromethane and chloroform. Increasing the methane-chlorine ratio to 3:1 resulted in an increase in the methyl chloride yield to 40 per cent of the theoretical, based on the chlorine consumption. Attempts made to increase the yield of carbon tetrachloride by increasing the chlorine content of the reacting gases resulted in violent explosions. However, by employing an inert diluent, namely nitrogen, in conjunction with higher chlorine-methane ratios, risks of explosion were minimized and the products then consisted only of chloroform and carbon tetrachloride. Thus passage of a mixture of 1 volume of methane, 2 volumes of nitrogen and 3 volumes of chlorine over the catalyst resulted in the formation of the two higher chlorinated products only. Table 118 shows some of the experimental results of these workers.

Important work on the chlorination of a Pittsburgh natural gas (containing 89.5 per cent CH_4, 10.1 per cent C_2H_6, and 0.4 per cent N_2) in the presence of various catalysts was carried out by Jones, Allison and Meighan.[13] The best catalysts tried were adsorbent charcoal (made from coconut shells), an active carbon called "Batchite", made from anthracite, and metallurgical coke, both alone and impregnated with the nitrates or chlorides of nickel, zinc, cadmium, barium, platinum, copper, etc., or with mixtures of these nitrates and chlorides. Such substances as silica gel, porcelain, asbestos, glass wool and pumice were also tried but proved to be very poor catalyzers. The chlorination process proceeded satisfactorily in the presence of the better catalysts at temperatures above 300° C., the optimum temperature being about 400° C. Temperatures above 500° C. were undesirable owing to the violence of the reaction and the deterioration of the catalysts under such conditions. The products of the chlorination consisted not only of all the four chloromethanes but also of the higher chlorinated ethanes, notably hexachloroethane. The salient features of this important investigation may be summarized as follows:

(1) Natural gas may be completely chlorinated to carbon tetrachloride in one operation with yields of over 90 per cent of the chlorinated products on using chlorine-methane ratios of 5:1 to 2.5:1.

(2) For the production of chloroform, coke impregnated with metals such as platinum, nickel, and iron are most suitable. Using platinized coke, 50 per cent of gas was converted into chloroform.

(3) Activated charcoals and "Batchite" furnished the highest yields of carbon tetrachloride.

(4) The highest yield (31 per cent) of methyl chloride was obtained by using a ratio of 2 volumes of chlorine to 1 volume of natural gas in the presence of coke impregnated with nickel, tin, and lead.

(5) Addition of small amounts (up to 1 per cent) of moisture to the reacting gases was stated to aid chlorination.

(6) Ethane tends to chlorinate much more readily than methane.

The catalysts which showed a high adsorption capacity for chlorine were unsuitable for the production of methyl chloride and favored the production of higher chlorinated products, especially carbon tetrachloride.[14] In view of the obviously cumulative nature of the process and the thermodynamic tendency for complete chlorination to occur, it is to be expected that active catalysts will not favor the formation of methyl chloride but rather of carbon tetrachloride.

---

[13] Jones and Allison, *J. Ind. Eng. Chem.*, 1919, 11, 639; Jones, Allison and Meighan, *U. S. Bur. Mines Tech. Paper* 225, 1921.

[14] It is also possible that such catalysts possess a powerful tendency to absorb the chlorides of methane rather than methane itself and hence hold them in the reaction zone until chlorination was complete.

Schleede and Luckow[15] made a study of the chlorination of methane at temperatures of the order of 400° C. in quartz and glass reaction tubes with and without the addition of catalysts. When the reacting gases were used in molar proportions, inflammation occurred but the flame was not permanent except when an excess of chlorine was used. Ignition was not observed when methane was present in excess but in this case the chlorine was only quantitatively utilized if the temperature was above a certain minimum depending upon the precise composition of the reacting gas mixture and upon the rate of flow. These phenomena were not greatly affected by the presence of catalysts or by an increase in temperature of 100° C. above the minimum. The rate of flow of the reacting gases over the surface of the catalyst was found to exert a marked influence on the nature of the products. If comparatively low rates of flow were employed, no ignition occurred but an increased production of chloroform and carbon tetrachloride took place at the expense of methyl chloride and dichloromethane. However, when the velocity of the reacting gases per unit of surface exceeded a certain value, the reaction was found to tend more and more to a steady ignition and increased formation of higher products (chlorinated products of higher paraffins) took place principally at the expense of the chloroform. Even at rates of flow below the ignition value, when higher products are not formed in any quantity, the relative proportions of the four chlorinated methanes produced were not in accordance with the formula of Martin and Fuchs[16] for a bimolecular step-wise reaction.

The production of chlorinated derivatives of higher paraffin hydrocarbons as observed by Schleede and Luckow in the flaming gases (at high gas rates) is probably the result of thermal dissociation of methane and of chlorinated methanes with subsequent changes of the following types:

$$CH_4 + CH_3Cl \longrightarrow C_2H_6 + HCl,$$
$$CH_2Cl_2 + CH_4 \longrightarrow CH_3CH_2Cl + HCl, \text{ etc.}$$

Also the change in the type of reaction on increasing the gas velocity *may* be due to local development of high temperatures as a result of highly exothermic chlorination. Another possible explanation for the formation of such compounds is indicated by the work of Besson.[17] The latter observed that when chloroform vapors, containing about 1 per cent of iodine, were heated to high temperatures a portion of the chloroform is decomposed yielding compounds such as carbon dichloride (C_2Cl_4), carbon tetrachloride, carbon hexachloride (C_2Cl_6), carbon sesquichloride (C_4Cl_6), hexachlorobenzene, and pentachloroethane. Presumably some such decomposition of chloroform, made during the chlorination of methane, may take place in the presence of chlorine.

All of the four possible chlorinated methanes were obtained by Gault and Benlian[18] on the chlorination of natural gas of Vaux (France), using equal volumes of reactants, in the presence of ferric chloride catalysts in the dark at 245° to 415° C.

The work of Boswell and McLaughlin[19] was directed especially toward the production of maximum yields of methyl chloride from methane by chlorination in the presence of catalysts at about 450° C. Experiments on a small analytical scale were later translated to a larger-scale apparatus in which it was possible to produce 25 grams of methyl chloride per run. The catalyst used throughout these experiments was prepared by impregnating 18 grams of pumice (passing a 12-mesh sieve) with a solution of 10 grams of cupric chloride, $CuCl_2.2H_2O$, in 15 cc. of water, followed by drying at 110° C. and heating in a current of moist nitrogen at 450° C. for 9 hours. This latter treatment effects a reduction to the cuprous condition to the extent of about 75 per cent. A number of factors were examined with regard to their influence on the yield of methyl chloride and the following conclusions were drawn:

---

[15] *Ber.*, 1922, 55B, 3710; *Chem. Abs.*, 1923, 17, 2864.
[16] *Z. Elektrochem.*, 1921, 27, 160.
[17] *Compt. rend.*, 1893, 116, 102; *Chem. Soc. Abs.*, 1893, 64 (1), 242.
[18] *Chimie et Industrie*, Special No. (May), 1924, 272; *Chem. Abs.*, 1924, 18, 3109.
[19] *Canad. J. Research*, 1929, 1, 240; *Chem. Abs.*, 1930, 24, 53.

(1) It was found desirable to utilize moist gases in order to maintain the catalyst in a partially reduced and constant condition.

(2) The most favorable reaction temperature was 450° C.

(3) Other factors being equal, the yields of methyl chloride improved as the proportion of the chlorine was reduced.

(4) The effect of diluting the reacting gases with a large volume of nitrogen was found to be advantageous both from the viewpoint of the methyl chloride yield and also in the suppression of explosions.

(5) The best yields of methyl chloride in the presence of the partially reduced cupric chloride-pumice catalysts were obtained under the following conditions: nitrogen to methane ratio of 10:1, and methane to chlorine ratio of 7 or 8:1, using moist gases; reaction temperature of 450° C. In the presence of 8 per cent hydrogen in the methane, the methane to chlorine ratio could be reduced to 3:1. Under these conditions it was found possible to chlorinate methane to methyl chloride with a yield, based on the chlorine used, of 75 to 80 per cent or higher. A small amount of methylene dichloride was also formed.

An attempt was also made by Boswell and McLaughlin to control the chlorination so as to obtain principally carbon tetrachloride. A mixture of pure methane and chlorine in the volume ratio of 1:4 was passed at a rate of 2.5 liters per hour (per 173 grams of cupric chloride on 300 grams of pumice) at 450° C. and gave a 90 per cent yield of carbon tetrachloride. There was no indication of the formation of chloroform or other lower-boiling products but a slight residue boiling above 100° C. was obtained. On doubling the velocity of the reacting gases a series of explosions occurred and these could be suppressed only by diluting the gases with a large quantity of nitrogen. Thus on passing a mixture of 6.28 liters of methane, 26.0 liters of chlorine, and 47.0 liters of nitrogen during 6.5 hours over the catalyst, smooth reaction ensued and the products consisted of 34.5 grams carbon tetrachloride, 3.0 grams of chloroform, and 1.0 gram of higher-boiling liquid. The yield of carbon tetrachloride was thus 80.2 per cent of the theoretical, based on the chlorine.

The employment of catalysts in conjunction with photochemical excitation has been discussed by a number of workers and Tanaka[20] observed that silver chloride was an effective catalyst for the chlorination of methane in the presence of ultraviolet light. The catalytic chlorination and bromination of gases rich in methane hydrocarbons has also been investigated by Zapan.[21]

PHOTOCHEMICAL CHLORINATION

The chlorination of methane is a remarkable example of a reaction powerfully activated by light radiation. Sunlight, diffused daylight, light from a carbon arc, from a metallic filament, and from a mercury vapor lamp have been recommended to promote the chlorination process. In most cases, photochemical combination may be effected at room temperature or even at lower temperatures if methyl chloride is desired, while the reaction may become explosive if the illumination is not carefully controlled.[21a]

According to Bedford, blue light is by far the most effective and though many investigators have suggested ultraviolet light as a suitable activating influence, it is by no means certain that the active radiation is necessarily in the ultraviolet range of wave length.

The marked influence of sunlight on the combination of chlorine and methane was shown as early as 1840 by Dumas,[22] who observed that although methane and chlorine could be mixed in all proportions in the dark without evidence of immediate reactions, exposure of 3 volumes of chlorine and 1 volume of methane to daylight, even when diffused, resulted in a violent explosion. Dilution of this reaction mixture with a volume of carbon dioxide equal to that of the methane suppressed explosive reaction and the combination proceeded smoothly with the formation of carbon tetrachloride and smaller amounts of chloroform. The explosive reaction of methane with chlorine in bright daylight was also noticed by Bischoff[23] and Berthelot[24] but, on the other hand, Phillips[25] reported that a mixture of chlorine and methane could be exposed over water to bright sunlight without appreciable reaction. These differences in results are possibly explicable on the basis of the influence of foreign substances on chain processes in general.

Baskerville and Riederer[26] studied the photochemical chlorination of natural gas. Radiation from a "Uviol" ultraviolet lamp was found, contrary to a number of statements in the literature, to effect no noticeable reaction. However, the remarkable observation was made that light from either an unscreened carbon arc or from the arc screened with blue greatly accelerated the combination but the interposition of green, yellow, or red screens almost immediately decreased the rate of chlorination. Reimposition of the blue screen again accelerated the combination. It appears from this work that the blue radiation is the most effective activating influence and that red, yellow, and green exerted little influence. In further experiments, Baskerville and Riederer obtained yields of 20 to 25 per cent of chloroform and carbon tetrachloride by exposing a heated mixture of chlorine and natural gas to the excitative influence of light from an iron arc.

The influence of the light from a mercury vapor lamp on the combination of chlorine and methane at temperatures of 80° to 100° C. was investigated by Tolloczko and Kling.[27] No explosions occurred even when equal volumes of chlorine and hydrocarbon gas were used. Using a natural gas-chlorine ratio of 1:2, and a gas rate of 4 liters per hour, the relative proportions of the chlorinated methanes formed were as follows: methyl chloride, 16 per cent; methylene chloride, 37 per cent; chloroform, 38 per cent; and carbon tetrachloride, 10 per cent. Besides these products, various chloro-derivatives of ethane were produced, including the solid hexachloroethane.

The work of Bedford[28] on the chlorination of natural gas at low temperatures in the presence of illumination from a white flame arc is of considerable interest. The stepwise nature of the chlorination process was demonstrated by adding the chlorine in small increments to the natural gas confined over water at room temperature when the lower chloro-derivatives were first produced. In order to obtain better control of the reaction and to suppress the formation of carbon tetrachloride, the chlorination was initiated (by means of a white flaming arc) in a gas mixture containing 12.5 per cent of chlorine in an apparatus so arranged that combination occurred in interstices between cakes of ice. The hydrocarbon gas and chlorine were then admitted at regular intervals as the reaction proceeded. The products obtained in this way consisted of 166 cc. of a mixture of methylene chloride and chloroform from 2.6 cubic feet of natural gas. This method of operation was also studied in a larger wooden reaction chamber, provided with a plate glass window through which illumination from a white flame arc could be effected. In this apparatus, 250 cubic feet of natural gas, consumed at the rate of 14 to 30 cubic feet per hour, yielded several gallons of product consisting of the following proportions by volume of the various chlorinated hydrocarbons: 35 per cent of dichloromethane; 35 per cent of chloroform; 5 per cent of carbon tetrachloride, as well as 20 per cent of chloroethanes. About 14 per cent of the product (consisting of 61 per cent dichloromethane, 28 per cent chloroform, 1.5 per cent carbon tetrachloride, and 6 per cent chloroethanes) had dissolved in the water produced by the melting of the ice blocks.

[21a] The use of ultraviolet radiation in the halogenation of methane was also discussed by Ellis and Wells, "The Chemical Action of Ultraviolet Rays," Chemical Catalog Co., Inc., New York, 1925, 196.

Whiston[29] carried out work on the photochemical chlorination of methane from the viewpoint of the production of methyl chloride. No reaction took place in a mixture containing 2 volumes of methane and 1 volume of chlorine in the dark but a slow combination occurred under the influence of light from an ordinary 60-watt metallic filament lamp, placed 30 cm. away from the reaction vessel. Exposure of equal volumes of chlorine and methane to the action of daylight for 4 hours, followed by arc light for 1 hour, produced only 9 per cent of methyl chloride, calculated on the chlorine, together with higher products which were not examined. The conversion of the chlorine into methyl chloride was increased to 24 per cent by employing an excess of methane (2.8 volumes of methane to 1 volume of chlorine).

The observation of Whiston that the photochemical chlorination of methane is powerfully inhibited by nitrosyl chloride, together with the deviation from the law of photochemical equivalence observed in this reaction by Coehn and Cordes,[30] make it appear that the photochemical reaction is of the chain type. The purely thermal chlorination of methane is also probably of the same nature.

INDUSTRIAL PROCESSES

Thermal Chlorination of Methane

Colin[31] proposed to produce chloromethanes by the reaction of a mixture of methane and the appropriate quantity of chlorine in a heated reaction chamber. The temperature was maintained at 100° to 200° C. for the production of chloroform. The reaction is induced and maintained by the passage of an electric spark discharge. Too high combustion chamber temperatures are stated to result in the dissociation of the products. The gaseous products of reaction are freed from hydrogen chloride by washing with water and the chlorinated products cooled and liquefied.

[31] U. S. Patent 427,744, May 13, 1890.

Weickel[32] described the chlorination of methane to yield methyl chloride mainly without deposition of carbon by heating a mixture of chlorine (1 volume) and an excess of methane (e.g., 10 volumes) at a temperature not exceeding 400° C. for about 10 seconds. *Porous catalysts*, such as animal charcoal, are stated to assist the reaction and reduce the temperature required to about 350° C., while vessels of quartz, porcelain, earthenware, or glass reduce the tendency for carbon separation and allow the employment of moist gases. The products of the reaction are washed with water to remove hydrogen chloride and the methyl chloride is separated from the excess methane by solidifying at —120° C. at 1 atmosphere pressure or, better, by liquefying at —80° C. and 10.5 atmospheres pressure or at —30° C. and 105 atmospheres pressure. The methyl chloride contains some higher chlorinated products from which it is separated readily by fractional distillation.

A number of processes which relate to the thermal chlorination of methane to yield mainly the monochloro-derivative without carbon deposition have been described by Lacy.[33] The chlorination is effected by passing a mixture of chlorine (1 volume) and a considerable excess of methane (e.g., 10 volumes) through a reaction vessel of quartz or porcelain, heated to a temperature of about 400° C. Even at such high gas rates that the period of exposure of the reacting gases is only a matter of a few seconds practically all the chlorine is consumed and mainly methyl chloride is produced. If less methane is employed, for example, 4 to 6 volumes of methane and 1 volume of chlorine, the reaction heat is sufficient to maintain the reaction temperature without an additional source of heating, but the products do not then consist merely of methyl chloride but contain higher chlorinated products.[34] Lacy later[35] described a method of operation in which a very large excess of methane, namely 15 volumes to 1 volume of chlorine, could be used, thus restricting the chlorination to the monochloro-stage. At the same time the process could be rendered thermally self-supporting. This method of operation consisted in preheating 10 volumes of methane to a temperature of 370° C. and then mixing with 5 volumes of methane and 1 volume of chlorine. No carbon deposition or inflammation of the gases occurs and the resulting mixture, now at a temperature of about 250° C., is passed immediately into the reaction chamber. The heat of reaction is then sufficient to maintain the temperature of the reaction chamber at 400° to 500° C. Only 0.01 per cent, or even less, of the chlorine introduced remains unconsumed. The final form of apparatus described by Lacy[36] consists essentially of a cylindrical iron shell with a lining composed of an "acid tile" brick or of silica. The annular space between the brick and the iron shell is filled with finely ground flint. The reaction products are washed with water to remove hydrogen chloride and the methyl chloride separated by cooling to —80° C. under 10 atmospheres pressure. For the production of higher chlorinated products it is claimed that the reaction can be advantageously carried out in steps, always having present an excess of the particular carbon compound entering the step in question.

Carter and Coxe[37] obtained higher chlorinated products by passing a mixture of methyl chloride, methane, and chlorine through a reaction chamber heated to 350° to 650° C. The higher chlorinated products, which, in a typical example, may consist of 80 per cent methylene chloride, 15 per cent of chloroform, and 5 per cent of carbon tetrachloride, are removed by cooling and the residual methane and methyl chloride are recirculated with the continuous addition of a mixture of chlorine and methane in the ratio of 2 volumes of chlorine to 1 volume of methane.

In another vapor-phase halogenation process[38] the hydrocarbons and halogen are mixed and heated in the dark. The temperature for the chlorination of methane is maintained at 380° to 400° C., but progressively lower temperatures are used for higher hydrocarbons (see Chapter 30). The products are said to be monohalogen derivatives, all the halogen is consumed, and no carbon deposition or inflammation occurs.

Wheeler and Mason[39] suggested exposing mixtures of chlorine and methane to a relatively high temperature in packed porcelain tubes for a very short period of heating whereby methyl chloride becomes the principal product of the reaction. The same process may be adapted to the chlorination of methyl chloride to yield mainly dichloromethane. The following example suffices to show the main features of the process. Three volumes methane and 1 volume of chlorine are passed through a packed porcelain tube, externally heated to 800° C., at a space velocity (calculated on volume of unpacked tube) of 5500 reciprocal minutes. This results in the production of about 25 per cent methyl chloride, 15 per cent dichloromethane, 1.5 per cent of chloroform, and 1.5 per cent carbon tetrachloride.

Catalytic Chlorination of Methane

In the processes dealing with the catalytic chlorination of methane it is usually proposed to mix the reactants in the cold and then pass such mixtures over a solid catalyst in the dark. The tendency to result in violent reaction or explosions is reduced by the presence of suitable diluent gases or by the use of excess of methane.

Mallet[40] suggested the production of methyl chloride and other chlorinated derivatives by passing a mixture of methane and chlorine over a catalyst of animal charcoal or other porous material at 30° to 90° C., while MacKaye[41] described a process for the chlorination of methane in a reaction chamber packed with granulated coke (said to prevent carbon formation) and heated to 250° to 600° C., optimum about 400° C. The theoretical proportions of reactants (4 volumes of chlorine to 1 volume of methane) are said to be satisfactory for this process, when carbon tetrachloride is desired, or 3 volumes of chlorine to 1 volume of methane if chloroform is sought. Apparatus in which to conduct this reaction has been fully described by MacKaye.[42]

The use of charcoal as a catalyst for the chlorination of methane or natural gas has also been proposed by Garner and Clayton.[43] Methyl chloride, methylene chloride and chloroform are said to be the main products of the reaction between 5 volumes of natural gas and 3 volumes of chlorine, which are first mixed in the cold in the presence of charcoal and then passed through a chamber packed with charcoal and heated to 300° C. The whole process is carried out in the absence of light.

[41] U. S. Patent 880,900, Mar. 3, 1908; assigned to Stone and Webster.

[42] U. S. Patent 1,009,428, Nov. 21, 1911; assigned to Stone and Webster.

The chlorination of methane at temperatures of 150° to 500° C. in the presence of polyvalent metals, such as iron, copper, or antimony, or their salts, has been described by Pfeifer.[44] A mixture of chloro-derivatives is obtained, the proportions of which depend upon the operating conditions.

The employment of some kind of inert porous packing material, such as charcoal, has been described by a number of investigators. Thus, Yoneyama and Ban [45] converted methane to a large extent into methyl chloride by passing a dry mixture of methane and chlorine over a catalyst of animal charcoal and finely divided lime at 250° C.

Curme [46] converted methane into a mixture of chlorinated products by passing a dry mixture of an excess of methane and chlorine, having a chlorine content of 5 to 30 per cent according to the desired products, over heated activated carbon. In Curme's process perfectly dry reagents are used and methyl chloride and dichloromethane are the main products. The prime requirement of the absence of water vapor permits the use of apparatus made of iron or steel. The hydrogen chloride may be recovered in the anhydrous condition. The operation is cyclical in character and the methane, substantially undiluted with nitrogen or other gas, is repeatedly circulated with fresh additions of dry chlorine. Dry methane and dry chlorine are continuously supplied to the apparatus but the methane is always maintained in excess. The reaction is carried out at an elevated temperature in the presence of activated carbon prepared by the Chaney process. The products of the reaction are first water-cooled to condense chloroform and carbon tetrachloride partly and are then compressed and liquefied in a Linde tower. Conditions are arranged in this pressure liquefaction so that substantially all the substances present except the methane are condensed, the excess methane alone being carried forward in a gaseous state. The liquid mixture contains the following substances in varying proportions: hydrogen chloride (b.p. —80° C.), methyl chloride (b.p. —24° C.), dichloromethane (b.p. +42° C.), chloroform (b.p. +61° C.), and carbon tetrachloride (b.p. +78° C.). The mixture is then subjected to fractional separation and rectification. The hydrogen chloride may be adsorbed to yield commercial hydrochloric acid, but generally it is stored in steel cylinders in the anhydrous form.

Chlorination has been effected by passing cold methane and chlorine into a liquid medium of high boiling point, such as a melt of inorganic salts, which may also contain a catalyst consisting of ferric or cupric chlorides.[47] For example, a mixture of 1 volume of chlorine and 2 volumes of methane are passed into molten potassium hydrogen sulphate at 320° C. to furnish mainly methyl chloride. Róka [48] proposed to conduct the chlorination of methane in the presence of an excess of superheated steam (2 to 5 volumes of steam per volume of chlorine) at 400° to 500° C.; and in the presence of catalysts such as a chloride of copper, iron, calcium, or magnesium. The proportions of chlorine and methane used depend upon the degree of chlorination required. For example, a mixture of 25 volumes of methane, 38 volumes of chlorine, and 100 volumes of steam on catalytic treatment at 400° to 500° C. yields 8 per cent of methyl chloride, 13 per cent methylene dichloride, 20 per cent chloroform, and 5 per cent carbon tetrachloride, the yields being based on the chlorine consumed.

A combination of the photochemical and catalytic methods of procedure for the chlorination of methane has been described by Payne and Montgomery,[49] who propose to employ as a catalyst the porous solid material produced by intensive chlorination of a light paraffinic oil.[50] A mixture of 3 volumes of chlorine and 1 volume of methane are brought into contact with this catalyst at 150° F. in the presence of suitable illumination.

Polanyi and von Bogdandy[51] stated that methyl chloride may be produced by the addition of small amounts of the vapors of sodium, cadmium, or zinc to a mixture of chlorine and methane, while Martin and Lux[52] effected the chlorination of methane in the presence of the vapor of the lower chloride of a polyvalent element capable of yielding a higher chloride, e.g., in the presence of antimony chloride. Sper[53] has described a method of chlorinating saturated hydrocarbons, including methane, in a heated reaction chamber packed with pieces of graphite.

PHOTOCHEMICAL CHLORINATION OF METHANE

A considerable number of processes has been proposed for the photochemical chlorination of methane. Usually sunlight, either direct or diffused, is employed in these processes but ultraviolet radiation or other chemically active rays is also mentioned. Elworthy and Lance[54] proposed the chlorination of methane in the presence of a diluent gas such as nitrogen or carbon dioxide in a series of glass tubes exposed to sunlight or other illumination. Walter[55] described the chlorination of methane in air-cooled glass tubes exposed to light of increasing intensity. Treatment of a mixture of 1 volume of methane and 4 volumes of chlorine is said to yield a mixture consisting of methyl chloride, methylene chloride, and chloroform, and 45 per cent of the chlorine was utilized. The chlorination of hydrocarbons such as methane in the presence of ultraviolet radiation has been reported by Graul and Hanschke.[56] In the process of Bedford and Tallmadge,[57] the reaction is induced in direct and intimate contact with a cooling agent capable of removing halogen acids, e.g., ice blocks, in order to limit the reaction and also to remove the lower chlorinated products by condensation. The main products are said to be methyl chloride and methylene chloride while at higher temperatures, without the cooling effect of the ice blocks, quantities of higher chlorinated products are always formed.

In the various methods of Snelling,[58] a calm and steady chlorination is induced by varying the intensity of illumination in accordance with the variation in the chlorine content of the reacting gases, the gases containing more reactable constituents being exposed to weaker radiation and *vice versa.* Control of the chlorination process is also enhanced by cooling and also by diluting the reacting gases with inert gases. The products of the reaction contain methylene chloride, chloroform, and carbon tetrachloride.

An apparatus for conducting photochemical chlorination in accord with this principle was devised by Snelling.[59] It consists essentially of an enclosed box, all the sides of which except one (the one nearest the source of illumination) are opaque. The box is fitted with a series of parallel plates composed of transparent material such as glass, quartz, celluloid, or mica and as a source of illumination a mercury vapor lamp or any other type of artificial light, or even sunlight, may be used. As a reactive gaseous mixture passes through the apparatus, it is illuminated by light of gradually increasing intensity. A multiple cell unit, operating on the same principle, is arranged for drawing off condensed products or for preheating the gases or modifying the temperature between different cells and different compartments of the same cell.

Another form of apparatus developed by Snelling is of special value because of the small amounts of glass or other transparent media necessary for its construction. This cell possesses only one transparent side, all the other sides and partitions being of opaque material. The single transparent window is screened or clouded in a suitable manner so that its transparency is progressively increased from the point of entry of the reacting gases, where it is opaque, to the point of exit, where it is quite transparent. The gradation in transparency of this window may be effected either uniformly or in steps.

An apparatus has been described by Brooks, Essex and Ward[60] for the photochemical chlorination of a wide variety of hydrocarbons in presence of actinic light. The chlorination is carried out in an opaque container so that the mixture, or solution, of chlorine in hydrocarbons approaches the source of light gradually and so becomes illuminated by light of steadily increasing intensity. In the process of Riesenfeld,[61] the chlorination of methane is effected under the influence of actinic light in an apparatus designed with safety devices for preventing sudden release of flow of materials, which has a tendency to result in explosions. The products of the process were stated by Riesenfeld to vary with the proportions of reactants. By using equal volumes of chlorine and natural gas a product was obtained containing about 80 per cent of methyl chloride, 10 per cent of methylene chloride, 6 per cent of chloroform, 2 per cent of carbon tetrachloride, and 2 per cent of hexachloroethane.

Leiser and Ziffer[62] described a process for the production of methyl chloride mainly in which a mixture of 1 volume of chlorine and 6 volumes of methane is passed successively through four reaction chambers of increasing size in which the gases are exposed to light from mercury vapor lamps extending axially through the chambers. The addition of small quantities of aqueous vapors and hydrogen chloride to the reacting gases prevents the separation of carbon and the formation of products other than methyl chloride. Only 15 per cent of the chlorine is said to appear in the form of products other than methyl chloride.

Padovani and Magaldi[62a] studied the conditions for maximum yields of methyl chloride by the photochemical chlorination of methane, using a mercury arc with radiation rich in rays of wave-length of 2530 Ångstrom units. Best yields were obtained by using methane-chlorine volume ratios of from 15 to 1 up to 19 to 1, converting as high as 29 per cent of chlorine to methyl chloride.

The use of the silent electric discharge as an activating agent in the chlorination of methane has been proposed by Pfeifer and Szarvasy.[63]

CHLORINATION OF METHANE BY CHEMICAL REAGENTS OTHER THAN CHLORINE

Hochstetter[64] reported the production of methyl chloride by passing a mixture of 3 volumes of methane and 2 volumes of phosgene over finely divided charcoal at 400° C., and Bosshard, Steinitz and Strauss[65] proposed the use of sulphuryl chloride as a chlorinating agent. By passing a mixture of sulphuryl chloride and methane, in the weight proportions of 16 to 135, through an iron tube containing a catalyst, such as charcoal or metal halides, at 300° to 450° C., 30 to 35 per cent of the methane was stated to be converted into methyl chloride, and 15 to 20 per cent into methylene chloride and chloroform.[66]

Krause[67] effected the chlorination of methane by means of antimony pentachloride at 290° to 350° C. in the presence of refractory clay or pumice with the production of mainly methyl chloride with small amounts of methylene chloride and chloroform. In the presence of catalysts such as the chlorides of copper, iron, or calcium, the reaction temperature may be reduced to 250° C. During the reaction, the antimony pentachloride is dechlorinated to the trichloride, which is recovered and rechlorinated in a separate stage. A similar two-stage chlorination process has been described by Tizard, Chapman, and Taylor,[68] who proposed the use of cupric chloride on pumice at a temperature of 500° C., or lower, to convert methane into a mixture of chlorinated derivatives. The dehalogenated copper salt is chlorinated for re-use. It is necessary to exclude oxygen from the chlorinating gases.

Several processes have been described in which hydrogen chloride and oxygen are used as sources of nascent chlorine for the chlorination of methane. Thus, Krause and Róka[69] reported a 60 to 80 per cent yield of chloromethanes, based on the hydrogen chloride used, by treatment of a mixture of methane, hydrogen chloride, and oxygen at 300° to 650° C., and preferably 450° to 550° C., in the presence of catalysts such as active carbon, cupric chloride, ferric chloride, thallic chloride, alkaline earth chlorides and rare earth chlorides. Krause and Róka[69a] prevented the formation of hydrogen chloride in the chlorination

of methane by the addition of oxygen to the mixture, together with diluents such as steam, carbon dioxide or nitrogen. Ernst and Wahl[70] converted methane into chloromethanes by treatment of that hydrocarbon with a mixture of hydrogen chloride and oxygen at 300° to 450° C. in the presence of cupric chloride as a catalyst. These processes, in which hydrogen chloride is utilized as a source of chlorine, would appear to possess considerable technical possibilities provided chlorination is sufficiently controllable at the rather high temperatures essential to such procedure.

Gremli[71] described a process for the chlorination of hydrocarbons such as methane, ethane, or benzene in which a mixture of the hydrocarbon and chlorine, together with oxygen and, if desired, hydrogen chloride and other gaseous diluents, is passed at 300° to 650° C. over catalysts, such as iron, thallium, alkaline earth and rare earth chlorides, or charcoal.

INDUSTRIAL POSSIBILITIES OF THE METHANE CHLORINATION

The results of many investigators indicate the possibility, starting with chlorine and methane, of synthesizing mixtures of chloromethanes either catalytically or in a purely thermal manner without the aid of contact materials. The difficulties inherent in the chlorination process become more pronounced when an attempt is made to effect the reaction on a large scale. The very highly exothermic nature of the process together with the corrosive nature of the reactants and products present difficulties, though they may not be insuperable, in large scale application. At present it does not appear feasible to control the reaction so that only one product is obtained, though in some instances it seems possible to produce a preponderance of one of the chlorinated derivatives. The production of methyl chloride together with only relatively small proportions of higher chlorinated substances has been achieved, while complete chlorination to carbon tetrachloride may also be accomplished though the latter process presents considerable technical difficulties on account of the high heat evolution and the necessity of employing large proportions of chlorine in the reacting mixture, under which conditions the tendency for the explosive reaction, $CH_4 + 2Cl_2 \rightarrow 4HCl + C$, to occur is greatly increased. On the other hand, no methods apparently have been described for controlling the process so as to result in the production of dichloromethane or chloroform in relatively pure state.

For the optimum yield of methyl chloride a considerable excess of methane over chlorine and a fairly high reaction tube temperature (with or without porous packing material) appear to be required, but for the manufacture of carbon tetrachloride principally, an excess of chlorine over methane is necessary in conjunction with active catalysts. In the latter case, the explosive tendency exhibited by the reaction mixture may be suppressed by the addition of a diluent gas such as carbon dioxide or nitrogen. Most of the processes which have been given a large scale trial appear to yield a mixture of chloromethanes. Numerous processes employing light energy as the accelerating agency have been suggested but none has attained any commercial success, probably owing to the difficulty of controlling such photochemical reactions.

Little information is available as to the extent to which the chlorination of methane has been utilized industrially to yield various chloromethanes, but the indications are that the method has not yet achieved a very extensive application. This is probably to be ascribed to the perfection of the existing methods for making chloroform and carbon tetrachloride and to the economy in chlorine consumption which the latter processes present. It is known, however, that methyl chloride is being manufactured from methane for industrial purposes by a number of concerns in the United States.

---

[70] German Patent 486,952, 1922; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1930, 24, 1393.

[71] Austrian Patents 108,421, 1924, and 108,424, 1924; *Brit. Chem. Abs.* B, 1930, 50.

The products produced by the chlorination of methane (or natural gas containing large proportions of methane) consist of the four chloromethanes, all of which have important industrial applications, besides large amounts of hydrogen chloride which may be marketed either as hydrochloric acid or in the anhydrous state.[72] From the economic standpoint, however, it would appear that a very cheap source of chlorine, as well as of methane, would need to be available in order to render the industrial production of the various chloromethanes (the more important of which can be synthesized cheaply in other ways) a commercial success. In particular, the production of carbon tetrachloride by chlorination involves the consumption of the maximum amount of chlorine, while this substance is by far the cheapest of the chlorohydrocarbons.[73]

PROPERTIES AND USES OF THE CHLOROMETHANES

Methyl chloride, CH_3Cl, is a colorless gas of ethereal odor which burns with a white flame. It boils at —24° C. at 760 mm., and dissolves in water to the extent of 4 volumes per volume of solvent and in alcohol to the extent of 35 volumes. The chief industrial application of this substance is as a refrigerant, for which purpose it possesses, in common with ethyl chloride, a particular value.[74] However, care must be taken in its utilization for refrigeration since a number of cases of asphyxiation caused by this gas have been reported.[75] It is also a possible source of methanol, which can be obtained by hydrolysis with steam in the presence of a catalyst. Actually, however, the reverse process, namely, the esterification of methanol by means of dry hydrogen chloride, has been utilized for its manufacture.[76]

The chlorination of methyl chloride is of interest in showing the cumulative nature of the chlorination of methane.[77] Pease and Walz,[78] for example, have shown that methyl chloride undergoes thermal chlorination at approximately twice the rate of methane. The products of the chlorination consist, as might be expected, of all the other three chloromethanes. By suitable adjustment of the conditions it has been found possible to stop the chlorination process principally at one stage. The thermal chlorination of methyl chloride to dichloromethane and to chloroform at temperatures up to about 500° C. has been described by the I. G. Farbenindustrie A.-G.[79] and by Carter and Coxe,[80] while Damoiseau[81] obtained chloroform by passing a mixture of methyl chloride and chlorine over active charcoal at 280° to 350° C. Mason and Wheeler[82] have shown that it is possible to chlorinate methyl chloride mainly to dichloromethane by the purely thermal method at high temperatures and high space velocities. Thus by passing a mixture of 1 part of chlorine and 5.4 parts of methyl chloride through a packed porcelain tube at a space velocity of 1660 reciprocal minutes and at 600° C. a 17.2 per cent conversion of methyl chloride to dichloromethane took place with the formation of only a trace of higher chloro compounds. The yield of dichloromethane based on the chlorine input was 96 per cent of the theoretical.

[72] It has been proposed to utilize the anhydrous hydrogen chloride produced in chlorination processes for the manufacture of alkyl chlorides from alcohols. I. G. Farbenindustrie A.-G., British Patent 283,877, 1928.

[73] Ethylene dichloride, which can be employed in the place of carbon tetrachloride in some instances, is cheaper on a gallon basis than carbon tetrachloride. For the production of ethylene dichloride, see Chapter 20.

[74] Henning, *Proc. Fourth Int. Congress of Refrigeration*, 1924, 1, 792. Kuenzli (U. S. Patent 1,808,604, June 2, 1931; assigned to Servel, Inc.; *Brit. Chem. Abs.* B, 1932, 84) suggested a refrigerant composition consisting of methyl chloride with 0.05 to 5 per cent of acraldehyde.

[75] Schwartz and Zanger, *Zentral. Gewerbehyg. u. Unfallverh.*, 1926, 3. 246; *Chem. Abs.*, 1927, 21, 2946.

[76] Douane, U. S. Patent 777,406, Dec. 13, 1904; *J.S.C.I.*, 1905, 24, 455. I. G. Farbenindustrie A.-G., German Patent 503,716, 1927; *Chem. Abs.*, 1930, 24, 5768; British Patent 283,877, 1928; *Brit. Chem. Abs.* B, 1928, 886.

[77] In this connection it may be noted that Mason (*Nature*, 1932, 129, 97; *Chem. Abs.*, 1932, 26, 2696) has suggested that the more rapid chlorination of methyl chloride as compared with that of methane may be due to the four hydrogen atoms of methane not being equivalent. Brindley and Lowery (*Phil. Mag.*, 1931, 12, 945; *Chem. Abs.*, 1932, 26, 893), on the other hand, from a study of the refractivities and optical dispersions of methane and its substituted chlorine derivatives conclude that their results did imply the equality of the four carbon to hydrogen linkages in methane. Also as pointed out by Hass (private communication) the substitution of one hydrogen in methane by chlorine may affect the other three carbon to hydrogen linkages and this accounts for the more rapid chlorination of methyl chloride as compared with methane.

[78] *J.A.C.S.*, 1931, 53, 3728.

Dichloromethane (methylene chloride), CH_2Cl_2, is a colorless liquid of chloroform-like odor, boiling point 41° C., and d^{15} 1.337. Besides being an important product of the controlled chlorination of methane and methyl chloride it may be conveniently prepared, in 70 per cent yield, by the reduction of carbon tetrachloride with the theoretical amount of alkaline ferrous salt.[83] It may be separated from methyl chloride by fractional distillation or by hydrolysis of the latter with lime.[84]

The stability of methylene chloride under various conditions has been investigated by Carlisle and Levine.[85] This chlorohydrocarbon was found to be stable to heat up to 120° C. Small quantities of water did not affect its stability at temperatures below 100° C.; the presence of an excess of water brought about no decomposition at its boiling point, but at higher temperatures some decomposition did take place. Pure oxygen or air had only a slight effect up to 120° C. Various metals, such as soft steel, aluminum, copper, tin and lead were not corroded by either dry methylene chloride or the chloride saturated with water up to 140° C. Brass, however, was attacked at 60° C. Methylene chloride appears to be the least corrosive of the higher chlorinated hydrocarbons and its corrosive effect is hardly greater than that of water. Davenport[85a] suggested the addition of a base to inhibit the reaction of refrigerants such as methylene chloride with water. Methylene chloride and other chlorinated hydrocarbons are also said to be rendered more stable by the presence of a small quantity of amylene.[85b] Chloroform, as well as carbon tetrachloride, hexachloroethane, trichloroethylene and other chlorinated hydrocarbons may be stabilized by the addition of oil-soluble azo-dyes such as amino-azobenzene, according to Zuckermandel.[85c] Alkylamines have also been suggested[85d] for preventing or reducing the decomposition of liquid chlorinated hydrocarbons.

Methylene chloride is a valuable solvent for fats, oils or resins, but it must always be used with caution and in well-ventilated rooms. This substance, as well as dichloroethylene, has been suggested as a refrigerant for air-conditioning plants.[86]

It has also been suggested as a solvent for the dewaxing of lubricating oils since it dissolves only very small quantities of wax at low temperatures and is still miscible with the oils in all proportions.[87] Other advantages claimed for its use follow. (1) The wax cake, after filtering, can be freed of oil by washing with methylene chloride and therefore fractional melting and sweating need not be resorted to as in the usual dewaxing processes to free the wax of oil. (2) The rate of chilling is not an important factor as when solvents such as naphtha are used, since with the latter solvents too rapid chilling may cause difficulties in the filtration operation. (3) Dewaxing and chilling may be carried out in one operation by reducing the pressure, whereby part of the methylene chloride is evaporated, thus lowering the temperature of the remaining liquid.

The progressive chlorination of methylene chloride to yield chloroform and carbon tetrachloride has been described by Lacy.[88] Six volumes of methylene chloride and 1 volume of chlorine are led in gaseous form through a reaction vessel maintained at 350° to 450° C.

On treatment of dichloromethane (methylene dichloride) with ammonia, hexamethylenetetramine [$(CH_2)_6N_4$] results, according to Carter.[88a] The condensation of dichloromethane with phenols in the presence of ammonia (apparently through the intermediate formation of hexamethylenetetramine) to form synthetic resins has been described by Coxe and Carter.[88b]

Chloroform, $CHCl_3$, because of its use as an anesthetic and also as a solvent and extraction agent for ethereal oils, fats, resins, rubber, sulphur, and some of the alkaloids, is an important chlorinated derivative of methane. It may be produced not only by the chlorination of methane but also by other well-known methods. In the United States a common method of preparation is the reduction of carbon tetrachloride by means of finely divided iron in the presence of dilute acid, a process which proceeds smoothly to the chloroform stage.[89] The Soc. chim. des usines du Rhône[90] reported that the reduction of carbon tetrachloride to chloroform can be accomplished with 90 per cent yield by treatment with a warm alkaline ferrous salt. Chloroform is a heavy colorless liquid of boiling point 61.2° C. and d_4^0 1.5264.

Carbon tetrachloride, CCl_4, is a colorless heavy liquid of boiling point 76.7° C. at 760 mm. It finds very extensive application as a solvent for resins, fats, bitumens, etc. It is a solvent for asphalts, refined bitumens, rubber, most natural gums, but not for cellulose esters, celluloids, gum arabic or gum tragacanth. Carbon tetrachloride and dichloroethane (ethylene dichloride) have been suggested by Britton[90a] as solvents for the extraction of o-hydroxydiphenyl (o-phenylphenol) from alkaline solutions of the crude product. It is produced industrially on a very large scale by the chlorination of carbon disulphide in the presence of a catalyst, such as sulphur chloride[91] or iodine.[92] It may also be produced by passing chlorine through a mass of incandescent coke.[93] Although used considerably as a cleansing agent and solvent it does possess toxic qualities[94] and also tends to liberate hydrochloric acid slowly in the presence of water; when dry it is non-corrosive to iron, nickel, and aluminum. Another of its important applications is as a component of fire-extinguishing solutions or emulsions, in conjunction with emulsified carbon dioxide solutions, etc. Unfortunately it tends to decompose, liberating hydrogen chloride and chlorine when exposed to burning materials in the presence of water-vapor. This tendency to decompose under such conditions may be partly suppressed by the addition of various chemical agents.

[93] Maywald, U. S. Patent 870,518, Nov. 5, 1907.

Because of their high specific gravities carbon tetrachloride as well as chloroform and tetrachloroethylene have been suggested as solvents for dewaxing operations in which the wax or solid paraffin and chilled oil are separated by centrifugal methods.[94a] The chlorinated hydrocarbon, in which the wax is insoluble or only slightly soluble, is added to the chilled oil in such a quantity as to produce a mixture of hydrocarbon and halogenated hydrocarbon which possesses a higher specific gravity than the wax. If necessary the viscosity of the mixture may be diminished by the addition of a light hydrocarbon.

According to Daur,[94b] carbon tetrachloride reacts with methane to form compounds such as chloroform, tetrachloroethylene, carbon, hydrogen chloride and hexachloroethane. Bartlett[95] prepared hexachloroethane by treating carbon tetrachloride with aluminum and aluminum chloride at a temperature of about 60° to 75° C.

ACTION OF OTHER HALOGENS ON METHANE

Very little work on the *bromination* of methane has been reported and only a few processes have been described dealing with this subject. The bromination of the higher paraffins appears to take place with much greater difficulty than chlorination and also there is less tendency for polysubstitution products to be formed. From the standpoint of toxicity, Henning[95a] found methyl bromide safe to use as a refrigerant or fire extinguisher. Kudicke and Weise[95b] observed that bromoform, tetrachloroethane, dibromoethylene, and in high concentrations, tetrachloroethylene, proved effective germicides in vapor form.

According to Schroeter,[96] methyl bromide may be produced by passing a gaseous mixture of bromine and methane over a catalyst at temperatures above 200° C. The catalysts suggested comprise iron, copper, copper bromide, nickel, cobalt, or salts of these metals and their mixtures, and, in general, of compounds of polyvalent metals. An excess of methane is said to favor the production of methyl bromide, while methylene bromide and bromoform are also formed if higher bromine concentrations and higher temperatures are employed.

In the process developed by Bosshard, Steinitz, and Strauss[97] a gaseous mixture of bromine and methane is subjected to a temperature of 300° to 450° C. at atmospheric pressure, or at higher pressures, in the absence of active catalytic agents. Thus, on passing a mixture of 1 part of methane and 12 parts of bromine through a quartz tube at 400° C. about 3.1 parts of methylene bromide and 3.1 parts of bromoform, as well as small amounts of carbon tetrabromide, are produced. It is maintained that by varying the concentration of the reactants, any of the four bromo-derivatives may be produced in predominating amount.

The direct iodination of methane by elemental iodine has not been reported. The only industrially important iodomethane, namely iodoform, CHI_3, can readily be prepared by the action of iodine in alkaline solution on many alcohols, ketones, and aliphatic oxygenated compounds. It is interesting to note that the iodine atoms in many iodomethanes may be replaced by the other halogens by direct treatment with the halogen. Thus bromiodomethane, CH_2BrI, may be obtained by the action of a limited quantity of bromine, or better of iodine bromide, on diiodomethane, while chlorobromomethane, CH_2BrCl, is produced by treatment of chloriodomethane with bromine.[98]

FLUORINE DERIVATIVES OF METHANE

The direct combination of fluorine and methane occurs with explosive violence. Moissan[99] found that, on passing a current of fluorine through a platinum tube into an atmosphere of methane, a violent reaction occurred, accompanied by incandescence and carbon deposition. A mixture of fluoromethanes was obtained from which he was able to isolate carbon tetrafluoride. Even at very low temperatures the reaction takes place with extreme violence, for Moissan and Chavanne[100] found that solid methane at —187° C. combined with liquid fluorine with a bright flash and an explosion.

Although the simple fluoromethanes are of no industrial importance, certain mixed fluorochloro compounds are attracting much attention from the viewpoint of their use as refrigerants, particularly the *dichlorodifluoromethane,* CCl_2F_2, which has been developed for this purpose by Midgley.

It is essential that a medium for mechanical refrigeration should be stable, and non-corrosive, and possess suitable vapor-pressure characteristics. In addition, when certain special cases are contemplated, non-toxicity and non-inflammability become of equal importance. It has been shown that dichlorodifluoromethane fulfills these conditions to an unusual degree.

PREPARATION AND PROPERTIES OF DICHLORODIFLUOROMETHANE

The pioneer work of F. Swarts[100a] supplied the basis for the large scale manufacture of dichlorodifluoromethane, which is carried out by treating carbon tetrachloride with pure dry (sublimed) antimony trifluoride in the presence of a small amount of antimony pentachloride as catalyst. The reaction may be represented as follows:

$$3CCl_4 + 2SbF_3 \xrightarrow{(SbCl_5)} 3CCl_2F_2 + 2SbCl_3$$

and although small amounts of trichlorofluoromethane are formed, under suitable conditions the yield of CCl_2F_2 may be as high as 94 per cent of the theoretical. The apparatus, described by Midgley and Henne[101] for carrying out this process, is represented in Figure 26, and consists essentially of a steam-jacketed autoclave, *A,* with loading hole, *B,* and a dump valve at bottom. *C* is a flat spiral fraction-

ating column made from monel metal; *D* is a monel metal dephlegmator. The pipe, *P*, leads the gases escaping from the dephlegmator to the washer, *F*, in which a caustic solution eliminates any traces of phosgene, chlorine, or any derivative of pentavalent antimony. From there the gases pass through a regulating valve to the gasometer, *G*, and thence to pump, *H*, which delivers the liquefied product to receivers located on a lower level.

The operation is as follows: 125 pounds of sublimed antimony trifluoride is delivered to the autoclave through *B*, and the required amount of antimony pentachloride is added. Hole *B* is closed, the carbon tetrachloride supply pump, *I*, is started, and steam is turned on. The reaction starts immediately and in a short while the pressure reaches 60 pounds; the subsequent operation is automatic. The end point is very sharp and corresponds to the theoretical quantity of tetrachloride. The pressure is then released through a by-pass valve on the pressure-regulating system. The dump valve is opened and the molten antimony trichloride flows by gravity into hooded containers. No further cleaning is required. After the dump valve is closed the apparatus is ready for the next run.

(Midgley and Henne)

Another method for preparing fluorinated hydrocarbons consists in passing chlorinated hydrocarbons over an alkali or alkaline-earth fluoride at temperatures above 350° C.[101a] For example, carbon tetrachloride reacted with calcium fluoride at 500° C. yields 61 per cent of dichlorodifluoromethane, 35 per cent of trichlorofluoromethane and 4 per cent of unchanged carbon tetrachloride.

The preparation of fluorinated hydrocarbons by the reaction of hydrogen fluoride with aliphatic hydrocarbons or their halogen derivatives, in the presence of antimony trichloride or pentachloride at raised temperatures and pressures, has also been suggested.[101b] Carbon tetrachloride, chloroform, methylene chloride, fluorotrichloromethane, ethyl chloride, isopropyl bromide, ethylene dibromide, tetrachloroethane and similar compounds may be used as starting materials.

The general properties of dichlorodifluoromethane have been described by Midgley and Henne,[102] while a very full account of the general thermodynamic properties of this compound has been given by Buffington, Gilkey, and others.[103]

Dichlorodifluoromethane is a colorless gas having the following physical constants: boiling point, —30° C.; freezing point, —155° C.; density of liquid 1.40—0.00326 t; C_p (liquid), 0.224; C_p (vapor), 0.15; $\frac{C_p}{C_v}$ vapor = 1.124; latent heat, 39 cal. per gram at boiling point and 34 cal. per gram at 30° C.; vapor pressure, $\log p = 4.321 - \frac{1047}{\text{T abs.}}$.

According to vapor-phase tests, the vapor of this compound is stable for at least 30 days at 175° C. if pure and dry and in an unreactive container, i.e., one made of carbon steels and stainless steels, aluminum, copper, monel metal, tin, and tin-lead solders. Water always causes corrosion and decomposition; zinc, magnesium, and water all attack the combined chlorine but not the fluorine. At room temperature, liquid dichlorodifluoromethane is neither decomposed nor corrosive in contact with the ordinary structural materials. The compound is non-inflammable and its fire-extinguishing properties may be gaged by the fact that gaseous mixtures of it and butane, containing as high as 30 per cent butane, are non-inflammable. Table 119a, in which the toxicity of this compound is compared with some of the refrigeration media at present employed, shows that dichlorodifluoromethane is non-toxic from the practical viewpoint of health hazards.

TABLE 119B.—*Comparative Toxicity of Dichlorodifluoromethane and Some Refrigerants.*

(Concentrations in per cent by volume.)

Gas	Kills Animals in Very Short Time	Dangerous to Life in 30–60 Minutes	Maximum for Several Hours Without Danger to Life
Ammonia	0.5–1.0	0.25–0.45	0.01
Methyl chloride	15–30	2–4	0.05–0.1
Carbon dioxide	30	6–8	2–3
Dichlorodifluoromethane	not attainable	80	40

The diagrams (Figs. 27 and 28), which have been made by Midgley and Henne, give an approximate representation of the variation of boiling points of various chloro- and fluorochloro-methanes, and help to demonstrate the superiority of dichlorodifluoromethane for practical refrigeration purposes.

In addition to their use as refrigerants the fluorine derivatives of methane have been proposed as fire-extinguishers and as anesthetics. This applies particularly to those derivatives which are prepared by replacing another halogen element by fluorine in compounds containing at least two halogen atoms. Examples of such substances are dichlorodifluoromethane and trichloromonofluoroethane prepared from carbon tetrachloride and tetrachloroethane, respectively, by treatment with antimony trifluoride in the presence of antimony pentachloride.[104]

Chapter 30

Halogenation of Methane Homologues. Properties and Uses of Halogen Derivatives

As the series of paraffin hydrocarbons is ascended the number of possible halogen-substituted derivatives increases enormously.[1] Direct halogenation of the methane homologues, though it furnishes only a relatively small proportion of the theoretically possible number of products, nevertheless results in the production of a diversity of derivatives so that the difficulties of controlling the process in order to obtain a preponderance of one compound are considerably increased. As in the case of methane, halogenation of the homologues of methane is an exothermic process the control of which often necessitates the use of diluent gases (in the vapor-phase halogenation) or diluent liquids (in liquid-phase operation). Methods of halogenation may be broadly summarized under the general heads of (1) thermal, (2) catalytic, and (3) photochemical, and (4) the use of chemical halogenating agents, other than the halogens themselves.

No general rules appear to apply adequately to the course of halogenation of higher paraffins, though Herzfelder[1a] has proposed the following generalizations:

> "When into a monohalogen compound a second halogen atom is introduced it always attaches itself to that carbon atom which is situated next to the carbon atom already united with halogen. In the case of further substitution, this rule only holds for bromine, of which it is never possible, by other than violent means, to attach more than one atom to each atom of carbon. On the other hand, when a third atom of chlorine is introduced it frequently attaches itself to a carbon atom that is already united with chlorine.
>
> "Bromides that already contain one atom of bromine united with each atom of carbon cannot easily be further brominated; chlorides, however, take up more chlorine. A normal hydrocarbon, when brominated by ordinary means, takes up as many atoms of bromine as it contains atoms of carbon; this was shown in the case of methane, and also, although not with absolute certainty, in that of butane, hexane, heptane and octane."

With respect to the chlorination of hydrocarbons the following generalizations, given by Hass and McBee[2] have been found to hold for propane, normal butane, isobutane, normal pentane and isopentane:

> "1. When a paraffin hydrocarbon is chlorinated either thermally or by the action of light, all of the theoretically possible isomers are formed.
>
> 2. At low temperatures tertiary and secondary hydrogen atoms are substituted more

---

[1] Blair and Henze (*J.A.C.S.*, 1932, 54, 1098) calculated the number of stereoisomeric and non-stereoisomeric mono-substitution products of paraffin hydrocarbons. Some of their values for the total number of both stereoisomers and non-stereoisomers of mono-substituted paraffins are as follows:

Carbon Atoms	*Total Isomers*	*Carbon Atoms*	*Total Isomers*
1	1	7	74
2	1	8	199
3	2	10	1,553
4	5	12	12,832
5	11	15	328,092
6	28	20	82,299,275

[1a] *Ber.*, 1893, 26, 2432; *Chem. Soc. Abs.*, 1894, 66, 1.

[2] Private communication from Professor H. B. Hass of Purdue University.

rapidly than primary ones. If the primary hydrogen atoms outnumber the tertiary and/or secondary ones sufficiently (isobutane, isopentane) the primary isomers will predominate at any temperature between 20° and 620° C. At still lower temperatures the tertiary isomer predominates even in the case of isobutane.

3. At 600° C. and above, there is a very close approach to non-selective chlorination, all hydrogen atoms being substituted at the same rate. Thus the yields of primary isomers relative to total monochlorides is approximately 90 per cent for isobutane, 60 per cent for n-butane and 75 per cent for propane.
4. Neither highly moist conditions nor careful drying affects appreciably the ratio of isomeric monochlorides. The same is true of the carbonaceous deposit which forms on the walls of the reaction tube.
5. An unnecessary prolonged reaction time results in appreciable pyrolysis, the tertiary isomers decomposing most rapidly followed in order by the secondary and primary.
6. The ratio by weight of total polychlorides to total monochlorides at any ratio of hydrocarbon to chlorine greater than 1:1 is approximated by the equation $X = KY$ where X is the ratio of monochlorides to polychlorides, K is an empirical constant peculiar for each hydrocarbon and Y is the ratio of moles of hydrocarbon to moles of chlorine in the unreacted gases.
7. A high proportion of primary hydrogen in the hydrocarbon molecule correlates with a high value of K in the above equation.
8. Dichlorination proceeds by two mechanisms: (1) loss of hydrogen chloride and addition of chlorine to the resulting olefin, and (2) progressive substitution.
9. A slow thermal chlorination favors mechanism (1), while a rapid thermal chlorination favors mechanism (2).
10. The presence of chlorine on a carbon atom does not tend to promote further reaction on that carbon atom during the second substitution."

From an industrial standpoint, the chlorination of lower homologues of methane has attracted much attention as a basis for the conversion of these abundant hydrocarbons into the lower aliphatic alcohols. For this purpose it is necessary to control the chlorination process so that monochlorinated products are formed either exclusively or to a preponderating extent. The hydrolysis of such monochlorinated products proceeds smoothly in the presence of alkalies to the corresponding alcohol. Because of the relatively high cost of bromine, bromination processes are of less interest from a commercial point of view, although ethyl bromide has attained a measure of importance in the manufacture of tetraethyl lead. Fluorinated paraffin hydrocarbons have been prepared and described, particularly by Swarts, but only the methane derivatives have been of commercial interest (see Chapter 29). Direct iodination of saturated hydrocarbons has received but little attention.

ETHANE

Thermal Chlorination. Ethane is so much more readily chlorinated than methane that it is possible to chlorinate this hydrocarbon in natural gases containing only 10 per cent of the hydrocarbon, mixed with upwards of 90 per cent of methane, without appreciable formation of chloromethanes.[2a]

For the purely thermal chlorination of ethane a number of investigators have used various contact materials at moderately high temperatures. Thus Jones, Allison, and Meighan[3] found that chlorination of natural gas, containing 10 per cent of ethane, took place at temperatures slightly below 250° C. in the presence of porous charcoal with the production of chlorinated ethanes mainly. The main product of the chlorination of ethane under such conditions was hexachloroethane, C_2Cl_6, but ethyl chloride, dichloroethane, trichloro- and tetrachloro-ethanes were also noted.

[2a] Britton and Prescott (U. S. Patent 1,908,312, May 9, 1933; assigned to Dow Chemical Co.; *Chem. Abs.*, 1933, 27, 3724) take advantage of this difference in reactivity in purifying methane from ethane and higher hydrocarbons. They proposed to react the mixture of gases with only sufficient chlorine to combine with ethane and the higher hydrocarbons at 200° to 400° C. in the presence of lead chloride.

[3] *U. S. Bur. Mines Tech. Paper*, 255, 1921.

As a method of obtaining principally ethyl chloride Lacy[4] proposed the passage of a gaseous mixture containing chlorine and an excess of ethane (1 volume of chlorine and 8 volumes of ethane) through a reaction chamber maintained at 300° to 500° C. The hydrogen chloride formed during the reaction was removed by washing with water and the ethyl chloride separated from the excess ethane by cooling to a low temperature and condensing; for example to —20° C. and 8 atmospheres pressure. The ethyl chloride obtained by this process can be passed over lime (calcium oxide) at 450° C. to yield ethyl ether.[5]

In still another process the paraffin hydrocarbon and chlorine (or bromine) are mixed in the vapor phase in the dark and heated.[6] In the reaction all of the halogen is used up and no carbonization or flame results; the product is principally the alkyl halide. The temperatures specified are 380° to 400° C. for methane; 360° to 380° C. for ethane; 330° to 380° C. for propane and butane; and 250° to 330° C. for pentane.

Catalytic Chlorination. Tolloczko and Kling[7] chlorinated natural gas in the presence of pumice or pumice impregnated with cupric chloride at temperatures of 400° C. or thereabouts. When chlorine was in excess the preponderating ethane derivative formed was hexachloroethane while in the presence of an excess of natural gas, ethyl chloride, dichloro- and tetrachloro-ethanes were obtained.

A pumice catalyst impregnated with cupric chloride which was reduced partially to the cuprous condition before use was employed by Boswell and McLaughlin.[8] It was found that the procedure followed in the chlorination of methane had to be considerably modified for the chlorination of ethane. Only a few experiments were performed but the yield of ethyl chloride, calculated from the ethane and chlorine used, was at least 75 per cent.

Charcoal, or other porous material, has also been suggested as a catalyst for the chlorination of ethane. For example, Mallet[9] suggested the chlorination of ethane in the presence of animal charcoal at 30° to 90° C. In another process[10] the mixture of halogen gas and excess hydrocarbon gas is caused to react with the liberation of the gaseous halogen acid and the formation of reaction products of higher boiling points than the original hydrocarbon. The gaseous reaction products are then separated from the unchanged hydrocarbon by liquefaction, and the latter is returned to the system for further treatment.

In the process developed by Gremli[11] methane, ethane, or benzene is treated with chlorine at 300° to 650° C. in the presence of oxygen together with hydrogen chloride, if desired. Diluents such as steam, carbon dioxide, or nitrogen may be added to the gaseous mixture. Catalysts such as iron, thallium, alkaline or rare earth chlorides, or charcoal are employed.

Photochemical Chlorination. Frankland and his collaborators employed photochemical chlorination in their early work on the structures of ethane and the other paraffins. Dry ethane and chlorine were mixed in the dark and then exposed to diffused daylight. Using equal volumes of reactants, ethyl chloride was produced;[12] by using two volumes of chlorine to one of ethane, some ethylene dichloride was formed.[13] Chlorination of ethyl chloride with an excess of chlorine in sunlight led to the production of a substance whose odor resembled camphor.[14] Schorlemmer[15] found that ethane from two sources, when treated with an equal volume of chlorine and exposed to diffused daylight at 5° C., yielded ethyl chloride with a small amount of ethylene dichloride. The same products were obtained when using dry and also moist gases and the chlorination reaction served to demonstrate the identity of ethanes synthesized in different ways. Similarly, Darling[16] obtained ethyl chloride and ethylene dichloride by exposure of an equimolecular mixture of ethane and chlorine to the influence of diffused daylight. The photochemical chlorination of natural gas under the influence of ultraviolet light at 80° to 100° C. was found by Tolloczko[17] to proceed smoothly without explosion when using equal volumes of chlorine and natural gas. Besides chloromethanes, di- and tetrachloroethanes were formed, as well as hexachloroethane when an excess of chlorine was employed.

Other methods have been suggested for the photochemical chlorination of ethane, as for example the chlorination of paraffin hydrocarbons by exposure of the hydrocarbons and chlorine to actinic light or light from a mercury vapor lamp.[18] Tompkins[19] proposed the chlorination of ethane from coal gas by one of two methods; either the separation of ethane and methane by liquefaction followed by chlorination of the former in the presence of actinic light, or the chlorination of the gaseous mixture in the presence of actinic light of such intensity that the methane is not attacked. Snelling,[20] on the other hand, effected the photochemical chlorination of ethane by means of an illuminated cell with transparent baffles and gradually increasing the intensity of the actinic light. The products of the reaction are circulated in contact with a solvent for the halogenated hydrocarbons, such as oil or carbon tetrachloride.[20a]

Miscellaneous Processes. There are several other processes which are said to be applicable to the treatment of methane homologues generally. Those of Polanyi and von Bogdandy[21] and Payne and Montgomery[22] concern the chlorination of gaseous paraffin hydrocarbons, among which may be included ethane. In the former process the chlorination of paraffin hydrocarbons, such as methane or its immediate homologues or higher paraffins, is accomplished by treatment with chlorine in the gaseous phase in contact with catalysts such as an alkali metal or arsenic or phosphorus. The process of Payne and Montgomery contemplates the chlorination of gaseous paraffins (3 vols. of Cl_2 per vol. of hydrocarbon gas) in the gaseous phase at temperatures of about 300° F. in the presence of a special porous solid catalyst made by the complete chlorination of higher petroleum fractions, or of such oils mixed with powdered coal.[23] The chlorination of the gaseous paraffins may be completed after this catalytic treatment, if so desired, by a further treatment consisting of exposure to ultraviolet light in quartz tubes.

The preparation of liquid compositions which may be used as dry-cleaning agents and as solvents in the paint and varnish industry, by the chlorination of natural gases containing mainly methane, ethane, propane, and butane, has been described by Vivas.[23a] Natural gas, under a pressure of about 120 pounds per square inch, is passed into a closed container (lined with material resistant to hydrogen chloride) containing antimony or phosphorus pentachloride equivalent to 2 per cent of the weight of gas. Chlorine gas is then introduced at a rate gradually increasing from 2.5 per cent of the natural gas for the first hour to 10 per cent after the seventh hour until chlorination is complete. The hydrogen chloride is removed during the process and the temperature is maintained at about —15° to —20° C. by cooling. The resulting liquid is neutralized with dilute sodium hydroxide and is later separated.

Graul and Hanschke [24] proposed to effect the chlorination of ethane by exposing a gaseous mixture of this hydrocarbon and chlorine to the influence of a silent electric discharge.

Alkyl halides may be obtained by heating a liquid alkyl hydrogen sulphate or dialkyl sulphate in the liquid phase with aqueous hydrogen halides at 130° to 140° C. under pressure. From appropriate compounds, a 90 to 95 per cent yield of ethyl chloride or 1-chlorobutane is said to result.[25] Daudt [25a] proposed to make ethyl chloride by passing a mixture of ethyl ether with an excess of hydrogen chloride over alumina at about 360° C.

Ethyl chloride results from the reaction of gaseous hydrogen chloride and ethylene in the presence of catalysts [26]; it is also formed in 10 per cent yield by passing moist methyl chloride over finely divided platinum on asbestos at 275° C. and in a larger yield at 200° C. when passed over activated charcoal impregnated with bismuth chloride or zirconium chloride.[27] Ethyl chloride is used as a local anaesthetic and as a refrigerant. A non-inflammable refrigerant containing ethyl chloride and ethyl bromide, together with alcohol and diethyl carbonate, has also been suggested.[27a]

Attempts made to prepare pentachloroethane by chlorination of acetylene tetrachloride in the presence of catalysts in the liquid phase were unsuccessful, the products being always the hexachloroethane; pentachloroethane, however, is said to be obtainable by chlorination of the tetrachloro-compound under the influence of actinic light.[28]

The physical properties of the chlorinated derivatives have been tabulated in Chapter 20. From the viewpoint of its possible application for the synthesis of ethyl alcohol and its derivatives, chloroethane (ethyl chloride) is of interest.

Bromination of Ethane. Merz and Weith,[29] from their experiments on the bromination of ethyl iodide, predicted that the bromination of this hydrocarbon should yield tetrabromoethane and hexabromoethane.

In an early process Mallet[30] reported the direct bromination of ethane by passage of a mixture of bromine and the hydrocarbon through charcoal or other porous material at 30° to 90° C.

PROPANE

Chlorination. The chlorination of propane has been very inadequately studied but it appears that this hydrocarbon is more easily chlorinated than methane and on chlorination readily yields monochlorides as well as highly chlorinated products. Chlorination may be effected thermally, or by the aid of catalysts or photochemically, the latter method having been investigated most thoroughly. The number of possible products is very great and a few of the lower chlorinated products are given in Table 119a. Only a relatively small number of the total possible chloro-derivatives have been definitely identified among the products of the chlorination of propane, most of the compounds in Table 118 having been prepared by indirect methods.

TABLE 119a.—*Lower Chloro-Derivatives of Propane.*

Systematic Name	Formula	B.P. ° C.	Density, d_0^t
1-Chloropropane (n-propyl chloride)	$CH_3CH_2CH_2Cl$	46.5°	0.9156 at 0° C. 0.8918 at 19.8° C.
2-Chloropropane (isopropyl chloride)	$CH_3CHClCH_3$	36.5°	0.8588 at 20° C.
1,2-Dichloropropane	$CH_3CHClCH_2Cl$	97.5°–98.5°	1.1656 at 14° C.
1,3-Dichloropropane	$CH_2ClCH_2CH_2Cl$	119°	1.201 at 15° C.
1,1-Dichloropropane	$CH_3CH_2CHCl_2$	85°–87°	1.143 at 10° C.
2,2-Dichloropropane	$CH_3CCl_2CH_3$	69.7°	1.827 at 16° C. (?)
1,1,2-Trichloropropane	$CH_3CHClCHCl_2$	140°	1.402 at 0° C.
1,1,3-Trichloropropane	$CH_2ClCH_2CHCl_2$	146°–148°	1.362 at 15° C.
1,2,3-Trichloropropane	$CH_2ClCHClCH_2Cl$	158°	1.417 at 15° C.

The purely thermal chlorination of propane, using an excess of hydrocarbon over chlorine and high temperatures and high space velocities, has been examined by Mason and Wheeler.[31] Under these conditions chlorination may be restricted to the production of the monochloro-compounds mainly. Both normal and iso-monochloro-compounds were formed, but the former always predominated. The experimental results of Mason and Wheeler are given in Table 120.

TABLE 120.—*Chlorination of Propane.*
(Empty reaction tube 1 cm. bore x 15 cm. long.)

	Expt. 1	Expt. 2

[30] U. S. Patent 220,397, Oct. 7, 1879.
[31] *J.C.S.*, 1931, 2282.

The experimental results are in good agreement with the theoretical formula of Martin and Fuchs for a bimolecular stage process.

No work on the catalytic chlorination of propane has been reported but Herzfelder [32] studied the chlorination of seven di- and tri-chloropropanes by means of antimony pentachloride at varying temperatures up to 190° C. The main products obtained by this worker are given in Table 120a:

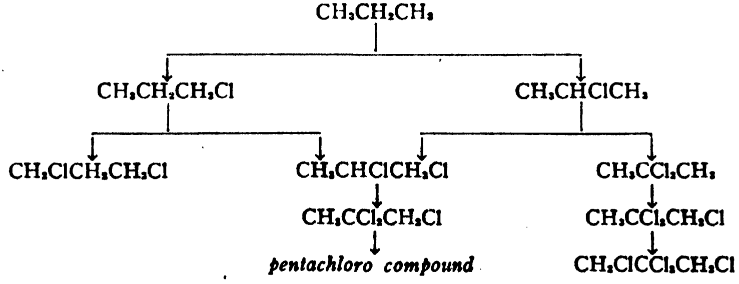
TABLE 120a.—*Products from Catalytic Chlorination of Di- and Tri-chloropropanes.*

Initial Material	Main Product
1,1-Dichloro-	1,1,2-Trichloro-
1,2-Dichloro-	1,1,2-Trichloro-
1,3-Dichloro-	1,1,3-Trichloro-
2,2-Dichloro-	1,2,2-Trichloro-
1,2,3-Trichloro	1,1,2,3-Tetrachloro-
1,2,2-Trichloro-	1,2,2,3-Tetrachloro-
1,1,2-Trichloro-	Pentachloro-

Mixtures of propane and chlorine appear to be stable in the dark but reaction takes place under the influence of sunlight, with the production of a complex mixture of chloro-substitution products. The reaction has been carefully investigated by Schorlemmer,[33] who found that exposure of equimolecular proportions of chlorine and propane to the influence of diffused sunlight led to the production of 1,2-dichloropropane, small quantities of n-propyl chloride, together with a mixture of more highly chlorinated products boiling between 100° and 200° C. Further exposure of a fraction boiling above 80° C. to the action of chlorine in direct sunlight led to the formation of trichloropropanes and a solid tetrachloropropane. A higher fraction boiling between 205° and 250° C. was acted on only very slightly by chlorine even in the presence of bright sunlight and complete chlorination to an octachloro-compound was not accomplished, though a liquid hexachloro-propane was isolated from the mixture.

The chlorination of isopropyl chloride in sunlight was found by Friedel and Silva [34] to furnish a mixture of 2,2-dichloro- and 1,2-dichloropropanes, the former being the preponderating product. However, by heating isopropyl chloride with pure iodine monochloride to 120° C. only 1,2-dichloropropane was formed and no 2,2-dichloropropane.

On the basis of the very inadequate state of our knowledge, the first few stages of the progressive chlorination of propane may perhaps be represented by the following scheme:



---

[32] *Ber.*, 1893, **26**, 2432; *Chem. Soc. Abs.*, 1894, **66**, (1), 1.

[33] *Proc. Roy. Soc. (London)*, 1868, **16**, 35; *Ann.*, 1869, **150**, 210; *Ann. chim. phys.*, 1870, (4), **19**, 439.

[34] *Z. für Chem.*, 1872, (2), **7**, 489.

The industrial methods relating specifically to the chlorination of propane are very few. Snelling[35] stated that his process of photochemical chlorination, in which the reacting gases are illuminated by light of gradually increasing intensity is applicable to propane and other paraffin hydrocarbons. The halogenation of propane and butane to yield monohalogen derivatives is accomplished by the Bataafsche Petroleum Maatschappij[36] by mixing that hydrocarbon with chlorine gas in the dark and then exposing to a temperature of 330° to 380° C. without access of light. All the halogen is said to be used up and no carbonization or flame production takes place. According to one process developed by the Union Carbide Co., dichloropropane may be obtained relatively free from higher chlorinated products by the treatment of an excess of liquid propane with liquefied chlorine, while an inert solvent (e.g., carbon tetrachloride or some preformed dichloropropane) may be used to control the reaction.[37] Use of an excess of chlorine or of propane in the gaseous condition is said to result in the formation of some trichloro-compounds.

With the exception of the two monochloro-derivatives (n- and iso-propyl chlorides) and of 1,2-dichloropropane (propylene dichloride) the chlorinated propanes are almost unknown except as laboratory preparations. The monochloro-derivatives might be utilized in the manufacture of the respective alcohols if their economical production in a relatively pure condition, i.e., free from higher chlorinated products, could be effected.

Bromination. By the action of bromine on propane in the presence of iron as a catalyst, Mereshkowsky[38] reported the formation of tetra-, penta-, and hexa-bromo-derivatives, but experimental details are not definite. A pentabromo-derivative of propane was obtained by Merz and Weith[39] by the action of bromine on allyl bromide at 210° C. in the presence of iodine.

The bromination of propane at elevated temperatures is described by Snelling,[40] who proposes to circulate the gas mixture after reaction in contact with an inert solvent to remove halogenated products.

NORMAL BUTANE

Chlorination. Like its lower homologues, n-butane does not appear to react directly with chlorine in the dark at ordinary temperatures but reaction immediately occurs under the influence of diffused daylight. As might be expected the reaction product is usually a mixture in which mono- and di-chloro-derivatives have been definitely found. As early as 1849, Frankland observed the reaction of dry chlorine with dry butane on exposure of diffused daylight. Schöyen[41] exposed a mixture of butane and chlorine (over water) to diffused sunlight and noted the formation of hydrochloric acid and of a liquid insoluble in water. This latter product consisted of a mixture of butyl chloride, butylene chloride, and more highly chlorinated products. The production of a butyl chloride when butane from American petroleum was allowed to react with two volumes of chlorine in the presence of light was reported by Ronalds.[42] On the other hand, by exposure of a mixture of ten volumes of butane and nine volumes of chlorine to daylight, Butlerov[43] obtained a liquid product containing more chlorine than a dichlorobutane.

The work of Mabery and Hudson[44] was carried out on a fraction of Pennsylvania and Ohio naphtha of boiling point —2° to +2° C. This was chlorinated in the cold in the presence of diffused light in order to obtain smooth chlorination and the maximum production of monochlorinated products. The main portion of the monochloro-compound fraction boiled, however, at 68° to 69° C. and was thought to be isobutyl chloride. In no case was n-butyl chloride found. Similarly Pelouze and Cahours[45] chlorinated a petroleum distillate of boiling point 5° to 10° C. in diffused light and obtained a product boiling between 65° and 70° C. possessing the properties and composition of a butyl chloride. This could hardly have been n-butyl chloride, which boils at 78.5° C. at 760 mm.[46]

n-Butane can give rise to two isomeric butyl chlorides of the formulas $CH_3CH_2CH_2CH_2Cl$ and $CH_3CH_2CHClCH_3$ respectively while there are six possible dichloro-derivatives. In the present inadequate state of our knowledge of the chlorination of n-butane it is impossible to assign definite formulas to the products observed.

Most processes which deal with the chlorination of higher hydrocarbons do not mention specifically the conditions necessary for butane alone but refer more generally to the chlorination of its immediate higher homologues, particularly pentane. The main accelerating agency mentioned is sunlight or actinic light but later work favors purely thermal chlorination in the absence of light, since it is claimed that by the latter method the chlorination reaction may be restricted to the formation of monochlorinated products.

Graul and Hanschke[47] suggested the vapor-phase chlorination of low-boiling paraffins in the presence of light from a mercury-vapor lamp. An excess of hydrocarbon vapor is used and the temperature is maintained at a point sufficient to maintain the hydrocarbon wholly in the vapor phase (reduced pressure may be employed). Snelling[48] proposed to convert butane mainly into butyl chloride by mixing chlorine with an excess of hydrocarbon vapor in a reaction vessel from which the gaseous mixture can be circulated and brought into contact with a solvent for the halogenated products (suitable solvent is carbon tetrachloride) and then a second solvent to remove hydrogen chloride. The photochemical chlorination of butane and other paraffins to butyl and alkyl chlorides can be carried out, according to Brooks, Essex and Smith,[49] in such a way that the mixture of gaseous or liquid reactants approaches the source of illumination in a gradual manner. The thermal chlorination of butane to form monochlorobutane (and also of other paraffins of more than two carbon atoms to furnish monochloro-derivatives generally) is accomplished by Ayres[50] by mixing the hydrocarbon vapor with a smaller volume of chlorine and heating (in the absence of actinic light, electric discharge, or catalyst) to a temperature sufficient to produce a preponderance of monochlorinated products and simultaneously to effect a complete consumption of the chlorine. Another proposal[51] was for the monochlorination of propane or butane in the vapor phase and in the dark at 330° to 380° C. and also presumably in the absence of catalysts. The main product is stated to be the alkyl halide and the reaction is said to be effected smoothly with complete utilization of the chlorine (or bromine) present in the reacting gases.

It has been stated that the presence of small proportions of unsaturated hydrocarbons facilitates the halogenation of saturated hydrocarbons, that is, halogenation by substitution is improved by conducting it simultaneously with an addition reaction.[51a] For example, a reaction between butane and chlorine carried out in the dark is accelerated by the presence of about 10 per cent of butylene. However, if air or oxygen is introduced into a mixture of saturated and unsaturated hydrocarbons, the substitution is apparently suppressed and the addition proceeds. Thus, in the above reaction most of the butane remains unchanged, dichlorobutane being mainly formed.[51b]

Bromination. As in the case of the chlorination of n-butane the bromination of this hydrocarbon has been very inadequately studied. Frankland[52] observed that bromination occurred under the influence of direct sunlight or at slightly elevated temperatures, and Carius and Lisenko[53] obtained a colorless liquid boiling between 155° to 162° C. (without decomposition), and having bromine content corresponding to that of butylene bromide ($C_4H_8Br_2$), by heating bromine and butane together for several hours in a sealed tube at 100° C. Butlerov[54] obtained a heavy oil, consisting mainly of polybrominated products, by the influence of daylight on an equimolecular mixture of butane and bromine.

Jacobson[54a] prepared 1,2,3,4-tetrabromobutane by passing 2,3-dibromobutane or crotyl chloride (4-chloro-2-butene) over soda-lime at 400° to 550° C. and subsequently absorbing the gaseous product in bromine. The compound, purified by two crystallizations from alcohol, melted at 116° to 117° C., the yields being about 13 to 20 per cent. The condensate which came over after the excess bromine was distilled off consisted of 2,3-dibromobutane (boiling point, 157.5° to 159° C.) and trans-2-bromo-2-butene (boiling point, 90.5° to 92.5° C.). The by-products found in the liquid residues were 1,2-dibromobutane (boiling point, 165° to 166° C.), 2,3-dibromobutane (boiling point, 158° to 159° C.), 1,3-dibromobutane (boiling point, 173° to 175° C.), 1,4-dibromobutane (boiling point, 197° to 198° C.), 1,1,4,4-tetrabromobutane (boiling point, 133° C. at 1 mm.), and isomeric 1,2,3,4-tetrabromobutane (melting point, 38° C.).

ISOBUTANE

Most of the work on this hydrocarbon has been carried out on petroleum fractions containing isobutane mixed with other homologous paraffins and also probably with some n-butane.

As previously mentioned Mabery and Hudson[55] found that chlorination of a petroleum fraction, boiling point —2° C. to +2° C., in the cold and in the presence of diffused sunlight resulted principally in monochlorination. On fractionation of the products about 80 per cent boiled at 68° to 69° C., and this portion was thought to be isobutyl chloride. A dichlorobutane, boiling point 121° to 122° C., was obtained also after prolonged fractional distillation. Similarly Aschan[56] chlorinated a petroleum fraction of boiling point 10° to 12° C. in the presence of water and obtained, as the main product, a monochloride with a

[56] *Översikt Finska Vetenskaps-Soc. Förh.*, 1915, 58, 122; *Chem. Abs.*, 1920, 14, 3654.

boiling range of 60° to 70° C., and which was considered to be derived from the isobutane present in the petroleum fraction.

Later work on the chlorination of the butanes by Hass and McBee[57] indicated that the monochloride isolated by Mabery and Hudson was 2-chlorobutane, rather than isobutyl chloride, and also that the dichloride isolated by these same workers was probably either 1,2- or 2,3-dichlorobutane. Possibly the monochloride isolated by Aschan consisted largely of 2-chlorobutane rather than isobutyl chloride.

On the other hand, Butlerov[58] studied the photochemical reaction of ten volumes of isobutane and nine volumes of chlorine and obtained tertiary butyl chloride, together with a higher-boiling mixture of products of slightly higher chlorine content than indicated by the formula $C_4H_8Cl_2$.

Heating isobutane with iodine monochloride[59] at 250° C. caused disruption of the molecule with the production of hexachloroethane and carbon tetrachloride.

Bromination. Only polybrominated products were obtained by Butlerov[60] by the reaction of equimolecular proportions of isobutane and bromine. The bromination, however, occurred more readily in this case than in the case of n-butane. The bromination of isobutane in the presence of iron as a catalyst was found by Mereshkovski[61] to give rise to tetra-, penta-, and hexa-brominated products. By the action of bromine on isobutyl bromide at 175° C. a hexabromoisobutane is produced, while at 300° to 340° C. hexabromoisobutylene was found among the products of reaction.[62]

NORMAL PENTANE

Chlorination. The action of chlorine in diffused daylight at ordinary temperature on a hydrocarbon fraction (boiling point 32° to 35° C.), obtained by the distillation of crude fatty acids with superheated steam was found by Cahours and Demarcay[63] to result in the production of a liquid boiling at about 100° C. and having the properties of an amyl chloride. Similarly Schorlemmer[64] obtained, by the vapor phase chlorination of a petroleum fraction boiling at 37° to 39° C., a mixture of amyl chlorides of boiling range 95° to 110° C., the main fraction distilling at 100° to 102° C.

Rather more definite information regarding the chlorination of pure n-pentane to amyl chlorides is furnished by the work of Lachowicz[65] and Aschan.[66] The former worker passed a slow stream of chlorine into the vapors of n-pentane at room temperature, the reaction being afterwards accelerated by heating at water-bath temperature. Two amyl chlorides were formed, one boiling at 106° C. (1-chloropentane?) being present in larger amount, and the other, possibly a secondary chloride, boiling at 104° C. Aschan found that the best results were obtained by using dry gaseous mixtures and definitely identified 1-chloropentane (boiling point 107° C.) among the products as well as a secondary amyl chloride (boiling point 96° to 98° C.). Bauer[67] passed chlorine into liquid pentane for several hours and obtained a product boiling at 230° to 240° C. and of a composition corresponding approximately with the formula $C_5H_8Cl_4$.

In connection with the chlorination of pentane as reported by Aschan it has been pointed out by Hass and Weber (unpublished) that 1-chloropentane boils about 10° C. higher than either 2-chloro- or 3-chloropentane, and that the two latter chloro derivatives boil within about 0.3° C. of each other. Separation of 2- and 3-chloropentane by distillation can hardly be expected, and this probably explains why Aschan reported only one secondary amyl chloride instead of two.

Ayres[68] and Clark[69] have reported the results of the large-scale chlorination of n- and isopentane by the Sharples Solvents Corporation. A fuller description of the technical development of this process is given in a later section of this chapter.

Chlorination of the two pentanes at temperatures below 100° C. in either vapor or liquid phase was found to need the accelerating influence of light or catalysts. In the presence of the latter, however, the chlorination tends to proceed beyond the monochloro stage and the yields of primary chlorides are low. On the other hand, chlorination above 200° C. in the vapor phase (liquid phase requires inconveniently high pressures) can be accomplished without the aid of catalysts and results in the highest yields of primary chlorides. The presence of anhydrous polyvalent metallic chlorides reduces the yield of primary chlorides while carbon or pumice have little influence either on yield of primary chloride or on reaction velocity. Catalysts, such as iodine, sulphur chloride, or red phosphorus, which are volatile and soluble in liquid pentane, cause the excessive production of polychloro-derivatives. The use of insoluble and non-volatile catalytic metallic chlorides results in the production of high yields of monochlorides in either liquid or vapor phase operation but unfortunately causes the isomerization of the primary chlorides to secondary and tertiary chlorides which are of less industrial value in alcohol manufacture. Particularly at higher temperature, such catalysts appear also to accelerate the formation of amylenes and the polymerization of these amylenes. This effect has been frequently noted in the case of the propyl and butyl chlorides.[70]

In the case of n-pentane all three possible monochloro-compounds, namely, 1-chloro-, 2-chloro- and 3-chloropentanes, are formed but in the presence of catalysts or under the prolonged influence of heat and pressure, both the 1-chloro- and the 2-chloro-derivatives are isomerized to the 3-chloro-derivative. This isomerization process undoubtedly proceeds by splitting off and subsequent addition of the elements of hydrogen chloride with the intermediate production of amylenes, thus:

$$\begin{array}{c}
CH_3CH_2CH_2CH_2CH_2Cl \\
\downarrow \\
CH_3CH_2CH_2CH{=}CH_2 + HCl \\
\downarrow \\
CH_3CH_2CH_2CHClCH_3 \\
\downarrow \\
CH_3CH_2CH{=}CHCH_3 + HCl \\
\downarrow \\
CH_3CH_2CHClCH_2CH_3
\end{array}$$

Only the last of these reactions is a reversible process.

---

[68] *Ind. Eng. Chem.*, 1929, 21, 899.

[69] *Ind. Eng. Chem.*, 1930, 22, 439.

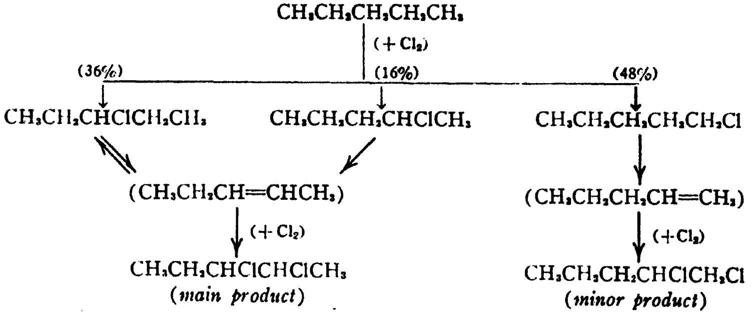
[70] Brunel, *Ber.*, 1911, 44, 1000; Eltekov, *Ber.*, 1875, 8, 1244; Favorsky, *Ann.*, 1907, 354, 325; Gustavson, *J. Russ. Phys.-Chem. Soc.*, 1883, 15, 61; Kekulé and Schrötter, *Ber.*, 1879, 12, 2279; Michael, Scharf and Voigt, *J.A.C.S.*, 1916, 38, 653; Mouneyrat, *Bull. soc. chim.*, 1899, 21 (3), 616.

The optimum conditions for the formation of primary monochlorides from pentanes with minimum production of secondary and tertiary monochlorides or of higher chloro-compounds, amylenes, or polymerized amylenes were found to be: Rapid passage of a gaseous mixture of chlorine and excess of pentanes through a hot reaction zone (at 315° to 371° C.) at such a rate that the period of reaction is shortened to about 2.5 seconds. Under these conditions, n-pentane yields the following proportions of isomeric monochlorides:

1-Chloropentane, boiling point 107° C., approximately 48%
2-Chloropentane, boiling point 97° C., approximately 16%
3-Chloropentane, boiling point 96° C., approximately 36%

Besides the above monochlorides a number of dichloro-compounds are formed simultaneously though in small yields. Almost none of the dichlorides formed by progressive chlorination of pentane, such as the 1,1- or 1,5-compounds, was found among the dichloro-products of this vapor phase thermal chlorination. 1,2-Dichloropentane was present in minor proportions while 2,3-dichloropentane was the major constituent. The formation of these products may be summarized as follows:

Vapor Phase Thermal Chlorination of N-Pentane.



Bromination. By exposing a mixture of a fraction of Rumanian petroleum (boiling at 0° to 10° C.) and bromine in the presence of water to diffused sunlight for 4 to 14 days, Poni[71] obtained a number of bromopentanes which were all derivatives of isopentane and tetramethylmethane.

Dow[72] has suggested the bromination of pentane in the presence of an iron catalyst to separate that hydrocarbon from carbon disulphide. Both the pentane and the carbon disulphide are among the recovered volatile products from the distillation of coal.

ISOPENTANE

Chlorination. The work on this hydrocarbon has been carried out using fractions of narrow boiling range and containing quantities of other hydrocarbons. Pelouze and Cahours[73] noted that a petroleum fraction of boiling point 30° to 32° C. absorbed chlorine rapidly in diffused daylight even at ordinary temperature. By stopping the reaction while some hydrocarbon was still unchlorinated, and thus avoiding an excess of chlorine, an amyl chloride mixture of boiling point

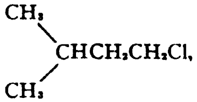
[71] *Ann. sci. univ. Jassy*, 1905, **3**, 212; *Chem. Soc. Abs.*, 1906 **90** (1), 1; *Chem. Zentr.*, 1906, **1**, 442.
[72] U. S. Patent 1,317,359, Sept. 30, 1919; *Chem. Abs.*, 1919, **13**, 3310.
[73] *Compt. rend.*, 1862, **54**, 1241; 1863, **56**, 505; **57**, 62.

98° to 103° C. was obtained. Monochloroisopentanes boiling at 99.8° to 100.5° C. (probably mainly primary isoamyl chloride) were obtained by Lachowicz[74] by chlorination of a fraction (boiling point 29° to 30° C.) of Galician petroleum. Mabery and Hudson[75] subjected a distillate of the same boiling range, from Pennsylvania and Ohio petroleums, to chlorination in the presence of diffused daylight at ordinary temperatures and obtained a chlorinated product about 85 per cent of which boiled at 96.5° C. This proved to be isoamyl chloride. Another constant boiling product, boiling point 144° to 145° C., was obtained after eighteen distillations and possessed the composition of a dichloropentane. According to Mott and Bedford,[76] the photochemical chlorination of isopentane at room temperature takes place twice as rapidly under the influence of a white flame arc as when exposed to a quartz mercury-vapor lamp. The active rays from the white flame arc were thought to be concentrated in the blue region of the visible spectrum.

One of the most comprehensive investigations of the chlorination of isopentane from petroleum is that of Aschan.[77] Dry chlorination of isopentane was found to yield a mixture of the four isopentyl chlorides:

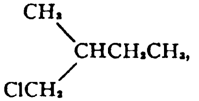
4-Chloro-2-methylbutane,



$$(CH_3)_2CHCH_2CH_2Cl$$

boiling point 99°–102° C., d_{15}^{15} 0.8692.

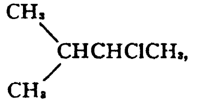
1-Chloro-2-methylbutane,



$$\begin{matrix}CH_3\\ClCH_2\end{matrix}\!\!>CHCH_2CH_3$$

boiling point 96°–99° C., d_{15}^{15} 0.8818.

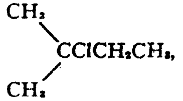
3-Chloro-2-methylbutane,



$$(CH_3)_2CHCHClCH_3$$

boiling point 90°–93° C., d_{15}^{15} 0.8752.

2-Chloro-2-methylbutane,



$$(CH_3)_2CClCH_2CH_3$$

boiling point 85.5°–88° C., d_{15}^{15} 0.8692.

Some dichlorides were also obtained.

On the other hand, chlorination of isopentane in the presence of water vapor led to the production of large proportions of *secondary* chloride but no *tertiary* isoamyl chloride.

By the purely thermal vapor phase chlorination process described by Ayres[78] for the production of maximum yields of primary monochlorides, isopentane is said to yield three monochlorides, of which two primary are present together with some tertiary but, in contradistinction to the results of Aschan, no secondary chloride.[79] The boiling points and proportions of the products are as follows:[80]

---

[74] *Ann.*, 1883, **220**, 173.

[75] *Proc. Amer. Acad. Arts Sci.*, 1897, **32**, 101; *Amer. Chem. J.*, 1897, **19**, 243.

[76] *J. Ind. Eng. Chem.*, 1916, **8**, 1033.

[77] *Översikt Finska Vetenskap-Soc. Förh*, 1915, **58**, 122; *Chem. Abs.*, 1920, **14**, 3654.

[78] *Ind. Eng. Chem.*, 1929, **21**, 899.

[79] The failure to obtain a secondary chloride in the process described by Ayres may be due to the relatively long periods of heating and digestion which cause it to disappear (Hass, private communication).

[80] Clark, *Ind. Eng. Chem.*, 1930, **22**, 439.

1-Chloro-2-methylbutane,  boiling point 99° C., 60 per cent.

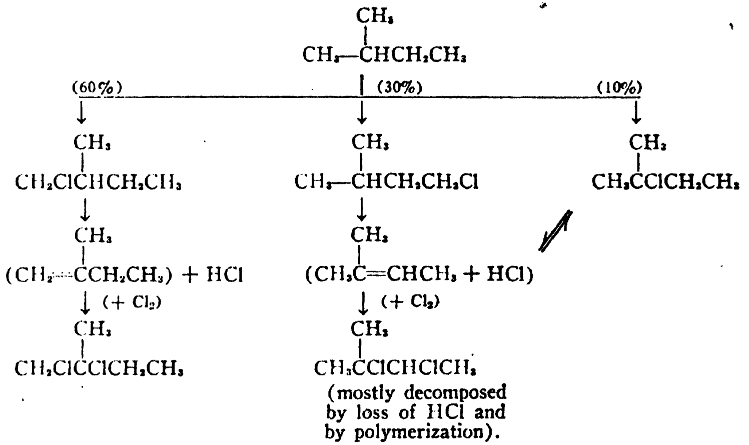
4-Chloro-2-methylbutane,  boiling point 101° C., 30 per cent.

2-Chloro-2-methylbutane,  boiling point 86° C., 10 per cent.

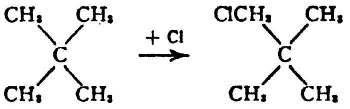
Besides monochlorinated products, this method of chlorination also yields quantities of isoamylenes and dichloroisopentanes. The latter substances are all dichloro-compounds evidently derived from isoamylenes produced by the splitting off of hydrogen chloride from the monochlorides. The dichloride of isopropylethylene (3,4-dichloro-2-methylbutane) does not occur, but 2,3-dichloro-2-methylbutane and 1,2-dichloro-2-methylbutane are present, though the first of these two is mostly destroyed by polymerization.

The chlorination of isopentane in the vapor phase at high temperatures using an excess of hydrocarbon over chlorine may be briefly summarized as follows:

Thermal Chlorination of Isopentane.



Chlorination of Tetramethylmethane. By allowing a mixture of this hydrocarbon and chlorine to remain in contact at room temperature in the presence of ordinary light, Tissier[81] obtained the only possible monochloro-derivative:



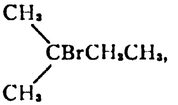
---

[81] *Ann. chim. phys.*, 1893, 29 (6), 344; *Chem. Soc. Abs.*, 1893, 64 (1), 542.

This monochloro-compound has been prepared in considerable quantities by the thermal vapor phase chlorination method just described.

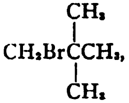
Bromination of Isopentane and Tetramethylmethane. By the bromination of a fraction, boiling point 0° to 10° C., of Colibasi petroleum in diffused sunlight in the presence of water vapor, Poni[82] obtained a number of bromo-compounds derived from isopentane and tetramethylmethane, and to these products the following formulas were assigned:

2-bromo-2-methylbutane



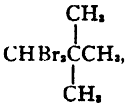
boiling point 108° to 109° C. at 745 mm.

1-bromo-2,2-dimethylpropane,



$CH_2Br\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}CH_3$, boiling point 89° to 91° C. at 749 mm.

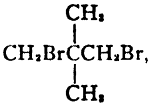
1,1-dibromo-2,2-dimethylpropane,



$CHBr_2\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}CH_3$, boiling point 64° to 65° C. at 43 mm.

and

1,3-dibromo-2,2-dimethylpropane,



$CH_2Br\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}CH_2Br$, boiling point 82° to 83° C. at 49 mm.

CHLORINATION OF MIXED PENTANES

Since the industrial separation of individual pentanes in a pure condition from petroleum fractions is a tedious process, a considerable amount of research has been directed toward the chlorination of a mixture of isomeric pentanes largely with a view to the commercial production of mixtures of amyl alcohols. The results of these efforts are embodied in a number of processes which are discussed later. Interesting details of the photochemical chlorination of a pentane fraction, boiling point 24° to 25° C., have been supplied by Brooks, Smith and Essex.[83] Chlorination in the vapor phase in diffused sunlight gave the best yields of amyl chlorides when a large excess of hydrocarbon was present, i.e., 2 to 4 times as much as that theoretically required. When employing 3 moles of hydrocarbon to 1 mole of chlorine, 88 per cent of the chlorinated products were monochloroderivatives. When chlorinating in the liquid phase, under the influence of illumination and at temperatures below 10° C., 90 to 94 per cent of the chlorinated products consisted of monochloro-derivatives, and the chlorination was stopped before the concentration of chlorine derivatives in the liquid exceeded about 20 per cent of the mixture. From the chlorinated products a monochloropentane fraction suitable for conversion into amyl acetate was obtained. Although illumination of the liquid reaction mixture was not absolutely necessary for reaction the process was usually initiated by exposure to light from a high-power tungsten bulb in the upper part of the reaction chamber. The presence of moisture appeared to aid the chlorination.

Garner[84] described a method in which natural-gas gasoline boiling between 40° and 70° C. was chlorinated in the presence of ultraviolet light to furnish amyl chloride. Later Dobryanski and Gurevich[85] investigated the chlorination of the pentane fraction (boiling point 31° to 38° C.) of Krasnodar aviation gasoline in artificial light. For the maximum production of monochloro-products, chlorination by means of dry chlorine in the vapor phase at 60° to 70° C. was found to be most suitable.

INDUSTRIAL APPLICATION OF THE CHLORINATION OF THE PENTANES

The chlorination of the pentanes for the production of monochloro-derivatives capable of being converted into various amyl alcohols or their esters has received much attention as a possible method for the large scale manufacture of these important solvents. While the development of such chlorination processes has taken place largely in the United States there has been considerable interest abroad in the possibilities of this type of synthesis. In many cases the method proposed is claimed to be applicable not only to mixtures of pentane and isopentane but also to hexanes, heptanes, and octanes. For convenience these are discussed at this point rather than under each individual higher homologue.

Photochemical Chlorination. The light fraction (b.p., 28° to 69° C.) of gasoline, consisting principally of pentane, isopentanes, hexanes, and isohexanes, can be chlorinated in the presence of light to yield principally mono- and dichloro-compounds.[86] These compounds may then be treated with sodium acetate and acetic acid to yield the corresponding acetates, which are solvents for cellulose nitrate. In another process Sparre and Masland[87] first saturated the liquid hydrocarbon with chlorine in the dark and then exposed the mixture to daylight or to the light from a mercury vapor lamp. By carrying out the chlorination in tubes in absence of any appreciable quantity of the gas phase and by regulating the intensity of the light risk of explosion was greatly reduced.

According to Graul,[88] the vapors of a petroleum fraction consisting principally of n-pentane and isopentane and boiling between 40° and 45° C. are chlorinated by mixing with chlorine and then exposing the mixture to chemically active illumination. The monochloro products thus formed are next treated with calcium oxide at 375° to 450° C. to effect the elimination of hydrogen chloride and the formation of the olefin. The olefin is then allowed to react with hydrogen chloride to obtain 2-chloroisopentane.

The photochemical chlorination of liquid saturated hydrocarbons was carried out by Brooks, Essex and Smith.[89] The liquid hydrocarbons are introduced into a container made of some suitable chlorine-resisting material and provided with a pair of windows through which the color of the liquid may be observed. Inside the container is placed a coil, through which either a cooling or heating medium may be circulated. Near the top of this container is suspended a lamp which is the source of irradiation, while at the bottom is a perforated pipe through which the chlorine is fed. A stirrer is also provided so as to keep the hydrocarbons well agitated while chlorine is being introduced. Furthermore the container is connected to a series of condensers and receivers for collecting any volatile products which may be formed. The intensity of illumination from the lamp is diminished as it travels downward through the liquid while the concentration of chlorine diminishes steadily from the bottom of the liquid upwards. This results in the illumination being the most intense in that portion of the liquid which contains the lower chlorine concentration. Therefore a smooth reaction is obtained which yields principally monochlorinated products. In addition, formation of di- and polychlorinated products is prevented by stopping chlorination as soon as about 20 per cent of the hydrocarbons have been converted to monochlorides.

The process of Graul and Hanschke[90] refers to the photochemical chlorination of saturated hydrocarbons (which are normally liquid) in the vapor phase under the influence of ultraviolet light. For example 1000 parts of a purified Galician petroleum fraction, of boiling point 88° to 92° C., consisting chiefly of isopentane, is placed in a lead-lined vessel provided with a fractionating column, and raised to the boiling point at an absolute pressure of 50 mm. The vapors are mixed with (700 parts) chlorine and the mixture then passed through a vessel containing a mercury vapor lamp where chlorination occurs. The chlorination product consists chiefly of a monochloro-isoheptane of boiling point about 140° C. By treatment of a Galician petroleum fraction of boiling point 75° to 81° C. in a similar manner there is obtained a product boiling at 135° to 145° C., the analysis of which agreed with that of a monochlorocyclohexane. The chlorination products are condensed together with unchanged hydrocarbon and returned to the vaporizer, while the vapors of hydrogen chloride pass on and are condensed.

In contrast to the two previous processes Boyd[91] proposed to employ a continuous two-phase process of photochemical chlorination.

According to Boyd, the use of a two stage process obviates the contamination of the resulting hydrochloric acid with unchanged chlorine, which is always obtained when employing a liquid phase process alone. Provided the production of monochloro-compounds is not allowed to exceed 25 per cent of the theoretical in either the liquid or gaseous phase reactors, the formation of polychloro-compounds is claimed to be held at a minimum. The apparatus consists of a series of reaction tubes, each of which is provided with transparent windows, one window at the top of the tube and the other at the bottom. The tubes are separated so as to allow a source of ultraviolet light to be placed between them: also a source of ultraviolet light above the uppermost tube and beneath the lowest tube. The liquid hydrocarbons are introduced into the system at the middle reaction tube and allowed to flow downwards through the reaction tubes countercurrent to the chlorine gas, which is introduced at the bottom of each reaction tube. From the bottom tube is withdrawn a mixture of unreacted hydrocarbons and chlorinated products. Any hydrocarbon gases pass upwards through this series of tubes, during which time they are continually mixed with chlorine and exposed to the action of ultraviolet light. From the top reaction tube the gaseous products are led through a condenser into a receiver and the liquid products so obtained added to those withdrawn from the bottom reaction tube. Any hydrogen chloride which has been formed during the process is collected at this point by passing the uncondensed gases through a scrubbing tank. The mixture of chlorinated products and hydrocarbons is pumped into a still which is heated to such a temperature as to effect distillation of the hydrocarbons but to leave the chlorinated products as a residue which is withdrawn.

---

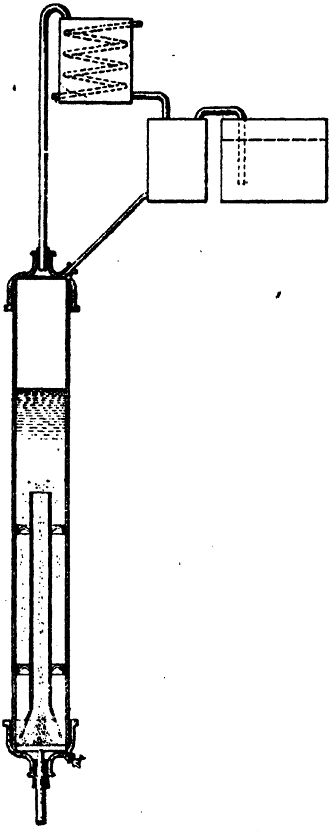
[90] U. S. Patent 1,032,822, July 16, 1912; assigned to Badische Anilin and Soda Fabrik; *Chem. Abs.*, 1912, 6, 2686.

[91] U. S. Patent 1,293,012, Feb. 4, 1919; assigned to Ohio Fuel Supply Co.; *Chem. Abs.*, 1919, 13, 1075.

The hydrocarbon vapors from the still are then passed through a condenser, and any liquid products are returned to the first system of reaction tubes, while the gaseous hydrocarbons are passed through a second series of reaction tubes in which they are mixed with chlorine, and again exposed to ultraviolet light. Separation of chlorinated products and hydrocarbons is again accomplished in exactly the same manner as described for the first series of reaction tubes and the hydrogen chloride formed is again separated by passing the uncondensed gases through a scrubbing tank.

Still another process for the chlorination of hydrocarbons is the one proposed by Lacy,[92] in which chlorine is dissolved in a liquid paraffin in contact with water, and the mixture subjected to the influence of chemically active light. The hydrogen chloride formed in this process is absorbed by the water layer.

Catalytic and Photochemical-Catalytic Processes. The photochemical-catalytic chlorination process developed by Koch and Stallkamp[93] and later described by Koch and Burrell[94] is applicable particularly to the conversion of pentane into amyl chlorides, which can then be hydrolyzed to alcohols. The apparatus, which is employed in this process (Fig. 29), consists of a lead-free glass tube fitted at the ends with reducers and screens. Inside this large tube is a smaller tube, also of lead-free glass, which extends approximately one-half of the vertical length of the large tube and is supported at a short distance above the bottom screen. A small nozzle projects through the bottom screen and this is directed into the lower end of the small tube. The lower end of the smaller tube is spread out in the shape of a funnel. Activated carbon, silica gel, or similar porous substances which possess large gas-absorption properties are used as catalyst or chlorine carriers. Activated carbon of 12- to 15-minute chloropicrin test was found to give the best results. The catalyst is placed on the bottom screen in the large tube to the depth of about 3 inches.



Courtesy Industrial and Engineering Chemistry

FIG. 29.—Apparatus for the Chlorination of Pentane. (Koch and Burrell.)

The large tube is filled about three-fourths full of pentane, and chlorine gas is forced into the apparatus through the small nozzle which is placed concentrically with respect to the funnel-shaped mouth of the smaller tube or percolator. The chlorine gas emerging from the nozzle passes up through the catalyst and then through the percolator tube, carrying some of the catalyst along with it. While flowing up through the percolator, the catalyzing material and chlorine are in intimate contact in the presence of a small quantity of the liquid, and large amounts of the chlorine are adsorbed by the catalyst. The catalyst passes out through the top of the percolator and enters the reaction zone, which is exposed to actinic light emanating from a battery of mercury vapor lamps. At this point it comes in contact with a large quantity of pentane and the chlorine is dropped or displaced from the catalyst and enters into reaction with the pentane. The particles of catalyst, stripped of their chlorine, fall back to the bottom of the large tube, in the space between it and the percolator, and are again picked up by the chlorine jet and forced through the percolator, thus being used over and over.

[92] U. S. Patent 1,308,760, July 8, 1919; assigned to Roessler and Hasslacher Chemical Co.; *J.S.C.I.*, 1919, 38, 676A.

[93] U. S. Patent 1,380,067, May 31, 1921; *Chem. Abs.*, 1921, 15, 3393; Koch, U. S. Patent 1,432,761, Oct. 24, 1922; *Chem. Abs.*, 1923, 17, 289; both patents assigned to Ohio Fuel Supply Co.

[94] *Ind. Eng. Chem.*, 1927, 19, 442.

Any vapors given off while the reaction is in progress pass into a refrigerated condenser and are refluxed back into the reaction tube. Some of the hydrogen chloride vapors pass through the condenser into a washer, where they are absorbed to form a dilute solution of hydrochloric acid.

Chlorination is stopped when the chlorinated derivatives are about 20 to 25 per cent of the total volume of hydrocarbons being treated. This is necessary in order to keep the formation of di- and trichloride derivatives at a minimum. Using the apparatus as described above, Koch and Burrell were able to carry the reaction to this point in about an hour to an hour and a quarter. In actual plant practice the recoveries of chloropentane were about 78 per cent, with an average conversion to amyl chloride of about 19 per cent.

The chlorinated hydrocarbons prepared in this manner contain a large proportion of hydrogen chloride and must be washed and neutralized before being fractionated to recover the amyl chloride. This is done by using a 10 to 20 per cent caustic solution followed by two or three washes with pure water. The washed hydrocarbon is then run into the fractionating still. The first fraction consists of untreated pentane and is retained for further chlorination. The amyl chloride cut is the fraction distilling between 90° and 110° C. This fraction amounts to approximately 25 per cent of the original charge, depending upon the degree of conversion during chlorination, and is about 80 per cent pure amyl chloride. The residue amounting to about 5 per cent consists principally of the di- and trichloro derivatives.

Several other processes of this same general type have been developed. For instance, Blanc[95] proposed the chlorination of liquid paraffin hydrocarbons with moist chlorine in the presence of actinic light and also a halogen carrier such as ferric chloride. Gasoline can be chlorinated in the presence of a solid catalyst such as aluminum or molybdenum chloride and ammonium carbonate;[96] or, after the removal of the heavy ends, it can be treated with chlorine in the presence of carbon tetrachloride, about 1 per cent aqueous ammonia and a metallic chloride such as aluminum or ferric chloride.[97] In the latter case the product is principally heptachlorohexane.

[95] U. S. Patent 1,248,065, Nov. 27, 1917; assigned to Goodyear Tire and Rubber Co.; *J.S.C.I.*, 1918, 37, 74A.

[97] Vivas, U. S. Patent 1,733,843, Oct. 29, 1929; *Chem. Abs.*, 1930, 24, 512; also British Patent 286,726, 1928; *Brit. Chem. Abs.* B, 1929, 349; both patents assigned to International Fireproof Products Corp.

In the process developed by Payne and Montgomery[98] the catalyst is first prepared by mixing a paraffin distillate (initial boiling point of about 450° F.) with powdered coal and completely chlorinating the mixture. Moist hydrocarbon gases, such as natural gas or pressure still gases, together with chlorine in the proportion of 3 volumes of gas to 1 volume of chlorine are passed over this catalyst at 300° F. The mixture is next passed through quartz tubes exposed to rays from a mercury vapor lamp in order to complete the chlorination. The liquid products are then condensed, and the remaining gases are cooled to obtain methyl chloride. Very little uncombined chlorine is found among the products.

The direct chlorination of hydrocarbons by passing vapors mixed with chlorine over a heated graphite catalyst has also been proposed.[99]

Thermal Chlorination. An interesting process for the thermal vapor phase chlorination of n- and iso-pentanes to amyl chlorides is the one described by Ayres.[100] The chemistry of this process has been previously discussed so that only the technical aspects of the operation need be considered here. The pentanes which were used were obtained as a narrow cut fraction (95 per cent boiling between 28° and 39° C.) of natural gasoline containing approximately equal proportions of normal and isopentanes. The scale of operations to which this process has been developed may be gaged by the following details which have been supplied by Ayres. Twenty-two tons of chlorine per day are fed into a flowing stream of hot pentane vapor. The daily throughput of pentane is of the order of 100,000 gallons though owing to the very short time of reaction (2.5 seconds) only about 3 gallons of pentane and 8 ounces of chlorine are present in the reaction zone at any given moment.

A general outline of plant operation has been supplied by Clark.[101] As indicated in the flow sheet in Figure 30, the pentane cut is pumped from storage to a mixing tank, where pentanes recovered from the system are added and the mixture is thoroughly dehydrated. From the mixing tank the pentanes are passed through a vaporizer. Chlorine is passed through another vaporizer and the two gas streams are combined in a mixing throat. From this they pass immediately into a gas-fired pipe still.

The exit gases from the pipe still pass through pipe banks cooled with a water spray and enter the first of four continuous fractionating columns. The first column is operated to take off an overhead product containing only pentanes and the hydrogen chloride produced in the chlorination. This product is returned to the mixing tank at the start of the system, while the bottom product, a mixture of amyl chlorides and unchlorinated pentanes, is pumped to the second continuous column. The pentane-rich overhead product from this column is returned to the feed of the first column, while the bottom product, low in pentanes and high in chlorides, passes to the third column. In the latter column the amyl dichlorides and more highly chlorinated substances are removed in the still liquor and sent to a separate discontinuous still, and the amyl chlorides are sent to the fourth column. Here a practically pure mixture of amyl chlorides is obtained as a bottom product, while the residual pentanes are taken off overhead together with some amyl chlorides and are returned to the feed of the first still.

The dichlorides and polychlorides in the still liquor from the third column are worked up in batches in a caustic still, only the dichlorides being recovered. The more highly chlorinated compounds are discarded.

CHLORINATION

RECOVERY HYDROCHLORIC ACID & PENTANE

Courtesy Industrial and Engineering Chemistry

FIG. 30.—Flowsheet for Industrial Chlorination of Pentane and Recovery of Hydrochloric Acid. (Clark.)

The recovery of the hydrogen chloride produced during the chlorination process is carried out as follows: This substance, together with unchlorinated pentanes, constitutes the overhead product from the first continuous still and is returned to the mixing tank at the start of the chlorination system, as shown in Figure 30. Here it is introduced at the bottom, and the dry hydrogen chloride, bubbling up through the liquid pentanes, combines with any water present to form hydrochloric acid, which settles out at the bottom of the tank and is drawn off from time to time. Only a fraction of the hydrogen chloride is removed in this way, the rest being recovered in a continuous system which withdraws gas from the top of the mixing tank, passes it through a condenser to remove most of the pentanes, and then through a double countercurrent absorption system of fused silica, where the hydrogen chloride is taken up in water. The exit gases from the absorption system are scrubbed with dilute caustic brine liquor from the subsequent hydrolysis operations and, after passing through a condenser, are compressed and condensed. The liquid pentanes are returned to the mixing tank.

An alternative procedure[102] for the recovery of hydrogen chloride is as follows: The gases leaving the reaction chamber, which are at a temperature of 275° C. or higher and under a pressure of 15 to 25 pounds, are led through a rectifier which is kept at a temperature just low enough to condense the chlorinated hydrocarbons and yet to allow the unreacted hydrocarbons and the hydrogen chloride to pass on. These latter gases are then passed through a condenser, which partially separates the hydrocarbons, and finally through an absorber. The temperature of the absorber is high enough, regulated by the rate at which water is fed to it, to prevent the condensation of the hydrocarbon gases and at the same time secure practically complete extraction of the hydrogen chloride.

Other processes for the thermal chlorination of hydrocarbons are those developed by Ayres[103] and by the Bataafsche Petroleum Maatschappij.[104] In the former process the hydrocarbon vapors together with small volumes of chlorine are heated to 315° to 370° C. for very short periods of time in the absence of any catalyst or illumination. In the latter process pentanes can be either brominated or chlorinated by heating the vapors mixed with bromine or chlorine in the dark to 250° to 330° C. To control chlorination of hydrocarbons such as pentane and avoid explosion, Lunt[104a] proposed to bring together chlorine under a pressure of 4 to 5 atmospheres and pentane vapor under about the same pressure in a mixing chamber at a lower pressure (about 2.6 atmospheres).

CHLORINATION OF HIGHER PARAFFIN HYDROCARBONS

The chlorination of paraffin hydrocarbons of six or more carbon atoms has been carried out either on mixtures of isomeric hydrocarbons or on petroleum fractions of narrow boiling range. Since usually very little information has been obtained regarding the constitution of even the monochlorinated products, on the whole our exact knowledge of the chlorination of the higher paraffins is extremely limited, and much work needs to be performed before any generalizations can be formulated. It appears, however, that the higher paraffins can be readily chlorinated either in the liquid or gaseous phases in the presence of diffused daylight or of catalysts, such as iodine. Chlorination in bright sunlight usually leads to intensive action resulting in carbon deposition. Most of the workers in this field have endeavored to restrict the chlorination process to the monochloro-derivatives, e.g., by carrying out the process in the absence of catalysts and stopping it as soon as somewhat less than the theoretical amount of chlorine required for monochlorination had been absorbed. As a rule catalysts tend to favor the production of polychlorinated products. Though the monochloro-compounds have been most generally produced, there is no difficulty in carrying the chlorination much further.

---

[102] The hydrogen chloride can also be extracted from such a mixture by contacting the mixture in the vapor phase under pressure with water. The formation of a film of chlorinated hydrocarbons on the surface of the water is thus prevented, according to Ayres (U. S. Patent 1,831,474, Nov. 10, 1931; assigned to B. A. S. Co.), and the efficiency of the extraction is increased.

[103] U. S. Patent 1,717,136, June 11, 1929; *Chem. Abs.*, 1929, **23**, 3713; British Patent 320,406, 1928; *Chem. Abs.*, 1930, **24**, 2468; U. S. Patent 1,741,393, Dec. 31, 1929; *Chem. Abs.*, 1930, **24**, 1119; French Patent 657,518, June 16, 1928; *Chem. Abs.*, 1929, **23**, 4228; Canadian Patent 278,537, 1928; all patents assigned to B. A. S. Co. Ayres (U. S. Patent 1,835,202, Dec. 8, 1931; assigned to B. A. S. Co.; *Brit. Chem. Abs.* **B**, 1932, 878) suggests dehydrating the hydrocarbons before chlorination by treating them with dry hydrogen chloride. Amylene dichloride can be used in a paint-removing composition (Wilson, U. S. Patent 1,918,224, July 11, 1933; assigned to Sharples Solvents Corp.; *Chem. Abs.*, 1933, **27**, 4642) or for removing road tar from vehicles (Valee, U. S. Patent 1,913,647, June 13, 1933; assigned to Sharples Solvents Corp.; *Chem. Abs.*, 1933, **27**, 4364).

[104a] U. S. Patent 1,824,558, Sept. 22, 1931; assigned to E. B. Badger and Sons Co.; *Chem. Abs.*, 1932, **26**, 150.

The methods employed for chlorinating the higher paraffins are largely modifications of Schorlemmer's classical series of experiments on the chlorination of hexane. Schorlemmer[105] employed the following four methods of chlorination: (1) chlorination of the cooled liquid hydrocarbon in diffused daylight; (2) chlorination in the liquid phase in the presence of iodine; (3) chlorine alone passed into the vapors of the boiling hydrocarbon; and (4) chlorination in the vapor phase in the presence of iodine vapor. In all four cases the bulk of the products consisted of a mixture of primary and secondary monochlorohexanes but it was noted that liquid phase chlorination tended to result in the production of large quantities of polychloro-derivatives. Thus Schorlemmer obtained a hexachlorohexane by passing chlorine into hexane from petroleum as long as any action could be observed, first in diffused daylight and afterwards in direct sunlight.

Morgan[106] reported that on the vapor phase chlorination of hexane, obtained from petroleum naphtha, about nine-tenths was converted into a mixture of monochlorides boiling from 124° to 130° C., the remainder consisting of more highly chlorinated products. Passage of chlorine into boiling hexane, according to Michael and Turner,[107] yielded a mixture of chlorohexanes, of which about 10 per cent was 1-chlorohexane. A small amount of 2-chlorohexane, and less of 3-chlorohexane, was formed at the same time.

The vapor phase chlorination of both n-hexane and isohexane (obtained from Pennsylvania straight run gasoline) in the presence of diffused light was investigated by Faragher and Garner.[108] In both instances the products consisted principally of a mixture of monochlorinated hydrocarbons, together with small quantities of dichloro and higher chlorinated compounds. From the chlorinated n-hexane a fraction (boiling point 120° to 124° C.) was obtained which corresponded in properties to 2-chlorohexane.

On subjecting boiling diisopropyl to chlorination the chief product formed, according to Schorlemmer,[109] was a monochloride boiling at 127° C. In the presence of iodine a dichloride melting at 160° C. was the main product. Silva[110] observed, however, that when diisopropyl was chlorinated in the presence of sunlight two monochlorides were formed; one boiling at 122° C. and the other at 118° C. Aschan[111] obtained two monochlorides from the diisopropyl fraction of

Baku petroleum (boiling range 57° to 59° C.), one boiling at 117° to 119° C. and considered to be a tertiary chloride, and the other boiling at 123° to 125° C. was unidentified.

Heptanes. Chlorination of heptane[112] in the liquid phase and in the presence of diffused daylight yielded a monochloro-product boiling at 150° C., and a dichloro-product boiling at 190° C. The vapor phase chlorination of heptane from *Pinus sabiniana,* however, resulted in the formation of 1-chloro- and 2-chloropentane. Principally mixtures of monochloro-derivatives of heptane have been obtained on the chlorination of the appropriate petroleum fraction by Pelouze and Cahours,[113] Morgan,[114] and Faragher and Garner.[115] The last-named investigators were also able to isolate a dichloroheptane fraction boiling at 90° to 100° C. at 15 mm. pressure from their products.

Isoheptane, prepared from ethyl and isoamyl bromides, was chlorinated by Grimshaw.[116] This was done in the vapor phase and in diffused illumination. The latter condition was necessary in order to control the reaction. The products consisted of monochlorides, together with small quantities of higher chlorinated products.

Octanes. Very little work has been done with pure octane, the initial material in most instances being a petroleum fraction with a very narrow boiling range. Only in rare instances have the structures of the chlorinated products been determined.

From a petroleum fraction boiling at 122° to 125° C. Schorlemmer[117] prepared an octyl chloride boiling at 173° to 176° C. By conversion to the corresponding alcohol it was shown to be principally 2-chlorooctane. Previously he had noted the formation of monochlorooctane, boiling point 170° to 172° C., by the action of chlorine on octane. Monochlorooctanes of about this same boiling range, 172° to 176° C., have been made from petroleum fractions by Pelouze and Cahours[118] and by Mabery and Hudson.[119] n-Octyl chloride, boiling at 182° C., was obtained by Cahours and Demarcay[120] by the chlorination of an octane formed during the distillation of crude fatty acids with superheated steam.

Schorlemmer[121] observed the formation of a monochloro-compound boiling at 165° C. on the chlorination of diisobutyl. Carleton-Williams[122] noted the formation of a mixture of primary and secondary chlorides when diisobutyl was chlorinated in the vapor phase in the presence of sunlight, but was unable to effect separation of the products by fractional distillation.

Rather energetic chlorination of diisoamyl has been reported by Hartmann.[123] The treatment consists first in chlorinating in the cold with chlorine, then with antimony pentachloride in sealed tubes at 190° to 200° C., and finally a second treatment with antimony pentachloride at 450° C. Under such conditions the products were tetrachloromethane and hexachlorobenzene, together with a small quantity of hexachlorobutadiene.

Nonanes. Monochloro-derivatives of this hydrocarbon were prepared by Pelouze and Cahours[124] and by Lemoine[125] from nonane isolated from petroleum fractions. Chlorination was effected by passing chlorine into the gently heated hydrocarbon.

Thorpe and Young[126] passed chlorine into purified nonane in the presence of direct sunlight. Vigorous reaction took place, and occasionally the passage of chlorine was stopped and the mixture distilled. The portion distilling below 200° C.

TABLE 121.—*Products of Chlorination of the Higher Paraffins.*

Hydrocarbon	Source of Hydrocarbon	Conditions of Chlorination	Products
n-Hexane	Synthetic petroleum	Vapor phase	Primary and secondary monochlorides, b.p. 125°-130° C.[a]
	Petroleum	Chlorination in diffused daylight	Monochlorohexanes, b.p. 125°-128° C.[b]
	Petroleum	Vapor phase	90% of monochloro-compounds, b.p. 120°-134° C.[c]
	——	Liquid phase at b.p. in diffused daylight	1-,2-, and 3-chlorohexanes.[d]
	Petroleum	Vapor phase	Monochloride, b.p. 120°-124° C. (2-chloro-compound?)[e]
	——	Further chlorination of monochlorides in diffused daylight	Dichlorohexane, b.p. 180°-184° C. Trichlorohexane, b.p. 215°-218° C. Tetra- and hexachlorohexanes.[b]
Isohexane	Petroleum (b.p. 61°-64° C.)	Vapor phase	Mixture of monochlorides, b.p. 119°-123° C.[e]
Diisopropyl (2,3-Dimethylbutane)	Synthetic	Liquid phase in cold	Two monochlorides, b.p. 122° and 118° C., also a dichloride of b.p. 160° C.[e, f]
	From Baku petroleum (b.p. 57°-59° C.)	Liquid phase at 0° C.	Three monochlorides, the one of b.p. 117°-119° C. being the tertiary compound.[g]
n-Heptane	Synthetic	Liquid phase in diffused daylight	A monochloride, b.p. 150° C. and a dichloride, b.p. 190° C.[h]
	From *Pinus sabiniana*	Vapor phase	Mixture of 1-chloro- and 2-chloro-heptanes, boiling at 143°-157° C.[i]
	Petroleum (b.p. 92°-94° C.)	Chlorine passed into warm liquid hydrocarbon	Monochlorides, b.p. 148°-152° C.[j]
	Petroleum (b.p. 96°-99° C.)		Monochlorides, b.p. 144°-156° C.[k]
	Petroleum (b.p. 97°-100° C.)	Liquid phase at 20°-25° C.	Monochloride, b.p. 150°-160° C., and a dichloride, b.p. 90°-100° at 15 mm.[l]
Isoheptane (2-methylhexane)	Synthetic	Vapor phase in weak illumination	Almost entirely monochlorides, b.p. 140°-150° C., with small amounts of higher chlorinated products.[m]

was again subjected to chlorination. This procedure was adopted to avoid as far as possible the formation of higher chlorinated products. Upon completion of chlorination the product was distilled and a nonyl chloride fraction boiling at 190° to 198° C. obtained. This fraction, however, was thought to be a mixture of primary and secondary monochlorononanes.

Decanes, Undecanes and Dodecanes. Decyl chlorides have been prepared by Mabery[127] from petroleum fractions boiling at 173° to 174° C. and from different crude petroleums. Chlorination was effected in diffused light, and the products were separated by fractionation. The monochloro-derivatives generally boiled around 130° to 140° C. at 80 mm., and the dichloro-derivatives at 160° to 170° C. at 80 mm. The monochloro-derivatives of undecane, boiling at 225° to 230° C. in 747 mm., were obtained in a similar manner. Indications were also obtained that some dichloro-derivatives were formed at the same time. Monochlorododecane boiled at 142° to 153° C. at 80 mm., while a possible dichloro-derivative boiled at 150° to 160° C. at 80 mm.

A résumé of the most important contributions on the chlorination of paraffin hydrocarbons from hexane to dodecane, as compiled by Egloff, Schaad and Lowry,[128] is given in Table 121.

The chlorination of kerosene, from Pennsylvania petroleum, by means of antimony pentachloride in the presence of iodine and at 350° to 360° C. has been reported by Hartmann.[129] The products of such chlorination were stated to be principally hexachloroethane and hexachlorobenzene, together with small quantities of tetrachloromethane and perchloromesole (hexachlorobutadiene, C_4Cl_6). Using another fraction (boiling at 300° to 350° C.) of this same petroleum and chlorinating at 450° C. with antimony pentachloride the products were almost entirely tetrachloromethane and hexachlorobenzene.

The chlorination of various petroleum fractions corresponding with tridecane, tetradecane, pentadecane, hexadecane, heptadecane and octadecane has been described by Mabery and also by Pelouze and Cahours but the data available are fragmentary. These higher paraffins appear to chlorinate very readily in diffused daylight at room temperatures and monochloro-derivatives (which are probably mixtures of isomers) have been obtained. In the case of paraffins with more than 17 carbon atoms, it is stated that chlorination proceeds readily without catalysts.[129a] The chlorination of the higher paraffins has been mainly investigated from the viewpoint of the subsequent dechlorination of the monochlorides so obtained, to yield drying oils of unsaturated character. The olefins produced by the removal of hydrogen chloride from monochlorinated products of paraffin wax may be oxidized to fatty acids which are of value in the manufacture of soaps. The chlorination of paraffin wax for the ultimate production of fatty acids by the latter series of processes has been described by Schaarschmidt and Thiele.[130] These workers found that when chlorine is passed into liquid paraffin at 160° C. the gas is completely utilized and the operation proceeds without external heating. The process is interrupted when the requisite gain in weight has been attained. Chlorination does not occur quite uniformly and, in addition to isomeric monochloro-derivatives, dichloro-products are also formed before all the paraffin is attacked.

[130] *Ber.*, 1920, 53B, 2128.

A series of chlorinated paraffins varying in chlorine content from 20 to 48.5 per cent was prepared by Gardner[130a] by bubbling dry chlorine through paraffin wax at a temperature of about 70° C. Introduction of more than 40 per cent of chlorine is accomplished with difficulty. The relationship between chlorine content and density, congealing point, viscosity, and surface tension was examined. Viscosity increases sharply after more than 40 per cent chlorine has combined. As the chlorine content increases the congealing point drops to a minimum (at about 37 per cent chlorine in these experiments) and then increases sharply.

UTILIZATION OF CHLORO-DERIVATIVES OF HIGHER PARAFFINS

A number of industrial methods dealing with the chlorination of the immediate homologues of the pentanes have been dealt with previously. Most of the methods for the chlorination of higher paraffins have for their object the utilization of the monochlorinated products as raw materials in the manufacture of fatty acids, drying oils, and similar materials.

According to Perkin, Weizmann and Davies,[131] n-heptane may be chlorinated in the liquid phase at 90° C. under the influence of ultraviolet radiations. The chlorination process may also be accelerated by catalysts such as phosphorus compounds or iodine. Thus, when chlorine was passed into 300 grams of heptane until the increase in weight was 50 grams the products consisted of 225 grams of monochloroheptanes and 10 grams of dichloroheptanes.

Strauss[132] stated that the higher paraffin hydrocarbons, such as undecane and dodecane, or petroleum fractions corresponding with these hydrocarbons or their mixtures, could be converted mainly into monochloro-derivatives by vapor phase chlorination under diminished pressure at a temperature approximately double that of the boiling point of the hydrocarbon. A controlled quantity of chlorine was employed and the reaction was catalyzed by the addition of a small amount of iodine vapor.

The chlorination of the higher paraffins to yield highly chlorinated substances (useful as coating or impregnating materials or for varnishing) is described by Buchner,[133] who proposed to pass chlorine into a solution of the hydrocarbon in carbon tetrachloride at ordinary or elevated temperatures and under the influence of chemically active radiation. The carbon tetrachloride is said to exert a definite accelerating action. Many of the products are solid non-plastic substances melting at 100° to 115° C. Introduction of chlorine into a solution of paraffin in carbon tetrachloride at 70° to 75° C. yielded a material containing 77 per cent of chlorine.

The use of chlorinated hydrocarbons in the preparation of flame-proof insulation has been described by Ellis. One method[134] consists in chlorinating solvent naphtha until about 40 to 50 per cent of chlorine by weight has been absorbed, and a crystalline product separates from the mother-liquor. This crystalline chlorinated product is then incorporated with wax, asphalt or similar combustible organic insulating material and imparts to the latter flame-proof qualities. Such a composition is suitable, for example, for use on copper wire. Another method[135] of preparing such compositions is by chlorination of heavy petroleum, for example an "asphaltic oil" such as Mexican petroleum, and incorporating a sufficient quantity of the chlorinated product with a plastic insulating material so as to render the composition flame-proof. Waxes, such as paraffin wax, ceresin wax or Japan wax, can be chlorinated until the quantity of chlorine absorbed is 10 per cent or more. Such chlorinated substances, either alone, admixed with the chlorinated compounds described in the two previous examples, or incorporated with asphalts, pitches, malthas or similar substances, furnish flame-proof insulating materials.[136]

[134] Ellis, U. S. Patent 1,248,638, Dec. 4, 1917; *Chem. Abs.*, 1918, **12**, 412.

Thiele[137] described a method of making drying oils, to be used as linseed oil substitutes, from kerosenes containing large proportions of cyclic hydrocarbons. The first stage in the process is chlorination with moist chlorine.

Deschauer[138] has reported the chlorination of montan wax to yield highly chlorinated products, which may resemble fossil resins, such as copals, when their chlorine content is sufficiently high. He introduced chlorine into a warm mixture of the liquid wax and dilute alkali (10 per cent caustic soda). Chlorinated products of montan wax are claimed to be excellent substitutes for beeswax, i.e., for insulation purposes or floor polish. By changing the chlorine content of the products, their properties may be varied.

In the preservation of fruit while in transit, to the market the fruit is first treated with a mold-inhibiting agent, such as a solution of sodium hypochlorite containing sodium bicarbonate, and then, while still wet, with a shrinkage-retarding film of a coating material which includes "chlorocosane." Chlorocosane, which is made by completely chlorinating paraffin wax, melting point 145° F., contains about 40 to 50 per cent chlorine, and has the consistency of a heavy oil.[139]

The use of chloroparaffin resin as a chewing-gum base has been described by Geller.[140] Examples are: (1) a mixture of soft chloroparaffin resin, hard chloroparaffin resin, and a small proportion of depolymerized rubber; (2) a mixture of fat, fatty acids, chloroparaffin resin and rubber.

Schrauth[141] described the preparation of dry, odorless soaps, soluble in hot water and forming an abundant lather, by alkali fusion of the chlorination products of petroleum fractions. The chlorination is carried only to the monochloro-stage and the monochloro-derivatives are then subjected to alkali fusion at 200° to 300° C. for 6 to 8 hours. Hydrogen is evolved during the process. Under these conditions cetyl chloride yields palmitic acid.

Bosshard and Strauss[142] described the production of certain derivatives (e.g., arylalkyl ethers) from the halogenated aliphatic saturated hydrocarbons containing at least 16 carbon atoms. Thus a *monochloroparaffin* of melting point 35° to 40° C., produced by chlorination of paraffin wax, may readily be condensed with phenol and alkali carbonate to yield *phenoxyparaffin,* a soap-like mass of melting point 60° C., the sulphonic acid of which may be used in tanning. Similarly a dichloroparaffin (melting point 40° to 60° C.) may be condensed with phenol to furnish a *phenoxychloroparaffin.*

The preparation and properties of a synthetic hydrocarbon oil formed by the condensation of a monochlorinated wax and an aromatic hydrocarbon has been described by Davis.[143] The paraffin wax is chlorinated by passing chlorine through it until the chlorine content of the wax is about 10 to 12 per cent. During chlorination the temperature should be above 140° F., but should not exceed 300° F. The chlorinated product is then slowly added to a mixture of equal weights of an aromatic hydrocarbon (e.g., benzene, naphthalene or anthracene) and aluminum chloride. To keep the mixture well stirred during the addition of the chlorinated wax it is necessary that some inert solvent, such as kerosene, should be present and during this operation the temperature is maintained at 140° to 160° F. After the reaction is completed the aluminum chloride sludge is withdrawn and the kerosene and unreacted wax are removed by distillation, using reduced pressures for the latter. The addition of small proportions of the hydrocarbon oil so prepared to wax-bearing lubricating oils greatly reduces the pour point of the latter, thereby eliminating the necessity for severe dewaxing operations. As an example, the addition of 1 per cent of the synthetic hydrocarbon oil to a lubricating oil (from a Pennsylvania crude petroleum) lowered its pour point from 30° F. to below —5° F.

The work of Gardner and Bielouss[144] on the production of drying oils from chlorinated products of higher petroleum fractions is of interest. The chlorination of the high boiling liquid paraffin hydrocarbons was found to proceed smoothly in the absence of catalysts. The chlorinated products may then be dechlorinated by heating to 250° C. without the addition of any catalysts, under which conditions complete removal of chlorine, as hydrogen chloride, can be effected. The products consist of olefins mixed with cyclic hydrocarbons produced by ring closure during the dechlorination. According to Gardner,[145] excellent drying oils are produced by heating chlorinated hydrocarbons, containing 30 to 54 per cent of chlorine, to 240° to 320° C. for periods of 0.5 to 8 hours with small amounts of rosin and fatty acids from linseed oil. During the heating, the chlorine is removed as hydrogen chloride, some water passes off, and the acid number of the reaction mixture decreases continuously. Bielouss[146] stated that a satisfactory drying oil can be made by dechlorinating at 240° C. or lower without a catalyst. Also by successive chlorination and nitration of a mineral oil distillate, of specific gravity not less than 0.882, products are obtained of use in varnishes or pyroxylin compositions.[147]

The chlorination of higher petroleum fractions immediately after these hydrocarbons have been subjected to thermal decomposition has been reported by Messenger[148] to yield chlorohydrocarbons suitable as solvents and raw materials for synthesis. This process, however, is not strictly a substitutive chlorination of saturated hydrocarbons but rather an addition of chlorine to unsaturated hydrocarbons produced by the preliminary pyrolytic treatment.

Lilienfeld[148a] treated cellulose xanthate with di- or poly-halogenated paraffins in which at least 2 halogens are attached to a carbon atom (for example, 1,1-dichloroethane, 1,1-dichlorodimethylmethane) to produce artificial threads. The cellulose xanthate is prepared by xanthating alkali-cellulose which has been treated with a hydroxyalkylating agent such as ethylene chlorohydrin.[148b]

Cone, Davidson and Laucks[149] suggested a mixture of a halogenated paraffin hydrocarbon and a dispersed vegetable protein, such as soya-bean protein, as a suitable water-resistant adhesive, while the I. G. Farbenindustrie A.-G.[150] proposed the manufacture of materials capable of being used as lubricant and greasing agents in the textile and leather industries, by treating halogenated mixtures of paraffin hydrocarbons, containing more than 8 carbon atoms and at least 2 halogen atoms, with caustic alkalies, alkali carbonates or alkaline earths.

Insecticides have been prepared by Goulenko[150a] by mixing chlorinated petroleum compounds with terpenes. Pirard[150b] used a stain-removing composition prepared from crude chlorinated petroleum hydrocarbons, aromatic hydrocarbons, and ether.

BROMINATION OF HIGHER PARAFFINS

From an industrial standpoint, the bromination of paraffin hydrocarbons of 6 or more carbon atoms is of little interest. The available data on this subject are very incomplete and only in a few cases have definite chemical individuals been isolated among the products. Bromine reacts with these hydrocarbons either very slowly or not at all in the cold, but in sunlight, at higher temperatures, and in the presence of catalysts, reaction is more rapid. In all cases bromination is much slower than chlorination.

Hexanes. Monobromides, and dibromo-compounds as well, have been produced from n-hexane. Michael and Garner,[151] using Schorlemmer's method, dropped bromine slowly into the upper part of a reflux condenser while hexane was kept boiling in an attached flask. Reaction took place immediately in sunlight and the main product, boiling at 143° to 146° C., consisted of 2-bromohexane and 3-bromohexane together with some higher boiling products. Herzfelder[152] obtained hexabromohexane by bromination of n-hexane at its boiling point in the presence of iron wire, while Pelouze and Cahours[153] prepared a dibromohexane, boiling point 210° to 212° C., by bromination of liquid n-hexane.

By the bromination of 2,3-dimethylbutane (diisopropyl) at a mild temperature and in sunlight, Silva[154] obtained a crystalline dibromo-compound but no monobromide was isolated.

Heptanes. The bromination of heptane appears to proceed more readily than in the case of the lower paraffins, and the main initial product appears to be a 2-bromoheptane, though more highly brominated products are also obtained. Bromination does not occur in the dark even in the presence of catalysts but the process is rapid at 100° C. or in sunlight. The most complete investigation of this reaction is due to Venable,[155] who used n-heptane from *Pinus sabiniana.* For the production of optimum yields of monobromo-compounds, less than the theoretical amount of bromine was added, as rapidly as it was absorbed, to the gently boiling hydrocarbon. Distillation of the products yielded unchanged heptane, a main fraction of heptyl bromide (25 to 30 per cent of the theoretical), and higher boiling products of polybromo-compounds and their decomposition products. This fraction was difficult to examine on account of its instability. The monobromo-compound fraction, boiling at 165° to 167° C., appeared to be identical with the 2-bromoheptane previously isolated by Schorlemmer. Later attempts to increase the yield of secondary monobromide were unsuccessful.[156]

Chapter 31

Halogenation of Cycloparaffins

The reactions of the cycloparaffin hydrocarbons, containing five- and six-membered carbon rings, with halogens are markedly similar to those of the straight chain paraffins and lead to the production of substitution products containing one or more halogen atoms. Not only are these reactions of the cycloparaffins and paraffins similar in kind but they are also often strikingly alike in degree. Thus, for example, cyclohexane exhibits a degree of reactivity to chlorine and bromine similar to that of n-hexane. In the case of cyclopropane and cyclobutane and their homologues, the substitutive halogenation reaction has also been observed but it is frequently associated with an *addition reaction* leading to the formation of halogenated derivatives of straight chain hydrocarbons and thus involving the rupture of the somewhat unstable three- and four-membered carbon rings. Since however the predominating cycloparaffinic hydrocarbons occurring in crude petroleum, at least in so far as their chemical constitution has been determined, appear to be those possessing cyclopentane or cyclohexane rings, attention is specially directed to the halogenation reactions of these types in the following account.

Perhaps the most striking aspect of the subject of halogenation of these hydrocarbons is the extremely limited character of the information available. Much work on the halogenation of five- and six-membered cycloparaffin hydrocarbons has been carried out with petroleum fractions of doubtful homogeneity while the conditions of halogenation are often incompletely specified. Moreover in relatively few instances have even the primary products of halogenation been definitely identified. Though more work has been carried out on cyclohexane and its immediate homologues, the halogenation reactions of the cyclopentane hydrocarbons, and even of cyclopentane itself, have never been subjected to more than a superficial examination. Under such circumstances, therefore, any account of the halogenation reactions of these hydrocarbons must, of necessity, be quite inadequate. Nevertheless, it has been deemed advisable to collect the available information on this subject in the hope that this long-neglected field of research will be subjected to further investigation. Not only would a more complete investigation of the halogenation reactions of the simple cyclopentane and cyclohexane hydrocarbons be of considerable scientific interest, but it might also open up avenues of technical exploitation of such hydrocarbons, for example, in the production of cyclic secondary alcohols and their derivatives.

Despite the extreme meagerness and oftentimes lack of specificity of much of the work on the halogenation of the cyclopentane and cyclohexane hydrocarbons, the available information permits of a few generalizations. Chlorination appears to take place much more readily than bromination especially in the presence of sunlight or other actinic light. As in the case of the paraffin hydrocarbons, the reaction appears to be of a cumulative nature, prolonged treatment favoring the formation of polychlorinated products. The presence of catalysts also favors multiple substitution. By operating in the presence of actinic light either in the liquid or gaseous phases it appears possible to obtain considerable proportions of monochlorinated products. Mixtures of monochlorinated products of the homologues of cyclohexane have been obtained but the composition of such mixtures has been investigated only in the case of methylcyclohexane. According to the work of Sabatier and Mailhe on the chlorination of this hydrocarbon, monochlorination results in the introduction of chlorine atoms into the ring with the production of both 3- and 2-chloro compounds as well as a trace of the 4-chloro compound. Dichloro and higher chlorinated compounds have also been produced by the direct chlorination of cyclohexane and a number of its homologues but the constitutions of these products have not been determined.

The cyclopentane and cyclohexane hydrocarbons appear to be relatively resistant to the action of bromine. At temperatures above 100° C., however, bromine attacks many of these hydrocarbons with the formation of bromo-derivatives but no monobromides have been definitely obtained. In the presence of catalysts, such as aluminum bromide or iron wire, bromination takes place more readily and, in the presence of excess of bromine, frequently converts cyclohexane hydrocarbons into polybrominated derivatives of the corresponding benzenoid hydrocarbon.

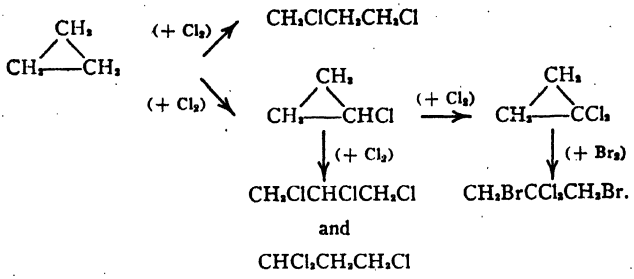
CYCLOPROPANE AND ITS HOMOLOGUES

The photochemical chlorination of cyclopropane has been studied by Gustavson,[1] who found that, though no chlorination occurred in the dark, in direct sunlight the reaction is explosive. Accordingly Gustavson effected the chlorination of cyclopropane in diffused daylight over water in a cooled container. The compounds produced under these conditions included not only mono- and di-chlorinated cyclopropane derivatives but also chlorinated derivatives of propane, showing that there is a tendency for the cyclopropane ring to be ruptured. The straight chain chlorinated products actually found were 1,3-dichloropropane, 1,1,3-trichloropropane, and a relatively small amount of 1,2,3-trichloropropane.[2] *Monochlorocyclopropane* produced by the photochemical chlorination process, was obtained as a liquid of pleasant odor, boiling point 43° C. at 744 mm.[3] On heating the compound with potassium acetate and glacial acetic acid, quantities of allyl acetate were obtained,[4] while it was more readily brominated by bromine in a sealed tube at 16° to 18° C. than dichlorocyclopropane. The *dichlorocyclopropane* obtained in the photochemical chlorination of cyclopropane[5] was considered by Gustavson to be 1,1-dichlorocyclopropane since it could be brominated in sunlight to furnish 2,2-dichloro-1,3-dibromopropane. This bromination reaction is another example of the relative ease with which the cyclopropane ring is ruptured under the influence of chemical reagents. 1,1-Dichlorocyclopropane is a colorless liquid of boiling point 75° C. at 746 mm. and d^{15}_{4} 1.206. It exhibits a much greater stability than monochlorocyclopropane and is not decomposed by metallic sodium at 140° C.

The halogenation of cyclopropane in diffused daylight may be summarized in the following scheme:

---

[1] *J. pr. Chem.*, 1890, (2) **42**, 495; *Chem. Soc. Abs.*, 1891, **60**, 159.
[2] Gustavson, *J. pr. Chem.*, 1894, (2) **50**, 380.
[3] Gustavson, *J. pr. Chem.*, 1891, (2) **43**, 396.
[4] Gustavson, *J. pr. Chem.*, 1892, (2) **46**, 159.
[5] Gustavson, *J. pr. Chem.*, 1890, (2) **42**, 495.



The bromination of cyclopropane has been the object of much study, particularly by Gustavson. In the presence of sunlight, combination of bromine with cyclopropane, either in the dry or moist condition, takes place very rapidly with the production of 1,3-dibromopropane as the sole product.[6] In the dark the bromination of perfectly dry cyclopropane at room temperature proceeds very slowly but the reaction is markedly accelerated by the presence of moisture[7] or of certain bromine carriers, including aluminum halides, ferric chloride, zinc chloride, and elemental iodine. In the presence of hydrogen bromide, which may also act as a catalyst for bromination, the reaction products consist of 1,3- and 1,2-dibromopropanes and their bromination products, as well as some propyl bromide;[8] but when aluminum bromide or ferric chloride is used as catalyst, 1,2-dibromopropane is the predominating material.[9] It is evident, therefore, that the main reaction involved in the action of bromine on cyclopropane is the rupture of the three-carbon ring system with subsequent bromination of the unsaturated system momentarily formed.

Under the influence of halogens, and particularly of bromine, a number of the homologues of cyclopropane undergo simultaneous ring rupture and halogenation with the formation of straight chain derivatives. Thus, bromination of *methylcyclopropane* in the absence of light leads mainly to 1,3-dibromobutane besides, possibly, 1-bromo-1-methylcyclopropane and 1,3,3-tribromobutane.[10] Similarly, the action of bromine on *1,1-dimethylcyclopropane* yields trimethylethylene dibromide.[11]

Cyclobutane. Apparently very little is known about the halogenation of the cyclobutane series of hydrocarbons, though cyclobutane is stated to be stable to bromine in chloroform in the cold.[12] In the bromination of the dihalogen derivatives of cyclobutane, the marked tendency for the occurrence of rupture of the carbon ring system, previously noticed in the case of cyclopropane derivatives, is also observable. Thus, 1,2-dichloro-cyclobutane is converted by heating with bromine at 60° C., and later at 100° to 110° C. in the presence of iron powder, into a mixture of dichlorodibromo-butane, dichlorotribromo-butane, and dichlorotetrabromo-butane. Similarly, 1,2-dibromo-cyclobutane may be brominated by heating with bromine in the presence of iron powder, or of iodine, to furnish a mixture of polybrominated butanes.

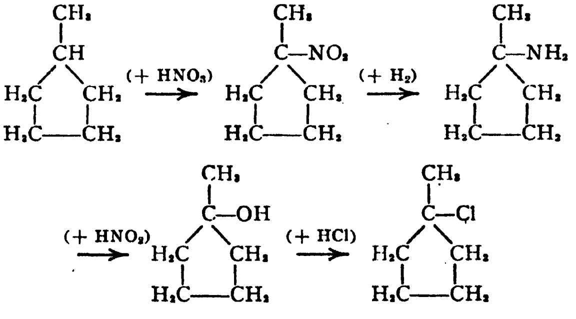
CYCLOPENTANE

There is apparently no published record of an experimental investigation of the chlorination of cyclopentane. In view of the undoubted presence of this hydrocarbon in many crude petroleums, a careful study of its halogenation reactions may prove of interest. A number of chlorinated cyclopentanes have been obtained indirectly, e.g., monochlorocyclopentane from cyclopentanol and hydrogen chloride;[13] a trichloro-compound from chlorocyclopentene; and a tetrachloride by chlorination of cyclopentadiene in chloroform solution at —15° C.[14]

Although cyclopentane is inert to bromine in the dark, exposure of a mixture of bromine and this hydrocarbon to sunlight results in substitution, with evolution of hydrogen bromide, at about the same rate as in the case of n-pentane. Even at 100° C. the dark reaction with bromine in a sealed tube is very slow but at 128° to 130° C. the reaction is more rapid and leads to the production of bromination products together with some carbon deposition.[15]

METHYLCYCLOPENTANE

Very little is known of the halogenation reaction of the homologues of cyclopentane. Markownikow[16] observed that methylcyclopentane was energetically chlorinated on introducing chlorine into the hydrocarbon at ordinary temperature and in diffused daylight. A mixture of chlorides was obtained but no definite individual compound could be isolated. Markownikow synthesized the tertiary monochloride, i.e., 1-chloro-1-methylcyclopentane, by means of the following series of reactions, starting with the tertiary nitro-compound.

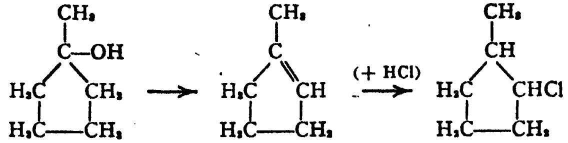


The tertiary monochloride was obtained as a liquid (boiling point 97° C. at 349 mm., or 122° to 123° C. at 757 mm.) which was partly decomposed at higher temperatures with the evolution of hydrogen chloride and the production of an unsaturated hydrocarbon of the formula C_6H_{10}.

Another monochloride was also synthesized by Markownikow by the following series of steps, starting with the tertiary alcohol:

---

[13] Zelinsky, *Ber.*, 1908, 41, 2627.
[14] Kraemer and Spilker, *Ber.*, 1896, 29, 555.
[15] Wislicenus and Hentzschel, *Ann.*, 1893, 275, 322.
[16] *Ann.*, 1899, 307, 335.



The resulting monochloride, namely 2-chloro-1-methylcyclopentane, boiled at 126° S. and had d_0^0 0.9281.

CYCLOHEXANE

Chlorination. The chlorination of cyclohexane has been the subject of a number of important researches. Markownikow [17] obtained *monochlorocyclohexane*, a liquid boiling at 142° C. at 750 mm., by the action of moist chlorine on the cold hydrocarbon in diffused sunlight. When dry chlorine gas was employed it became necessary to heat the hydrocarbon to near its boiling point in order to obtain a reaction but this procedure also resulted in the formation of polychloroderivatives. On fractionating the less volatile products from the chlorination of cyclohexane Markownikow was able to isolate what he considered to be two isomeric *dichlorocyclohexanes*, one boiling at 192° to 194° C. and having d_{15}^{15} 1.167, and the other of boiling point 196° to 198° C. and d_{15}^{15} 1.172.

A careful examination of the chlorination of cyclohexane has been recorded by Fortey.[18] The hydrocarbon was placed in a reflux apparatus together with a small quantity of iron filings and exposed to direct sunlight while a current of dry chlorine was passed through the liquid at room temperature. The reaction commenced in about one-quarter hour, the liquid became warm, and hydrogen chloride was evolved. After several hours the product was washed and yielded on distillation under reduced pressure a mixture of dichloro-derivatives, boiling point 110° to 115° C.; trichloro-compounds, boiling point 135° to 140° C.; and tetrachloro-derivatives, boiling point 160° to 165° C.; all under 30 mm. pressure. No monochlorinated cyclohexane was produced by Fortey on chlorination in the presence of the iron catalyst. The monochloride, however, was prepared, together with dichloro-cyclohexanes, by passing dry chlorine into cyclohexane in the cold in diffused daylight. Chlorination in the dark could not be effected while the application of heat or the employment of chlorine carriers (catalysts) gave rise to the formation of higher substitution products such as di-, tri-, and tetra-chlorocyclohexanes. Fortey observed that when chlorine was passed into cyclohexane in diffused daylight in the cold, it dissolved, forming initially a yellow solution; at a certain stage, combination began, heat was developed, and hydrogen chloride evolved. If from this point, chlorine was passed slowly for about 3 hours, a good yield of the monochloride was obtained.[19] The product was washed with sodium carbonate solution, then with water, and dried over calcium chloride and finally distilled. Monochlorocyclohexane was the fraction boiling at 141.3° to 141.6° C. at 768 mm., and having d_0^0 0.991. A purified dichlorocyclohexane fraction boiled at 193° to 194° C. while a third fraction boiling very constantly at 201° to 202° C. also gave analytical figures in agreement with those required by a dichloride. It appears very probable that the direct chlorination of cyclohexane furnishes more than one dichlorocyclohexane.

---

[17] *Ann.*, 1898, 302, 1.

[18] *J.C.S.*, 1898, 73, 932.

[19] Similar observations were made by Schorlemmer (*Ann.*, 1877, 188, 250) in the case of the chlorination of isoheptane. The results obtained by Fortey may be explained on the basis of the chain mechanism theory of the chlorination of saturated hydrocarbons and the known inhibiting effects of traces of oxygen. After the oxygen has been used up in breaking reaction chains the inhibitory effect disappears. (Hass, private communication.)

Sabatier and Mailhe[20] carried out the chlorination of cyclohexane (prepared by the catalytic hydrogenation of benzene) by the passage of chlorine into the hydrocarbon cooled to 0° C. in diffused sunlight. Energetic substitution was found to take place under these conditions with the production of mono-, di-, tri-, and tetrachlorinated products. The presence of iodine monochloride or antimony chloride exerted no influence on the reaction but aluminum chloride caused the formation of condensed products. Fractionation of the products of the chlorination of cyclohexane in diffused light at 0° C. yielded the following: (a) A monochlorocyclohexane, boiling point 141.6° to 142.6° C. at 749 mm. and having d_0^0 1.0161. (b) Two isomeric dichlorocyclohexanes; one boiling in two equal fractions at 105.4° to 106.4° C. (d_0^0 1.2056) and 106.4° to 107.4° C. at 50 mm. (d_0^0 1.2060), and the other boiling at 112.4° to 113.4° C. at 50 mm. (d_0^0 1.2222). The latter is probably a 1,2-dichloride. (c) Two *liquid* trichlorocyclohexanes, boiling at 139.5° to 141.5° C. at 50 mm. (d_0^0 1.3535) and 143.5° to 145.5° C. at 50 mm. (d_0^0 1.3611), as well as a *solid* trichlorocyclohexane of melting point 66° C., boiling point 150.4° to 151.4° C. at 50 mm., and d_0^0 1.5103. The latter compound is probably a symmetrical, or 1,3,5-trichloro-derivative, since it yielded benzene on heating with alcoholic potash at 100° C.

The continued action of chlorine on cyclohexane in sunlight led to the formation of a liquid and a solid tetrachloro-compound. The solid tetrachloride was crystalline and melted at 173° C.

Using Sabatier and Mailhe's method of chlorination, Faragher and Garner[21] converted cyclohexane into a mixture of the mono- (boiling point 139° to 144° C. and d_0^{20} 1.002), di- (boiling point 75° to 85° C. at 15 mm., and d_0^{20} 1.179), and tri-chlorides (boiling point 96° to 105° C. at 15 mm. and d_0^{20} 1.266).

The properties of the mono- and di-chlorides are of considerable interest. Monochlorocyclohexane may be readily converted into cyclohexene, with elimination of hydrogen chloride, by heating that chlorohydrocarbon with quinoline or alcoholic potash, and, to lesser extent, with silver oxide or silver acetate. The best yield of cyclohexene was obtained by Fortey by refluxing it with quinoline for 7 to 8 hours. The elimination of hydrogen chloride can also be accomplished by vapor phase decomposition with or without catalysts. With metallic magnesium in dry ethereal solution monochlorocyclohexane yields, besides dicyclohexyl, a Grignard compound which can be converted into a carboxylic acid[22] or a sulphonic acid[23] by decomposition with carbon dioxide or sulphur dioxide, respectively.

The higher chlorinated cyclohexanes are also decomposed by hot alkalies with the production of unsaturated or benzenoid substances. Cyclohexadiene was obtained by Fortey by distilling dichlorocyclohexane with quinoline. The solid trichlorocyclohexane yielded benzene on being heated with alcoholic potash under pressure at 100° C. while under similar conditions solid tetrachlorocyclohexane was converted into chlorobenzene.

Bromination of Cyclohexane. According to Markownikow,[24] bromine reacts with cyclohexane in sealed tubes at 110° C., but the monobromo-compound is not produced. When the halogen and hydrocarbon are employed in molecular proportions about 50 per cent of the hydrocarbon remains unchanged, the remainder being converted into polybrominated products. In the presence of aluminum bromide a product is formed which melts at 120° to 121° C. and is apparently a mixture of the compounds $C_6H_2Br_8$ and $C_6H_3Br_7$. This product was identical with that previously obtained by Kistner from methylpentamethylene, bromine and aluminum bromide, and probably represents a conversion of the hexamethylene into the pentamethylene ring. Fortey was unable to isolate any definite bromination products from the action of bromine on cyclohexane but produced pure monobromocyclohexane by the combination of cyclohexane and hydrogen bromide.

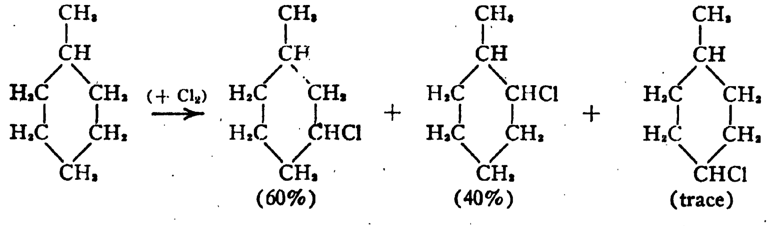
At higher temperatures and on prolonged treatment, cyclohexane is converted by bromine into brominated derivatives of benzene. Zelinsky[25] obtained symmetrical 1,2,4,5-tetrabromobenzene by heating 2 grams of cyclohexane and 36 grams of dry bromine in a sealed tube at 150° C. and finally at 200° C. for several days.

METHYLCYCLOHEXANE

Chlorination. The chlorination of methylcyclohexane was examined by Markownikow[26] and was considered by him to give rise to a mixture of the tertiary monochloride, 1-chloro-1-methylcyclohexane, boiling point 148° to 151° at 752 mm. (with decomposition), together with another chloride boiling at 155.5° to 157.7° C. under 740 mm. pressure. Almost simultaneously, Sabatier and Mailhe[27] made a careful examination of the mixed monochlorides, boiling point 157° to 159° C., produced by the chlorination of methylcyclohexane at ordinary temperatures. To ascertain the nature of the products formed in this chlorination, Sabatier and Mailhe prepared all of the five possible monochloro-derivatives and, from the data obtained, concluded that neither 1-chloro-1-methylcyclohexane nor hexahydrobenzyl chloride was present in the chlorinated product. The mixture of monochlorides prepared by the direct chlorination of methylcyclohexane was converted by Grignard's method into the magnesium methylcyclohexyl chlorides, which, on prolonged oxidation in a current of pure dry oxygen followed by treatment with cold water, gave the alcohols corresponding with the chloro-derivatives. From the results of the examination of these alcohols, it was concluded that the monochlorides formed in the direct chlorination of methylcyclohexane consist of about 40 per cent 2-chloro-1-methylcyclohexane, and about 60 per cent 3-chloro-1-methylcyclohexane, together with a small proportion of 4-chloro-1-methylcyclohexane.



Like other monohalides of the cycloparaffins, the monochloro methylcyclohexanes may be readily decomposed to yield hydrogen chloride and the corresponding methylcyclohexene. The tertiary chloride is particularly readily decomposable and cannot be distilled at ordinary pressure without profound decomposition into an olefin and hydrogen chloride. These monochlorides readily yield Grignard compounds which on treatment with carbon dioxide are converted into carboxylic acids.[28]

Bromination. According to Markownikow,[29] methylcyclohexane is resistant to the action of bromine in diffused light. Even in direct sunlight at temperatures of about 100° C., bromine exerts only a slow reaction on the hydrocarbon but bromination occurs readily at 115° C. In the presence of aluminum bromide, dry bromine reacts readily with methylcyclohexane forming pentabromotoluene.[29, 30]

CHLORINATION OF THE HIGHER HOMOLOGUES OF CYCLOHEXANE

From a fraction of Balachany (Caucasian) gasoline with a boiling range from 116° to 120° C., Markownikow and Oglobin[30a] isolated *1,3-dimethylcyclohexane,* the constitution of which was proved by its nitration to trinitro-m-xylene and by its conversion to m-xylene on heating with sulphur at 220° C. The chlorination of this hydrocarbon was studied by employing Schorlemmer's method.[31] Besides a dichloride fraction boiling at 225° to 235° C. a mixture of monochlorides of the formula $C_8H_{15}Cl$ was also produced. Fractionation of the monochloride mixture resulted in the separation of the following fractions, which were thought to be isomeric substances but were of doubtful homogeneity:[32]

Monochloride, boiling point 174° to 176° C., d_{20}^{20} 0.9374.

Monochloride, boiling point 169° to 171° C., d_{20}^{20} 0.9247.

None of the other isomeric dimethylcyclohexanes seems to have been chlorinated but an *isooctanaphthene,* C_8H_{16}, of unknown structure was isolated by Putochin[33] from Caucasian light petroleum. Chlorination of this hydrocarbon was found by Pautinsky[34] to result in the production of a mixture of monochlorides, which was fractionated to give two fractions, one of boiling point 176° to 179° C. and d_0^0 0.9680, and the other of boiling point 179° to 182° C. and d_0^0 0.9734. Here again the chemical homogeneity of these preparations is very doubtful.

Of the cyclohexane homologues with nine carbon atoms (nonanaphthenes), *1,2,4-trimethyl-cyclohexane* was isolated by Markownikow and Oglobin and also by Konowalow[35] from Caucasian petroleum. The same hydrocarbon was also found by Ahrens and von Mozdzenski[36] in the xylene fraction of high temperature coal tar. Konowalow chlorinated his specimen of this hydrocarbon (boiling point 135° to 137° C.) in the vapor phase, employing dry reagents and obtained a mixture of *monochlorides* which was resolved into two fractions by distillation, together with a dichloride fraction, boiling at 230° to 235° C. One fraction of the monochloride boiled at 185° to 187° C. and the other at 182° to 184° C. The dichloride, d_0^0 1.1035, on heating with sodium acetate and acetic acid for five hours at 200° C. yielded considerable amounts of an unsaturated hydrocarbon[37] of the formula C_9H_{14}.

Ahrens and von Mozdzenski[38] also submitted a specimen of *1,2,4-trimethylcyclohexane* (isolated from the xylene fraction of coal tar) to chlorination in diffused daylight at 30° C. and obtained a mixture of monochlorides of the formula $C_9H_{17}Cl$, as a liquid of pungent odor boiling at 103° to 104° C. under 40 mm. and having d^{20}_4 0.9229. The constitution of these chlorinated products is quite unknown.

The chlorination of *decanaphthenes* ($C_{10}H_{20}$) of established constitution has been studied in one case, namely in that of p-menthane, or *1-methyl-4-isopropylcyclohexane*. Berkenheim[39] chlorinated this hydrocarbon in the vapor phase and obtained a liquid monochloride boiling at 208° to 210° C. and of d^0_0 0.9553. The constitution of this monochloride is unknown, and its homogeneity doubtful. A decanaphthene fraction of Caucasian petroleum boiling at 160° to 162° C. and designated *α-decanaphthene* by Zubkoff[40] was chlorinated in the presence of water. The products consisted of monochlorides (boiling point 206° to 209° C.), dichlorides (boiling point 160° to 165° C. at 60 mm.), as well as trichlorinated and higher chlorinated products. When heated with sodium acetate and acetic acid at 200° C. the monochloride fraction yielded an unsaturated hydrocarbon, $C_{10}H_8$, and also the acetate of a decanaphthenol, which could be hydrolyzed to the alcohol. The *dichloride* fraction was decomposed by heating with quinoline to furnish an unsaturated hydrocarbon of the formula $C_{20}H_{16}$, boiling at 162° to 170° C.

Another decanaphthene, called *β-decanaphthene*, boiling at 168.5° to 170° C. at 752 mm., has been isolated from Baku petroleum.[41] This hydrocarbon, which is probably identical with *1,3-dimethyl-5-ethylcyclohexane*, was converted by the action of moist chlorine into a mixture of (at least) two monochlorides as well as a dichloride.[42] The monochlorides, one of which boiled at 213° to 216° C. at 760 mm. and the other at 216° to 219° C. at the same pressure, were converted into the unsaturated decanaphthylene, $C_{10}H_{18}$, to the extent of 44 per cent and 76 per cent by heating with sodium acetate at 250° C. and with quinoline, respectively. The dichloride fraction boiled at 164° to 167° C. under 60 mm. pressure.

A few higher boiling petroleum fractions, corresponding in composition to some of the higher cycloparaffins but of unknown structure, have been subjected to chlorination. A fraction of Baku petroleum boiling at 179° to 181° C. and possessing the formula $C_{11}H_{22}$ (*undecanaphthene*) was chlorinated with dry chlorine, in the vapor phase at the temperature of its boiling point, and in the presence of sunlight; the resulting product was a mixture of isomeric *monochlorides* boiling at 210° to 225° C. This monochloride mixture could be converted mainly into an unsaturated hydrocarbon $C_{11}H_{20}$ (boiling point 166° to 180° C.) by heating with alcoholic potash and was decomposed by heating with water in a sealed tube.

Mabery and his collaborators[43] have chlorinated a number of high boiling fractions of Californian and Canadian petroleums having compositions agreeing with the formula C_nH_{2n}. Since these hydrocarbons were fully saturated, it must be concluded that they belong to the cycloparaffin series though their constitutions were not determined. Chlorination was effected in most cases by passing chlorine into the hydrocarbon material floating on water. Table 122 shows the results of Mabery and Sieplein[44] on the chlorination of various naphthenic constituents of Californian petroleum:

BROMINATION OF THE HIGHER HOMOLOGUES OF CYCLOHEXANE

Little is known regarding the bromination of the higher cyclohexane hydrocarbons in the absence of aluminum bromide or similar catalysts. At low temperatures bromine does not appear to react with these hydrocarbons while at higher temperatures polybrominated products and brominated derivatives of benzenoid hydrocarbons are produced. *1,3-Dimethylcyclohexane* does not react with bromine at room temperature[45] but, according to Knoevenagel and MacGarvey,[46] combination takes place with evolution of hydrogen bromide on warming. No monobrominated products of the cyclohexane hydrocarbons have been prepared by direct bromination.

In the presence of aluminum bromide as a catalyst, bromine reacts vigorously with the higher cyclohexane hydrocarbons to furnish good yields of polybrominated compounds corresponding to the analogous benzene hydrocarbon. Since these latter compounds are usually well-defined crystalline solids, this reaction affords a valuable general method of identifying cyclohexane hydrocarbons of unknown structure, and has been used extensively for this purpose.[47] Instead of aluminum bromide, iron powder is said to be quite satisfactory in the bromination of 1,2,4-trimethylcyclohexane to tribromopseudocumene.

[47] For example, Morgan (*J.S.C.I.*, 1932, **51**, 67T) has employed this method in the identification of the cyclohexane derivatives in low temperature tars.

Chapter 32

Halogenation of Benzene and Its Immediate Homologues

The following account of the halogenation reactions of benzene and its homologues is necessarily a very brief résumé of a vast field which has received attention from a large number of investigators from the early days of organic chemistry until the present time. The chlorination reactions of these hydrocarbons are discussed more fully than those of bromination since the latter are at present of little significance from an industrial standpoint.

The technical applications of the chlorination reactions of aromatic monocyclic hydrocarbons are almost entirely centered around the production of monochlorobenzene from benzene and of benzyl and benzal chlorides from toluene. The pyrolysis of petroleum has also yielded aromatic hydrocarbons (Chapter 5). Hitherto, the only commercial source of aromatic hydrocarbons has been coal tar obtained by the high temperature carbonization of bituminous coal. The possibilities of utilizing certain petroleum fractions as sources of toluene were fully explored during the World War when large quantities of that hydrocarbon were extracted from certain petroleums for conversion into TNT. The extraction of individual aromatic hydrocarbons in a pure state from petroleum presents difficulties even when petroleum fractions very rich in aromatic constituents are available. Most of the work on the chlorination of aromatic hydrocarbons has been carried out on fairly pure materials and little is known as to the possibilities of using fractions of petroleum rich in aromatics as sources of chlorinated aromatic substances. In view of the greater reactivity of the aromatic hydrocarbons in the absence of light and in the presence of certain halogen carriers, the selective chlorination of the aromatic constituents of a mixture of such hydrocarbons and saturated hydrocarbons of the paraffin type appears to be a possibility. It would be of interest to determine to what extent it is possible to chlorinate benzene or toluene mixed with paraffinic hydrocarbons without the latter suffering chlorination.

Benzene reacts with halogens (bromine and chlorine) both by addition and by substitution, but toluene and the higher homologous alkylbenzenes undergo substitution almost exclusively. In the latter case, however, the substitution reaction can take place either in the aromatic nucleus or in the paraffinic side chain. The most remarkable feature of this field of halogenation is the extraordinary influence exerted by the conditions of reaction on the relative distribution of substitution between nucleus and side chains. The important factors operating in this way are temperature, illumination, catalysts, and also to a lesser degree the concentration of the reactants and the nature of the diluting medium, if any. Exposure to illumination and high temperatures favor substitution in the side chain, and low temperatures, absence of light, and, above all, the presence of the usual halogen carriers, promote nuclear substitution. Many halogen carriers, such as iodine, iron, or aluminum halides, exert such a powerful influence not only on the rate of nuclear substitution but also on the type of substitution that all other factors are completely nullified; no substitution whatever occurs in the side chain and the products are exclusively nuclear substituted derivatives.[1]

The mechanism of the action of halogen carriers seems to depend upon the formation of an addition compound with the halogen, which is then liberated under the conditions of halogenation in a more active state than before. This view is supported by the fact that aromatic hydrocarbons may be chlorinated in the nucleus by compounds such as iodine mono- and trichloride, ferric chloride, antimony pentachloride and molybdenum pentachloride, even in the absence of any free chlorine. The function of the chlorine in these processes appears to be, therefore, the constant regeneration of the original compound which effects the actual chlorination.

To account for the extraordinary influence of the conditions of halogenation on the type of substitution, a number of theories have been advanced. Bruner [1a] made the suggestion that side chain substitution is caused by interaction with molecular halogen and nuclear substitution results from the action of atomic halogen. On the other hand, Holleman [1b] believed that, whereas molecular halogen is responsible for side chain substitution, nuclear substitution occurs by interaction with a perhalide of the type HBr_x, a view also favored by Cohen.[1c] The view that nuclear substitution is caused by the action of ionized halogen atoms is now gaining favor. Schluederberg [2] pointed out that each of the halogen carriers mentioned above can dissociate with the production of negatively charged halogen atoms, thus:

$$ICl \longrightarrow I^+ + Cl^-$$

$$FeCl_3 \longrightarrow FeCl_2^+ + Cl^-$$

and hence he believed that nuclear chlorination of benzene is due to the action of negatively charged halogen. Schluederberg's theory also accounts for the nuclear substitution which occurs in the electrochemical chlorination of aromatic hydrocarbons since electrolytic chlorine may be considered to be negatively charged.

Directly opposed to the theory of Schluederberg is that of Fry,[3] who believed that nuclear substitution of aromatic hydrocarbons is effected by halogen atoms bearing a positive charge. The fact that the presence of moisture promotes nuclear substitution with toluene has been explained by Fry on the basis of his theory as follows: Chlorine first reacts with water to yield HCl and HOCl, and the latter then acts as a source of positive chlorine, HO^-Cl^+, which replaces a positive hydrogen in the ring.

THE CHLORINATION OF BENZENE

Chlorine can react with benzene in two entirely different ways, depending upon the conditions of chlorination. In the absence of the usual catalysts (halogen carriers) the photochemical reactions lead to a purely *addition* reaction with the formation of a hexachlorocyclohexane, according to the equation, $C_6H_6 + 3Cl_2 \rightarrow C_6H_6Cl_6$. The direct addition reaction also takes place when chlorine is passed into boiling benzene in the absence of catalysts. Passage of ethylene into a mixture of benzene and chlorine, in the dark, results in the formation of hexachlorocyclohexane (of which the α-form melting at 157° C. predominates) together with some substitution products.[4] On the other hand, chlorination of benzene in the presence of practically all usual halogen carriers yields exclusively chlorine *substitution* derivatives of that hydrocarbon, irrespective of whether the process is carried out in light or at the boiling point of the hydrocarbon. The substitution reactions, which are far more important than the addition reaction, may be represented by the following series of stepwise equations:

---

[1] Phosphorus halides appear to accelerate chlorination in aliphatic side-chains rather than in aromatic nuclei (see Erdmann, *Ann.*, 1893, 272, 148; *Chem. Soc. Abs.*, 1893, 64 (1), 160; Marckwald, U. S. Patent 721,961, Mar. 3, 1903; British Patent 17,695, 1902; *J.S.C.I.*, 1903, 22, 945).

By intensive chlorination in the presence of catalysts, tetra-, penta-, and hexachlorobenzenes may be obtained.

Although chlorine carriers accelerate the substitution reaction to the total exclusion of the addition reaction, the former can be accomplished without the aid of catalysts, i.e., by electrochemical chlorination or by chlorination at high temperatures in the vapor phase, both of which result in the formation of substitution products.

The chlorination of benzene can also be accomplished by subjecting that hydrocarbon to the action of certain substances capable of furnishing chlorine such as, for example, sulphuryl chloride, sulphur monochloride, or ferric chloride. All these reagents combine with benzene to yield substitution products exclusively.

Photochemical Chlorination. The velocity of the reactions of benzene with chlorine in the total absence of catalysts and in the dark is exceedingly small and, since traces of impurities or even the influence of the surface of the containing vessels may appreciably accelerate such reactions, exact measurements are difficult. According to Berthelot and Jungfleisch,[5] chlorine and benzene do not react in the dark to any appreciable extent below 300° C. A number of earlier workers obtained the lower melting form of 1,2,3,4,5,6-hexachlorocyclohexane by treatment of benzene with chlorine in direct sunlight at room temperature.[6] This hexachloro-derivative exists in two stereoisomeric forms, both of which are obtained by introducing chlorine into boiling benzene in the presence of light.[7] Although the direct addition of chlorine to benzene to yield hexachlorocyclohexane should proceed through the intermediate formation of a dichloride and a tetrachloride, these compounds have never been isolated from the reaction products, probably because they combine with chlorine at a much greater speed than does benzene itself.

The photochemical chlorination of benzene has been the subject of an intensive study by Luther and Goldberg,[8] who have shown that the reaction is powerfully inhibited by the presence of even a small amount of oxygen. Benzene free from dissolved oxygen was speedily chlorinated at ordinary temperatures when exposed to light from a "Uviol" lamp.[8a] The kinetics of the photochemical reaction between chlorine and benzene at 25° C. have been investigated by Slator,[9] who stressed the difficulty of removing the last traces of chlorine carriers from the sphere of reaction. In the absence of chlorine carriers the velocity of the photochemical reaction was found to be very small but Slator failed to realize the important inhibitory action of oxygen on this reaction.

Catalytic Chlorination. A large amount of work has been carried out on the catalytic chlorination of benzene in the liquid phase. In the presence of a chlorine carrier, the absorption of chlorine is very rapid even at 0° C. and the products consist exclusively of substitution derivatives of benzene. The catalytic chlorination of benzene is now carried out on a large scale for the production of monochlorobenzene and iron is used as a catalyst. The chlorination process under these conditions is cumulative and if carried to completion yields hexachlorobenzene. Although iron is employed as a catalyst almost exclusively in the technical chlorination of benzene, laboratory experiments have shown that a large number of other substances are capable of exerting a powerful catalytic action on the reaction. Among these may be mentioned iodine, molybdenum pentachloride, vanadium tetrachloride, aluminum chloride, tin tetrachloride, thallic chloride, and amalgamated aluminum.

One of the earliest discovered catalysts for the substitutive chlorination of benzene was *elemental iodine*. By treating benzene in the cold with rather less than two atomic proportions of chlorine, Jungfleisch[10] obtained monochlorobenzene. Continued chlorination in the cold and in the presence of iodine and water furnished p-dichlorobenzene[11] as well as a little o-dichlorobenzene[12] but prolonged chlorination in the presence of iodine at elevated temperatures was found by Jungfleisch[13] to give rise to a mixture of higher chlorinated substitution products of benzene including 1,2,4-trichloro-, 1,2,4,5-tetrachloro-, pentachloro-, and hexachloro-benzenes.

The catalytic activity of molybdenum pentachloride on the chlorination of aromatic hydrocarbons was discovered by Aronheim,[14] who considered that this carrier was preferable to iodine since it acts very rapidly and uniformly and is more readily separated from the products of reaction. Thus anhydrous benzene, containing about 1 per cent of its weight of molybdenum pentachloride, when heated on the water bath completely absorbed a rapid stream of chlorine. On cooling the resulting liquid solidified to a crystalline mass which, after washing with ammonia, was found to consist mainly of p-dichlorobenzene with no monochlorobenzene or unchanged hydrocarbon.

In connection with the catalytic chlorination of benzene the early work of Willgerodt[15] is of importance. This investigator pointed out that the chlorination reaction was greatly accelerated by the presence of elements whose chlorides were readily capable of giving up part of their chlorine. Iron, antimony and tin were found to be active and also, to a less extent, bismuth, arsenic and amorphous phosphorus. Later[16] it was found that, although metallic indium did not at first accelerate chlorination, as soon as it was partly converted into its chloride an immediate catalytic influence was noted and the product then consisted mainly of p-dichlorobenzene. An immediate acceleration of the chlorination reaction occurred with metallic gallium and the products consisted of mono- and di-chlorobenzenes together with a little hexachlorocyclohexane. Willgerodt considered that the catalytic power of various elements in the chlorination of aromatic hydrocarbons was a function of their atomic weights (being greatest with elements of highest atomic weight), provided that the elements were capable of combining with chlorine. In a later publication Willgerodt[17] gave the results of a comprehensive investigation of the catalytic influence of various elements and their chlorides on the chlorination of benzene in the dark. The results are briefly summarized below, substitution products being formed in all cases.

[8a] The use of ultraviolet radiation in the halogenation of aromatic hydrocarbons was also discussed by Ellis and Wells, "The Chemical Action of Ultraviolet Rays," Chemical Catalog Co., Inc., New York, 1925, 195.

Zirconium	"very active"
Molybdenum	
Tellurium	
Iodine	
Columbium and its chlorides	active
Tantalum and its chlorides	
Uranium and its chlorides	
Lanthanum	slightly active
Vanadyl chloride	
Thorium and its chloride	almost inactive

The following elements, or their chlorides, were found to be *quite inactive:* yttrium and its chloride, titanium, germanium and its chloride, cerium and its chloride, didymium, chromic chloride, and sulphur monochloride.

The catalytic influence of thallic chloride on the substitutive chlorination of benzene has been noted by Thomas[18] and that of tin by Pétricou.[19] The chlorination of benzene in the presence of anhydrous aluminum chloride has been studied by Mouneyrat and Pouret,[20] who found that this compound exerts a great accelerating influence on the reaction. Chlorine was rapidly absorbed when passed into dry benzene, containing 3 per cent of aluminum chloride, at 50° to 55° C. When one molecular proportion of chlorine was absorbed, the products were found to consist of monochlorobenzene and a mixture of the three dichlorobenzenes together with some unreacted benzene. Further chlorination of benzene or of mono- or di-chlorobenzenes under similar conditions gave a mixture of higher chlorinated substitution products, in which three trichlorobenzenes, 1,2,4,5-tetrachlorobenzene, pentachlorobenzene, and hexachlorobenzene were found.

An investigation of the chlorination of aromatic compounds in the presence of the aluminum-mercury couple has been recorded by Cohen and Dakin.[21] On passing chlorine into 50 grams of anhydrous benzene containing 0.5 gram of the aluminum-mercury couple, the whole being cooled in ice, the benzene became first yellow, then rapidly turned dark violet and large quantities of hydrogen chloride were evolved, the couple remaining practically unattacked. The process was stopped when the benzene had increased in weight by 13 grams. Distillation of the products gave the following fractions:

Below 127° C.	4 grams
127° to 137° C.	50 grams
137° to 160° C.	5 grams
Above 160° C.	4 grams

The amount of crude monochlorobenzene corresponds to about 70 per cent of the theoretical yield while p-dichlorobenzene was isolated from the residue boiling above 160°. Cohen and Dakin also studied the chlorination of chlorobenzene in the presence of an aluminum-mercury couple. Chlorination of 10 grams of crude monochlorobenzene in 10 grams of carbon tetrachloride yielded 14 grams of product boiling at 130° to 230° C. and consisting of 1,2,4,5-tetrachlorobenzene together with some trichlorobenzene, probably the 1,2,4-compound. A theoretical yield of hexachlorobenzene was obtained by further chlorination of the tetrachlorobenzene in the presence of amalgamated aluminum.

According to Lowy and Frank,[22] the chlorination of benzene to monochlorobenzene is accelerated by the presence of *water*.

As previously stated, in industrial practice iron is generally used as a catalyst for the chlorination of benzene to chlorobenzene. Mixtures of finely divided iron and ferric chloride have been stated to catalyze the reaction more completely than iron itself. In order to prevent the formation of dichlorobenzene, a deficiency of chlorine is usually employed (i.e., about 40 parts of chlorine are introduced per 78 parts of benzene instead of the theoretical 71 parts of chlorine, so that an excess of benzene remains unchanged after chlorination) and the temperature is not allowed to rise above a certain limit, which is usually considered to be about 40° C. In practice, about 60 per cent of the theoretical quantity of chlorobenzene can be obtained in one operation, the excess of benzene being recovered for re-chlorination. The results of three experiments[23] on the chlorination of benzene in the presence of 0.5 per cent of iron at a temperature not exceeding 40° C. are given in Table 125.

TABLE 125.—*Chlorination of Benzene in the Presence of Iron.*

	1	2	3
Benzene (parts by weight)	80	80	80
Increase in weight to	89	97	118
Fractionation of Products			
B.p. up to 100° C.	60	35	—
100° to 120° C.	6	25	—
120° to 140° C.	23	28	50
Above 140° C.	—	—	60
Residue	—	9	8
	89	97	118

Refractionation of the products of the second experiment yielded 35 parts of benzene, 10 parts of partially chlorinated benzene, 40 parts of chlorobenzene of boiling point 128° to 134° C., and 5 to 10 parts of dichlorobenzene. The third experiment furnished a considerable amount of dichlorobenzene.[24]

According to Bourion,[25] in the industrial chlorination of benzene in the presence of iron as a catalyst, the yield of monochloro-derivative increases with the velocity of chlorination but decreases slightly with rise in temperature. For a given concentration and a given temperature, the molar proportion of benzene converted into monochlorobenzene is about 8.5 greater than the molar proportion of benzene converted into p-dichlorobenzene.

Pyridine bases have also been used as halogen carriers in the chlorination of benzene. Cross and Cohen[26] obtained 30 parts of chlorobenzene together with some dichlorobenzene by bubbling chlorine through 50 parts of benzene at 50° C. containing a small proportion of pyridine. Similar results were obtained with other hydrocarbons (toluene and naphthalene), with another halogen (bromine), and with other bases (quinoline and isoquinoline).

[24] In connection with the use of iron in the chlorination of aromatic hydrocarbons, it is of interest to note that Fierz-David (*Naturwissenschaften*, 1929, **17**, 13; *Chem. Abs.*, 1929, **23**, 1886) observed that iron mixed with about 0.10% of iodine was a most powerful catalyst for chlorination reactions.

[25] *Compt. rend.*, 1920, **170**, 1319; *J.S.C.I.*, 1920, **39**, 480A.

[26] *Proc. Chem. Soc.*, 1908, **24**, 15; *Chem. Abs.*, 1908, **2**, 1450; *Chem. Zentr.*, 1908, **2**, 153.

It will be seen from the foregoing that the use of the majority of chlorine-carriers, which accelerate the chlorination of benzene, results in the production of substitution derivatives exclusively, the addition reaction being almost entirely suppressed even in bright sunlight. A few isolated statements appear to indicate, however, that not all catalysts induce substitutive chlorination but that on the contrary certain materials accelerate the addition reaction. Thus, Willgerodt[27] observed that in the presence of aluminum hydroxide or aluminum sulphate chlorination of benzene yielded mainly hexachlorocyclohexane. It has also been stated[28] that when a mixture of benzene and dry chlorine is passed in the vapor phase over a heated catalyst of partially reduced cupric chloride the products consist partly of the two isomeric hexachlorocyclohexanes together with some liquid products.

Electrolytic Chlorination of Benzene. The electrolytic chlorination of benzene dissolved in ether saturated with zinc chloride was studied by Schluederberg.[29] About 76 to 80 per cent of the chlorine was removed from inorganic combination. On the other hand, when benzene floating on a solution (160 grams of sodium chloride and 140 grams of sulphuric acid made up to 1 liter with water) was electrolyzed using a rotating anode, entirely immersed in the benzene layer, an efficiency of only 2.29 per cent was obtained. The necessity of employing a homogeneous solution was therefore clearly indicated. Schluederberg found that nascent chlorine produced during electrolysis yields substitution products with aromatic hydrocarbons and in this respect resembles chlorine in the presence of a halogen carrier rather than chlorine in the presence of chemically active radiation. To ensure homogeneity van Name and Maryott[30] used glacial acetic acid as a solvent for benzene and an electrolyzing agent of lithium chloride. On electrolysis of this solution chlorination was found to occur, but it also took place when chlorine was bubbled through the reaction mixture. They therefore concluded that the reaction between benzene and chlorine was catalyzed by the lithium chloride, and that chlorination took place due either to the chlorine liberated by electrolysis or simply bubbled into the solution, and not by anodic chlorination. One of the most exhaustive studies of the electrolytic chlorination of benzene has been made by Fichter and Glantzstein,[31] who electrolyzed a mixture of benzene and concentrated aqueous hydrochloric acid, rendered homogeneous by the addition of glacial acetic acid. A platinum anode was employed. Electrolysis of this solution gave under various conditions monochlorobenzene, p-dichlorobenzene, sym-tetrachlorobenzene and hexachlorobenzene. When the electrolysis was carried on for a long time, pentachlorophenol and chloroanil were also formed. The relative amounts of these substances present in the reaction product depended regularly upon the current density employed (other conditions being equal), indicating that an electrochemical reaction was taking place. The best yields were obtained with 3 faradays, i.e., a current yielding 3 gram-atoms of chlorine per mole of benzene. Increasing the concentration of the benzene up to the point where an emulsion was formed (nearly 1 mole per liter) improved the yield of chlorinated products. The most important factor in the course of the chlorination was current density. Thus, by raising the amperage up to about 1 ampere per sq. cm., the total yield was increased as well as that of the higher chlorinated products, while no hexachlorobenzene was formed at all with current densities less than 0.26 ampere per sq. cm. The best conditions for the production of higher chlorinated products, particularly hexachlorobenzene, were found to be low concentrations of benzene, high current densities and higher temperatures. The total yield and the yield of hexachlorobenzene were greater at platinum anodes than at graphite or magnetic iron oxide anodes, but in the presence of the last two substances oxidation reactions became more pronounced.

A comparison of the electrolytic and chemical chlorinations of benzene has been made by Lowy and Frank,[32] who electrolyzed a well agitated mixture of 12 per cent aqueous hydrochloric acid (or a 20 per cent aqueous sodium chloride solution) and benzene, using a platinum anode. Under the conditions of agitation the mixture resembled an emulsion. The yield of monochlorobenzene was found to increase with rise in temperature up to 60° C. and to be affected by the rate of stirring. The introduction of iodine as a catalyst into the electrolytic bath increased the yield of chlorobenzene. On the other hand, the amount of higher chlorinated products as well as the amount of anodic oxidation of the benzene increased with rise of temperature. In comparative experiments on the electrolytic and purely chemical chlorination of benzene in the presence of 12 per cent aqueous hydrochloric acid, the same yield of chlorobenzene was obtained but the former method gave a small amount of higher chloro-derivatives, which were not furnished under conditions used by the purely chemical process.

Thermal Chlorination of Benzene. A study of the thermal chlorination of benzene at high temperatures in the vapor phase was made by Mason, Smale, Thompson and Wheeler.[33] Mixtures of chlorine and benzene vapor, containing an excess of the latter, were passed at high space velocities through silica reaction tubes heated over 30 cm. of their length to temperatures up to 600° C., and the products were analyzed by distillation methods. It was found that for a given space velocity there is a critical temperature below which the amount of chlorine unconsumed increases rapidly, but above a certain temperature pyrolysis sets in and carbon is deposited. When using unpacked silica tubes and a space velocity

of 50 reciprocal minutes[34] some pyrolysis occurred at temperatures of 500° C. and above, though pyrolysis was also observed at 450° C. when using lower space velocities, i.e., 5 reciprocal minutes. The effect of varying space velocity on the proportion of reaction products is shown in Table 126.

In Table 126 it is demonstrated that with each tube and above a certain space velocity the percentage of unreacted chlorine increases rapidly. When large amounts of unconsumed chlorine were found in the reaction products trichlorobenzene was found also.

The effect of varying the molecular ratio of chlorine to benzene in the thermal chlorination at 450° C. in a silica tube 1.0 cm. diameter, using a space velocity of 50 reciprocal minutes is shown in Table 127.

TABLE 127.—*Thermal Chlorination of Benzene with Varying Molecular Ratios of Chlorine to Benzene.*

Temperature 450° C.; unpacked tube; space velocity 50 min^{-1}.

Molar Ratio $Cl_2:C_6H_6$	Benzene Converted into C_6H_5Cl	$C_6H_4Cl_2$	$C_6H_3Cl_3$	Unreacted Chlorine; on Input	Ratio $C_6H_5Cl:C_6H_4Cl_2$
	Per Cent				
1:1.1	44.7	15.2	Nil	Nil	2.9

1:2.2	34.3	3.7	Nil	0.3	9.3
1:3.4	24.0	2.2	Nil	0.5	10.9

It is evident that the production of dichlorobenzenes is depressed (relative to the monochlorobenzene) by an excess of benzene. There is an increased production of dichlorobenzenes without the formation of trichlorobenzene.

By packing the reaction tube with pieces of silica the speed of chlorination was increased but the reaction was not complete under these conditions at 375° C. with a space velocity of 10 reciprocal minutes. The influence of a number of volatile catalysts on the vapor phase chlorination was also studied and the results are shown in Table 128.

TABLE 128.—*Thermal Chlorination of Benzene with Various Catalysts.*

All these catalysts therefore accelerated the vapor phase chlorination especially ferric chloride, the use of which increased the production of dichlorobenzenes and also yielded some trichlorobenzene.

The vapor phase thermal chlorination of benzene is not as rapid as that of toluene. The results for both benzene and toluene are in excellent agreement (when only mono- and di-substitution products are formed) with the kinetic formula of Martin and Fuchs[85] for a bimolecular two-stage process. This is also demonstrated in Fig. 31, on page 773, in which the experimental values for the chlorination of toluene are very close to the theoretical curves.

---

[34] Space velocity in reciprocal minutes has been defined by Mason, Smale, Thompson and Wheeler as the number of volumes of gas, at the reaction-tube temperature, passing through the heated zone per minute.

Chlorination of Benzene by Substances other than Chlorine. A number of chlorine-containing substances are capable of effecting the chlorination of benzene under the influence of heat. Among these may be mentioned the usual chlorine carriers such as iodine chlorides, ferric chloride, antimony pentachloride, and molybdenum pentachloride. Chlorination may also be effected by nascent chlorine generated from manganese dioxide and hydrochloric acid, while the chlorination of benzene at high temperatures in the presence of mixtures of hydrogen chloride and oxygen has also been accomplished.

The fact that benzene can be chlorinated by many of the usual chlorine carriers used as catalysts in the direct chlorination of such hydrocarbons lends strong support to the view that these carriers are active by virtue of their ability to supply chlorine in a more active condition than the ordinary molecular state. Thus Page[86] has found that molybdenum trichloride does not assist chlorination below the temperature (70° C.) at which it is converted by the action of chlorine into the pentachloride. The chlorination of a number of aromatic hydrocarbons by means of ferric chloride alone has been described by Thomas.[87] On heating benzene with ferric chloride, hydrogen chloride was evolved and the products contained monochlorobenzene, 1,4-dichloro-, 1,2,4-trichloro-, 1,2,4,5-tetrachloro-, pentachloro-, and hexachlorobenzenes. The production of hexachlorobenzene during the intensive chlorination of benzene by means of ferric chloride[88] and also antimony pentachloride[89] has been observed. Sulphur monochloride is said to chlorinate benzene to monochlorobenzene at 250° C.,[40] while monochlorobenzene is also formed by heating benzene with sulphuryl chloride to 160° C.[41] Seyewitz and Biot[42] obtained monochlorobenzene by heating benzene with ammonium lead tetrachloride ($2NH_4Cl.PbCl_4$) in a sealed tube at 150° C.

A very powerful chlorinating agent, capable of bringing about a high degree of chlorination of benzene and also of its homologues, consists of a solution of sulphur monochloride in excess sulphuryl chloride in the presence of aluminum chloride.[43] With the aid of this reagent, Silberrad has succeeded in obtaining a number of polychloro-derivatives of benzene and nuclear polychloro-derivatives of toluene.

Industrial Methods for the Chlorination of Benzene. Chlorination of benzene is carried out technically on a very large scale for the production of monochlorobenzene[43a] exclusively. This substance finds extensive application as an intermediate in the production of synthetic dyestuffs and also in the production of phenol. With the possible exception of p-dichlorobenzene, which is produced as an unavoidable by-product in the technical manufacture of the monochloro-derivative, none of the other chlorobenzenes has become of industrial importance. On a technical scale, the chlorination is carried out in the presence of an iron catalyst with cooling to prevent the temperature rising above a certain point, and the chlorination is usually stopped when less than 1 mole of chlorine per mole of

[43a] The process used by the United Alkali Co., Ltd., for the manufacture of monochlorobenzene has been described (Anon., *Ind. Chem.*, 1925, **1**, 337; *Chem. Abs.*, 1925, **19**, 3148).

benzene has been absorbed in order to minimize the production of dichlorobenzene. A chlorination plant designed for this operation has been described by Marckwald.[44] In another similar process,[45] a mixture of ferric chloride and iron was proposed as a catalyst. The stream of chlorine is stopped before all the benzene is chlorinated and, at the end of the reaction, the contents are distilled under reduced pressure. The catalyst remains behind and can be used again, and the unreacted benzene is resubjected to chlorination. Thus, 156 kilos of chlorine were introduced into 300 kilos of benzene containing 1 kilo of ferric chloride and 1 kilo of powdered iron. On distillation, the product yielded 145 kilos of first runnings, containing a mixture of benzene and chlorobenzene which was subjected to further chlorination using 30 kilos of chlorine. The total yield from the initial 300 kilos of benzene was 335 kilos of pure monochlorobenzene and 24 kilos of p-dichlorobenzene, together with 13 kilos of mixed chlorinated benzenes.

Rabinovitz[46] chlorinated benzene in the presence of a special catalyst made by triturating in a mortar a mixture of equal weights of reduced iron powder and hydrated ferric chloride ($FeCl_3.6H_2O$). The resulting mass first liquefies and afterwards solidifies with evolution of heat and a sub-chloride is said to be formed. Chlorination of benzene is then carried out in the presence of 1 per cent by weight of the above catalyst at a temperature of 10°-15° C. with good agitation in a current of dry, air-free chlorine.

Coutagne[47] proposed to chlorinate benzene in the presence of iron at 15° C. in such a way that fresh chlorine comes in contact with fresh benzene. This is effected by allowing a stream of benzene to flow through a vertical series of basins exposed to a stream of dry chlorine also flowing in the same direction. The formation of higher chlorinated products is further reduced by admixture of hydrogen chloride with the chlorine.

In the continuous process of Auger[48] a stream of chlorine is totally absorbed in a controlled stream of liquid benzene (free from catalyst) in an absorption tower packed with siliceous pebbles. The solution of chlorine in benzene then passes to a cooled reaction chamber where it comes in contact with a catalyst of iron borings, whereupon reaction ensues and chlorobenzene and hydrogen chloride are produced. The hydrogen chloride passes off from the top of the reaction chamber while the chlorobenzene and unchanged benzene continuously overflow into a washer where neutralization is effected by means of moist chalk. The liquid mixture then passes through a container to a continuous still. It is estimated that the crude reaction product contains 30 per cent of monochlorobenzene and that the proportion of chlorobenzene to polychlorinated products is about 100:6. Auger's process is reported to have been used extensively in France and Italy.

Benzene may also be chlorinated by heating it with a mixture of manganese dioxide and hydrochloric acid to a temperature just below its boiling point.[49] Apparatus for the chlorination of benzene in the presence of an iron catalyst in the liquid phase has been described by Boulogne and Meillassoux,[50] and a method of recovering hydrogen chloride produced in the chlorination of benzene was described by Townsend.[51]

It has been proposed to utilize hydrogen chloride as a source of chlorine for the chlorination of benzene at high temperatures in the vapor phase. A mixture of benzene vapor, hydrogen chloride, and oxygen, with or without the addition of other gaseous diluents, is passed at high temperatures over catalysts such as iron, thallium, alkaline earth or rare earth chlorides, or charcoal.[52] The reaction is said to take place also in the presence of catalysts consisting of copper with one or more elements of the 3rd or 8th Groups.[53]

The chlorination of benzene has been effected[54] at 300° C. or higher by the passage of a mixture of benzene vapor, hydrogen chloride vapor, steam and oxygen, or air, over a catalyst of pumice impregnated with copper chloride. Monochlorobenzene and other chlorinated hydrocarbons have been suggested as selective solvents for the purification of crude anthracene and similar substances by fractional sublimation.[54a]

Monochlorobenzene is a colorless liquid with a faint aromatic odor; boiling at 132° C. and having d^{20}_{4} 1.10601. It is used in the manufacture of sulphur black and other dyestuffs, and is finding increasing application as a raw material for the production of both phenol and aniline. Although the chlorine atoms in nuclear substituted aromatic chlorohydrocarbons are firmly bound and undergo reaction with much greater difficulty than in the case of similar aliphatic chlorohydrocarbons, the application of high pressure renders possible the hydrolysis of chlorobenzene to phenol. Thus Brown[55] described the Aylsworth process in which chlorobenzene and sodium hydroxide solution are continuously pumped under a pressure of 2500 to 3000 lbs. per square inch through a coil of hydraulic pipe immersed in a bath of molten sodium nitrite at 370° C. The resulting sodium phenoxide is discharged, condensed, acidified, and the liberated phenol distilled. Griswold[56] hydrolyzed chlorobenzene to phenol continuously by heating it with caustic soda at 350° C. under a pressure of 280 kg. per sq. cm. The hydrolysis of chlorobenzene with steam at high pressure according to the equation,

$$C_6H_5Cl + H_2O \longrightarrow C_6H_5OH + HCl,$$

has been described by Hale and Britton[57] and more phenol is now being manufactured in the United States by this method than by the old method of alkali fusion of benzenesulphonic acid.[58]

Abs.* **B**, 1933, 220) obtains o- and p-hydroxydiphenyl (o- and p-phenylphenol) by distilling crude tar from the reaction of phenyl chloride and sodium hydroxide.

[57] *Ind. Eng. Chem.*, 1928, **20**, 114. See also Putnam, U. S. Patent 1,921,373, Aug. 8, 1933; assigned to Dow Chemical Co.; *Chem. Abs.*, 1933, **27**, 5086. In a similar method (Raschig G.m.b.H., British Patent 387,832, 1932; *Brit. Chem. Abs.* **B**, 1933, 297) the phenol and hydrogen chloride are recovered (without condensing the excess chlorobenzene and steam) by washing with water and alkali. Britton and Perkins (U. S. Patent 1,862,075, June 7, 1932; assigned to Dow Chemical Co.; *Chem. Abs.*, 1932, **26**, 4068) use this method for the hydrolysis of chlorocyclohexane to ortho- and para-cyclohexylphenol.

[58] Frolich, *Ind. Eng. Chem.*, 1931, **23**, 111.

According to Ushakov and Zelinsky,[58a] cuprous and cupric oxides are better catalysts than copper for the preparation of phenol from chlorobenzene. In the presence of a melt containing 2.5 parts of cuprous oxide and 60 parts of copper, the hydrolysis proceeds at 260° to 280° C. At 320° C. a 95 per cent yield is obtained after 25 minutes. Addition of 30 per cent diphenyl to the monochlorobenzene reduces the quantity of sodium hydroxide required. In a similar way, aniline is now being manufactured by heating chlorobenzene with ammonia[59] under pressure in the presence of copper catalysts,[59a] the reaction being:

$$C_6H_5Cl + NH_3 \longrightarrow C_6H_5NH_2 + HCl$$

The product is said to be purer than that obtained from benzene by nitration and reduction.

Similarly, Hale[59b] suggested the reaction of chlorobenzene with sodium acid sulphide in the presence of 10 per cent of diphenyl sulphide and 3 per cent of diphenyl oxide for the manufacture of thiophenols.

Chalkley[59c] studied the vapor-phase hydrolysis of phenyl halides in a search for new methods for the synthesis of phenol. He found that phenyl chloride and bromide are hydrolyzed to the extent of at least 25 to 40 per cent by passing their vapors mixed with steam over silica gel at 500°-550° C. and atmospheric pressure. The reaction is catalyzed also by titania, alumina, thoria, zirconia, and blue tungsten oxide, of which silica gel and titania appear to be the most active. The products are the halogen acid, phenol and diphenyl oxide. The activity of the catalysts may be restored by heating in air or oxygen.

p-Dichlorobenzene is a crystalline solid with a faint odor, melting at 52.9° C. and boiling at 173° C.[59d] It has found some application as a moth- and insect-repellant. Kipriyanov and Daschevski[59e] observed that on hydrolysis with aqueous sodium hydroxide it gives a maximum of 30 per cent of p-chlorophenol. With sodium methoxide and some copper powder at 225° C., yields as high as 85 per cent result. Further hydrolysis to pyrocatechol can be affected by sodium hydroxide in the presence of copper sulphate provided a copper or silver-lined autoclave is employed.[59f] Similarly, p-dichlorobenzene reacts with aqueous ammonia in the presence of copper to give p-aminophenol.[59g] Kipriyanov and his associates[59h] described the preparation of chloronitrophenols, chloronitroanilines, chloroaminophenols, and chloroaminophenolsulphonic acids from p- and o-dichlorobenzene.

THE BROMINATION OF BENZENE

On account of the relatively greater cost compared with the corresponding chloro-derivatives the bromine substitution products of benzene are of little industrial significance. From a scientific point of view, the bromination reactions of benzene are closely similar to those of chlorination. The direct addition of six atoms of bromine to benzene with the production of the lower melting hexabromocyclohexane occurs in the presence of sunlight using dry reagents.[60] The same compound is also formed by the addition of bromine to an ice cold mixture of benzene and 1 per cent caustic soda solution.[61] By the action of bromine vapor on boiling benzene, Couper[62] obtained monobromobenzene and p-dibromobenzene. Excess bromine reacts with boiling benzene to form mainly p-dibromobenzene with only a small proportion of isomeric dibromo-derivatives.[63] As in the chlorination reaction, the bromination of benzene is greatly accelerated by the use of certain catalysts, among which may be mentioned iodine,[64] aluminum halides,[65] amalgamated aluminum,[66] ferric halides,[67] phosphorus halides, and antimony halides.[68] In the presence of these halogen carriers, bromination occurs with the production of monobromobenzene and also of higher bromine substitution products, the degree of bromination depending upon the amount of bromine used and upon the temperature. By the action of two moles of bromine on benzene in the presence of iodine, Jannasch[69] obtained mainly p-dibromobenzene. The same compound with only small amounts of isomers was obtained by Leroy[70] by the action of 960 grams of bromine on 240 grams of benzene in the presence of aluminum chloride. Of the other two dibromo isomers formed the m-dibromobenzene was found to be present in the largest quantity, being equivalent to about 10 per cent of the bromine consumed. It would appear, therefore, that when the reaction takes place in the presence of aluminum chloride there is a tendency for the formation of the para- and meta-derivatives. Larger proportions of bromine result in the formation of increasing amounts of polybromo-derivatives. Thus Scheufelen[71] produced a mixture of p-dibromo-, 1,2,4-tribromo-, and 1,2,4,5-tetrabromobenzenes by the addition of 3.5 moles of bromine to cooled benzene in the presence of ferric chloride as a catalyst. By dropping benzene into an excess of cooled bromine in the presence of the same catalyst Scheufelen obtained the fully brominated product, hexabromobenzene.

The dynamics of the bromination of benzene in the presence of various catalysts has been investigated by Bruner,[72] who found that the reaction was retarded by hydrogen bromide. In experiments in which iodine was used as a catalyst, the velocity constant of bromination was approximately proportional to the square of the iodine concentration.

The electrolytic bromination of benzene has been studied by Croco and Lowy,[73] who found that the only product formed was monobromobenzene.

The Chlorination of Toluene

In the direct chlorination of toluene, as well as of its homologues, two types of substitution take place, namely, (1) *nuclear chlorination*, in which chlorine atoms are substituted for hydrogen atoms in the aromatic ring, and (2) *side chain chlorination,* in which the aliphatic side chain undergoes substitutive chlorination. The extent to which these two types of substitution reactions proceed depends markedly upon the conditions of chlorination. Thus chlorination in the absence of halogen carriers, either with illumination in the cold or in the dark at the boiling point of the hydrocarbon, results preponderatingly in the formation of products containing the halogen in the side chain. On the other hand, the presence of practically all the usual halogen carriers[74] causes nuclear chlorination to occur, even in the presence of strong sunlight or at the boiling point of the hydrocarbon. In the electrolytic chlorination of toluene, nuclear substitution products are chiefly formed. Thermal chlorination of toluene at high temperatures in the vapor phase in the absence of specific halogen carriers causes the substitution of chlorine atoms in the side chain exclusively, but when the thermal reaction is carried out in the presence of volatile halogen carriers some nuclear chlorination also takes place.

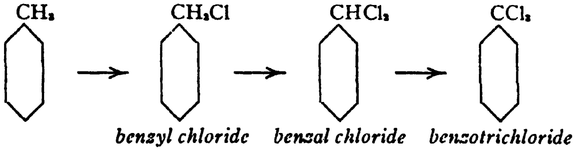
The addition reaction, which has been observed for benzene, has only been noted in a few instances with toluene, and appears to be quite unknown with higher homologues. Pieper[75] noted the separation of crystals of octachloromethylcyclohexane, $C_7H_6Cl_8$, melting at 150° C., from a solution of chlorine in toluene. Additive compounds of chlorine and toluene have also been reported by Qvist,[76] who obtained compounds from which about 50 per cent of the chlorine content could be eliminated in the form of hydrogen chloride by alcoholic potash with the production of di- and tri-chlorotoluenes.

Direct Chlorination in Absence of Catalysts and Illumination. The products of the direct (very slow) chlorination of toluene at room temperature in the dark or in diffused daylight are mainly nuclear substituted derivatives. According to Schramm,[77] o- and p-chlorotoluenes are produced under these conditions, but Limpricht[78] obtained a mixture of both nuclear and side chain substituted products. In direct sunlight, however, substitution occurs predominantly in the side chain even at room temperature. By introducing chlorine into boiling toluene, even in the dark, side chain substitution occurs almost exclusively and the products are benzyl chloride,[79] benzal chloride,[80] and benzotrichloride,[81] depending upon the extent of chlorination. The progressive chlorination of toluene at the boiling point in the absence of halogen carriers can therefore be represented as follows:



Book and Eggert[82] reported that the chlorination of toluene at 105° to 110° C. with a stream of chlorine of definite velocity yields the same products irrespective of whether the reaction takes place in the dark or in the presence of illumination. In the absence of chlorine carriers the product is benzyl chloride, but in the presence of ferric chloride, o- and p-chlorotoluenes are formed.

---

[74] Phosphorus trichloride appears to be an exception to this rule since, as previously mentioned, it catalyzes side chain substitution.

Both benzyl chloride and benzal chloride are of industrial importance and their production is carried out on a large scale by chlorinating toluene at its boiling point. Phosphorus trichloride is used as a catalyst in this process [83] and unlike other chlorine carriers it does not appear to induce nuclear substitution.

Photochemical Chlorination in Absence of Catalysts. In general, chemically active light radiation, such as sunlight or the light of a mercury vapor lamp, accelerates the chlorination of toluene at low temperatures and in the absence of the usual halogen carriers promotes substitution in the side chain. Schramm [84] found that the chlorination of toluene in the cold in direct sunlight resulted in the production of benzyl chloride, benzal chloride, and benzotrichloride without formation of nuclear substitution products. Schramm considered that the yellow and green rays were the most active in promoting this chlorination but the use of light from a mercury vapor lamp has been advocated in several instances. The results of Book and Eggert [85] showed that, though the purely chemical (dark) reaction of chlorine on toluene ceases at temperatures of the order of —80° C. and no reaction can be observed after 70 hours, combination can be initiated even at this low temperature under the influence of illumination from a mercury vapor lamp. On the other hand, the purely chemical reaction at 105° to 110° C. so predominates over the photochemical process that the influence of the latter is obscured at this higher temperature.[86] At room temperature, however, the reaction between chlorine and toluene is undoubtedly accelerated by illumination.[86a]

As with benzene, the photochemical chlorination of both toluene and xylene in acetic acid solution is retarded by the presence of oxygen.[87]

Catalytic Chlorination. Practically all the usual halogen carriers accelerate the chlorination of toluene and yield nuclear substitution products exclusively, with the exception of phosphorus trichloride. In the presence of 0.06 per cent of iodine, for example, chlorination of toluene takes place even at very low temperature (—80° C.).[88] By introducing a current of chlorine into toluene in the presence of iodine, no benzyl chloride is formed even at the boiling point, the products consisting of p-chlorotoluene [89] with some o-chlorotoluene [90] as well as nuclear polysubstitution products such as 2,4,5-trichlorotoluene.[91] Beilstein and Kuhlberg [92] obtained tetra- and penta-chlorotoluenes, consisting entirely of nuclear substituted derivatives, by chlorination in the presence of iodine followed by rechlorination of the product, boiling above 240° C., in the presence of antimony pentachloride.

Among the catalysts which have been found to accelerate the nuclear chlorination of toluene, the following may be specially mentioned: molybdenum pentachloride, sublimed ferric chloride, and aluminum amalgam. By passing dry chlorine into anhydrous toluene containing molybdenum pentachloride, Aronheim and Dietrich [93] obtained p-chlorotoluene as well as di- and tri-chlorotoluenes in which substitution had taken place exclusively in the nucleus. Seelig [94] studied the chlorination of toluene in the presence of this catalyst and also ferric chloride, and obtained o- and p-chlorotoluenes (the former predominating), 2,3- and 2,4-dichlorotoluenes, as well as trichlorotoluenes.

Cohen and Dakin [95] chlorinated toluene in the presence of an aluminum-mercury couple in the cold and obtained nuclear substituted derivatives exclusively. Thus, chlorination of 62 grams of dry toluene in the presence of the couple until an increase of 19.5 grams was obtained yielded the following fractions on distillation:

Below 140° C.	1.5 grams
140° to 163° C.	68.7 grams
Above 163° C.	2 grams

The yield of crude monochlorotoluene was about 80 per cent and this product was shown by oxidation to chlorobenzoic acids to consist of a mixture of about 65 per cent o-chlorotoluene and about 35 per cent of para-compound. By chlorination of toluene in the presence of the aluminum-mercury couple, so that larger proportions of chlorine were absorbed, Cohen and Dakin obtained good yields of dichlorotoluenes and trichlorotoluenes.

Lead chloride has also been shown to promote nuclear substitution of toluene. Thus, chlorination of toluene at 100° C. in the presence of lead chloride yielded a mixture of o- and p-chlorotoluenes containing about 62 per cent of the ortho isomer.[96] Selenium also catalyzes the nuclear substitution of chlorine atoms.[97]

Moisture promotes substitution of toluene in the ring, anhydrous halogens in the absence of carriers tending to substitute in the side chain.[98] Cohen, Dawson, Blockey, and Woodmansey [99] showed that although the chlorination of toluene in light by dry chlorine yields on the average 94 per cent of benzyl chloride and side chain substitution products, *moist* chlorine in the dark chlorinates *boiling* toluene with the formation of nuclear substitution derivatives to the extent of nearly 90 per cent. It thus appears definitely established that side chain substitution is favored by light, higher temperatures, and absence of moisture.

An apparent exception to the rule that halogen carriers promote nuclear substitution is phosphorus chlorides, which have been said to accelerate substitution in the side chain. Thus, Erdmann [100] observed that phosphorus pentachloride accelerated the chlorination of toluene in the side chain but not in the nucleus. This statement has been contested by Bergel,[101] but, on the other hand, Colson and Gautier [102] showed that benzal chloride is formed by heating toluene with phosphorus pentachloride in a sealed tube at 190° to 195° C. Moreover, in view of the fact that phosphorus trichloride has been repeatedly used as a catalyst for the production of benzyl and benzal chlorides by chlorination of boiling toluene,[103] it cannot be doubted that phosphorus chlorides differ markedly from other halogen carriers in their influence on the chlorination of benzene homologues. Another possible exception to the usual behavior of halogen carriers is sulphur, which is stated by Haeussermann and Beck[104] to promote side chain substitution in the chlorination of nitrotoluene.

Thermal Chlorination of Toluene. The thermal vapor phase chlorination of toluene was investigated by Ellis,[105] who showed that, in the absence of specific halogen carriers, chlorine enters the side chain exclusively. More recently these results have been extended by the work of Mason, Smale, Thompson and Wheeler.[106] These investigators studied the chlorination of toluene in the vapor phase at temperatures up to 700° C. in fireclay or silica tubes of various sizes. As the technical object desired was the complete utilization of the chlorine, an excess of toluene was usually employed. At temperatures above 600° C. pyrolysis of the products occurred even when using space velocities high enough to give no unchanged chlorine in the exit gas, i.e., with space velocities up to 3000 reciprocal minutes. In the temperature range 400° to 600° C., mixtures containing more than 1 volume of chlorine to 2 volumes of toluene could not be used owing to inflammation. Typical results of experiments at various temperatures in a fireclay tube 0.5 cm. in diameter are given in Table 129, and the experimental results were compared with theoretical figures calculated from the kinetic formula of Martin and Fuchs[107] for a bimolecular stepwise reaction (see Fig. 31).

In order to determine the speed of the vapor phase reaction at lower temperatures a fireclay tube of 2.3 cm. diameter was used and the results obtained are given in Table 130. These experimental results were also compared with those calculated from the formula of Martin and Fuchs (see Fig. 31).

[107] *Z. Elektrochem.*, 1921, 27, 150.

It will be seen that with an unpacked tube and a space velocity of 2.7 reciprocal minutes complete reaction was not obtained below 310° C. An increase in the proportion of chlorine resulted in the production of more benzal chloride. On the other hand, with a packed tube practically complete reaction could be obtained at 250° C. but the tendency to pyrolysis was enhanced.

FIG. 31.—Non-Catalytic Vapor-Phase Chlorination of Toluene and Methyl Chloride. (Mason, Smale, Thompson and Wheeler.)

Continuous curves = theoretical curves for three-stage reaction
Points marked x = experimental values, chlorination of toluene
Points marked Δ = experimental values, chlorination of methyl chloride

The effect of the addition of volatile catalysts in the vapor phase chlorination of toluene at 500° C. in a fireclay tube of 0.5 cm. bore was also examined by Mason and his co-workers, whose results are shown in Table 131.

TABLE 131.—*Catalytic Vapor-Phase Chlorination of Toluene.*
Tube diameter, 0.5 cm. Temperature 500° C. Space velocity 500 min.$^{-1}$
Molar ratio, $Cl_2:C_7H_8 = 1:2.2$

	Toluene Converted into		
Catalyst	Benzyl Chloride	Benzal Chloride	Chloro-toluenes
	Per Cent		
None	30.5	2.3	Nil
Iodine (1% on toluene)	12.0	4.0	16.9
NH_3 (1% on toluene)	18.9	6.1	9.5
$CHCl_3$ (1% on toluene)	28.4	4.8	Nil
$FeCl_3$ Amount not estimated; qualitative only.	6.7	8.9	14.5
Sulphur	22.1	3.9	3.9
H_2O	29.0	4.4	Nil

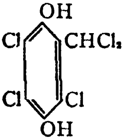
The above results show that iodine, ferric chloride, ammonia and sulphur promote chlorination in the nucleus, but the addition of chloroform and water vapors tend only to increase the proportion of benzal chloride.

Electrochemical Chlorination of Toluene. Electrolytic chlorination of toluene has been shown to result almost exclusively in the production of nuclear substitution products. Mülhofer[108] obtained a good current yield of chlorotoluenes (30 per cent ortho-, and 70 per cent para-isomer) by electrolyzing a well-stirred mixture of 20 grams of toluene and 250 cc. of concentrated aqueous hydrochloric acid. No benzyl chloride was formed and the addition of iodine did not influence the nature or yield of the products. Schluederberg[109] found that in the electrolytic chlorination of toluene 76 to 96 per cent of the chlorine acting substituted in the ring and the rest in the side chain. Similarly, Cohen, Dawson and Crosland[110] electrolyzed toluene over a layer of concentrated hydrochloric acid with a carbon anode and found that substitution occurred mainly in the nucleus. When chlorine was bubbled through the same mixture under similar conditions substitution occurred almost entirely in the side chain, so that a true electrochemical reaction is to be presumed.

---

[108] Dissertation, "Über die Einwirkung elektrolytisch erzeugter Halogene auf organischen Verbindungen," Munich, 1905.

Fichter and Glantzstein[111] studied the electrolytic chlorination of toluene in the presence of concentrated (aqueous) hydrochloric acid using a platinum anode. The bath was rendered homogeneous by the addition of sufficient glacial acetic acid. The complexity of the product obtained from toluene and the difficulty of isolating individual compounds, hindered the systematic study of the reactions involved, but the important discovery was made that in the dark at least three chlorine atoms are introduced into the nucleus before the methyl group begins to undergo chlorination. Fichter and Glantzstein believed this to be good evidence in favor of Bruner's theory that atomic halogen attacks the nucleus and that side chains are chlorinated by molecular chlorine. The compounds identified, either by isolation or by an examination of their hydrolytic products, were: o- and p-chlorotoluenes, 2,4-dichlorotoluene, 2,4,5-trichlorotoluene, pentachlorotoluene, hexachlorobenzene, pentachlorobenzyl chloride, 2,4,5-trichlorobenzylidene dichloride, and also the compound



With a current density of 0.005 ampere per sq. cm., mono- and di-chlorotoluenes are the only products; at 0.01 ampere per sq. cm., trichlorotoluene makes its appearance; but the substituted quinol, which renders so difficult the identification of the products, is not formed until a current density of at least 0.05 ampere per sq. cm. is attained.

Chlorination of Toluenes by Substances other than Chlorine. By heating toluene with many of the usual halogen carriers (except phosphorus pentachloride) nuclear substitution products are formed exclusively.[112] Thomas[113] obtained nuclear substitution products only with no benzyl chloride by boiling toluene with anhydrous ferric chloride, and Seyewetz and Biot[114] produced o-chlorotoluene by heating toluene with the double compound of ammonium chloride and lead tetrachloride ($2NH_4Cl.PbCl_4$). Tertiary butyl hypochlorite chlorinates toluene in the side chain to benzyl chloride.[115]

Perhaps the most important chlorinating agent of this class is sulphuryl chloride, which has been applied in the technical manufacture of benzyl chloride from toluene. Wöhl's[116] process consists in treating an excess of toluene with sulphuryl chloride in the dark at a temperature not exceeding 110° C. when benzyl chloride is produced almost exclusively. Thus, a mixture of 200 kilos of toluene and 180 kilos of sulphuryl chloride is gently heated under reflux to about 103° C., the temperature being maintained below 110° C. until the evolution of hydrogen chloride ceases. On fractionally distilling the mixture somewhat more than half the toluene is recovered unchanged and an almost theoretical yield of benzyl chloride is obtained (calculated on the toluene reacting).

Apparently sulphuryl chloride at higher temperatures tends to promote ring substitution, for Töhl and Eberhard[117] found that by heating toluene with sulphuryl chloride at 160° C. about one-third is converted into benzyl chloride and the residual two-thirds into p-chloro- and 3,4-dichlorotoluenes. The production of benzyl chloride was not reduced under these conditions by the addition of iodine though it was increased by exposure to light.

A very complete examination of the influence of a large number of catalysts on the course of the chlorination of toluene by means of sulphuryl chloride has been made by Silberrad, Silberrad and Parke.[118] Toluene was boiled with a 10 per cent excess of sulphuryl chloride (on an equimolar basis) for 8 hours in the presence of various catalysts and the products examined. Two types of catalysts were found, namely, (1) those that either exhibit chlorination or alter its course without accelerating it appreciably, and (2) those that accelerate substitution. Of the nineteen catalysts investigated, only phosphorus pentachloride, manganese chloride, and arsenic (in this order) were of the first class, inhibiting ring substitution and increasing the production of benzyl chloride. All the other catalysts (namely, auric chloride, aluminum chloride, carbon, stannic chloride, bismuth, antimony, sulphur monochloride, selenium, tellurium, chlorine, bromine, iodine, iron and platinum) accelerated ring substitution and, with the exception of sulphur and bromine, at the expense of benzyl chloride. Further, the catalytic activity of the elements (except bromine) was a function of their atomic weight, increasing with this property to a maximum. The elements of the same group showed a decreasing tendency to induce side chain substitution with increasing atomic weight.

It has been shown by Silberrad[119] that the efficacy of sulphuryl chloride as a nuclear chlorinating agent in the presence of aluminum chloride is greatly increased by the presence of sulphur monochloride. This combination is a very powerful chlorinating agent and is capable of bringing about the production of polychloro-derivatives very readily. By treating toluene (184 grams) in the presence of anhydrous aluminum chloride (10 grams) at 70° C. with varying amounts of the chlorinating agent (sulphuryl chloride + 1% sulphur monochloride), various nuclear polychloro-derivatives, including pentachlorotoluene, were obtained by Silberrad.[120]

Hypochlorous acid reacts with toluene to form either nuclear or side chain substitution products.[121] The following conditions favor nuclear substitution: absence of light, dilute (up to 1.0 N) solutions of hypochlorous acid, the use of solutions of hypochlorites and weak acids, such as boric and carbonic, and the presence of iron or copper salts. The most favorable conditions for side chain substitution are light rich in infra-red rays, temperatures higher than 40° C., and solutions of hypochlorites and strong acids.

Industrial Applications of the Chlorination of Toluene. In the various processes which have been developed for the industrial chlorination of toluene, the production of side chain substituted products, principally benzyl and benzal chlorides, has been exclusively sought. Both benzyl and benzal chlorides are employed in the manufacture of benzaldehyde and benzoic acid, which find extensive application in the organic chemical industries.

Marckwald[122] produced benzyl and benzal chlorides by chlorination of hot liquid toluene by a stream of chlorine at a temperature just below the boiling point of toluene and in the presence of about 1 per cent of phosphorus trichloride, which acts as a catalyst for side chain substitution. In order to avoid the production of higher chlorinated products, apparatus is used in which the chloro-compound as produced is removed continuously from the action of the chlorine.

A continuous process of producing benzyl chloride was described by Ellis[123] in which a vaporized mixture of toluene, phosphorus trichloride, and chlorine (containing sufficient chlorine to convert 25 to 50 per cent of the toluene to benzyl chloride) is heated to 180° to 220° C. and exposed to ultraviolet light. The benzyl chloride is condensed and the mixture of toluene and phosphorus trichloride mixed with further quantities of chlorine and toluene and again subjected to the same process. Ellis[124] also proposed a thermal process in which a mixture of toluene vapor and sufficient chlorine to combine with 25 to 50 per cent of the toluene present is passed through a heated zone where it is subjected to a gradually increasing temperature above the boiling point of toluene. The benzyl chloride formed is condensed and the residual toluene, after being freed from hydrogen chloride, is again subjected to a similar thermal chlorination.

Gibbs and Geiger[125] produced side chain substituted toluene derivatives by exposing a heated mixture of toluene containing the theoretical amount of chlorine for the desired stage of chlorination to the action of ultraviolet radiation. The process is carried out at a temperature not materially below 150° C., and by using a "low pressure" mercury vapor lamp benzyl and benzal chlorides are formed, while by employing a "high pressure" lamp and three molecular proportions of chlorine, benzotrichloride is the chief product.[126] Benzyl chloride and bromide may be produced by the action of the corresponding halogen on toluene in the presence of chlorates.[127] The thermal vapor phase chlorination of toluene to yield benzyl chloride has been utilized by Mason and Wheeler.[128] The side chain chlorination of benzene homologues by vapor phase operation in the presence of illumination has been described by Conklin.[129]

Wohl's[130] process for the production of benzyl chloride by heating toluene with sulphuryl chloride under reflux at 103° to 110° C. has already been mentioned. The production of benzyl chloride by treatment of a mixture of toluene and bleaching powder with sulphur dioxide has been described by Conant.[131]

An interesting process for the production of benzyl chloride and its homologues is by condensation of benzene hydrocarbons with monochloroacetone in the presence of tin tetrachloride.[132] The process is exemplified by the production of p-methylbenzyl chloride by treatment of an equimolecular mixture of toluene and chloroacetone, dissolved in twice its weight of carbon disulphide or carbon tetrachloride and cooled to —10° C., with about one-fourth molecular proportion of tin tetrachloride, which is added drop by drop. The reaction product is poured onto ice and distilled to furnish a 60 per cent yield of p-methylbenzyl chloride.

Sors[132a] described apparatus for the manufacture of benzyl chloride by chlorination of toluene at its boiling point, and its subsequent hydrolysis with aqueous sodium carbonate solution to benzyl alcohol. Lead, glass, or stoneware are said to be satisfactory materials for construction of plant, but iron must be carefully avoided or coated completely with lead.

THE BROMINATION OF TOLUENE

Though the bromination reactions of the benzenoid hydrocarbons are as yet of little industrial importance, the influence of various factors on the course of the bromination of toluene has been investigated much more completely than the chlorination reactions of that hydrocarbon so that a brief account of the bromination of toluene is desirable if only because of the light that it sheds on the course of halogenation in general.

In the absence of catalysts, bromine reacts slowly with cooled toluene in the dark with the initial production of o- and p-bromotoluenes.[133] Under similar conditions but in *diffused daylight* nuclear chlorination is also accompanied by the formation of some benzyl bromide,[134] while in *direct sunlight* in the cold and in the absence of catalysts benzyl bromide is formed to the total exclusion of bromotoluenes.[135] The photochemical process therefore induces side-chain substitution even at low temperatures.

The influence of temperature alone in the distribution of substitution is very marked, low temperatures favoring nuclear substitution and higher temperatures bromination of the side chain. Thus the vapor phase bromination of toluene at temperatures above the boiling point yields benzyl bromide almost exclusively even in the dark.[136] Holleman and van der Laan[137] investigated the influence of temperature in the dark on the relative proportions of side chain and nuclear substitution. Table 132 shows the results on the bromination of toluene (50 cc.) with bromine (3 cc.) in the dark.

It was found also that side chain substitution was so greatly accelerated by light that benzyl bromide becomes the main product of bromination in diffused daylight even at as low a temperature as 25° C. The influence of light is therefore much more pronounced than that of heat in promoting substitution in the side chain. In addition the results appeared to indicate that molecular bromine acted only on the side chain, and complex bromides, of the type represented by HBr_x, attacked the nucleus.[138]

Factors which exert a very important directive influence on the course of the dark bromination of toluene are concentration of bromine, and the nature of the medium. Thus with diminishing concentration of bromine the substitution in the side chain tends to increase.[139] The influence of the addition of certain solvents to the bromination mixture has also been investigated[140] and it has been shown that the influence of such solvents not only manifests itself in the dark but also in the photochemical reaction. Dilution with nitrobenzene, and to a lesser degree with acetic acid and benzonitrile, results in an increase of the relative proportion of nuclear substitution. Dilution with carbon tetrachloride gives a substitution distribution ratio similar to that obtained by dilution with the same amount of toluene.

As in the case of the chlorination process, the usual halogen carrier catalysts accelerate nuclear substitution so powerfully as to overrule all other influences. Thus bromination of toluene in the presence of iodine as catalyst produces o- and p-chlorotoluenes and no benzyl bromide either at the boiling point of the hydrocarbon[141] or in the presence of direct sunlight.[142] Fine iron powder, even in so small a concentration as 0.002 mole ferric bromide per mole of bromine, inhibits the formation of benzyl bromide in the bromination of 50 cc. of toluene by 2.5 cc. of bromine in light at 50° C.[143] Antimony pentachloride and especially aluminum bromide, or amalgamated aluminum[144] also exert a powerful accelerating influence on nuclear substitution. Nuclear bromination may be carried to the limit by employing excess of bromine in the presence of these catalysts. For example, Gustavson[145] obtained pentabromotoluene, $C_6Br_5CH_3$, by dropping toluene into excess of bromine containing a little anhydrous aluminum bromide.

According to van der Laan,[146] phosphorus pentabromide is very sharply differentiated from the other halogen carriers in that it increases the yield of benzyl bromide without influencing the relative proportions of o- and p-bromotoluenes. The remarkable action of phosphorus halides in promoting substitution of halogens in the side chains of benzene homologues has already been mentioned.

THE CHLORINATION OF THE HOMOLOGUES OF TOLUENE

As with toluene, the halogenation reactions of its homologues can occur in two ways, either by substitution in the nucleus or by substitution in the side chain or chains. In general, nuclear chlorination of the higher alkylbenzenes is favored by low temperatures and the absence of light and especially by the presence of the usual halogen carriers. On the other hand, chlorination in the presence of sunlight or other chemically active radiation, as well as chlorination at the boiling point of the hydrocarbon, results mainly in substitution in the side chains.

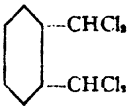
Chlorination of toluene homologues in the dark in the absence of catalysts in the cold yields mainly nuclear substitution products. Thus, under these conditions mesitylene was found by Fittig and Hoogewerff[147] to form mono-, di-, and trichloro-derivatives, and pseudocumene gave 5-chloro- and 3,5,6-trichloro-1,2,4-trimethylbenzenes.[148]

Chlorination of benzene homologues at high temperatures, e.g., at the boiling points of the hydrocarbons, in the absence of halogen carriers and with or without illumination, forms substitution products with the chlorine atoms in the side chains. In this way, the corresponding xylyl chlorides and xylylene dichlorides have been prepared from ortho-,[149] meta-[149a] and para-xylenes.[150] In the presence of an excess of chlorine and at 140° C. two hydrogen atoms are substituted in each of the two side chains of o-xylene with the production of tetrachloro-o-xylene[151] of the formula



By treating 200 grams of boiling m-xylene in a quartz vessel exposed to light from mercury vapor lamps with a stream of chlorine until 64.8 grams of chlorine had been absorbed, Posner and Schreiber[152] obtained, after fractionation of the products, 183 grams of m-xylyl chloride and 41 grams of m-xylylene dichloride, of the formula $C_6H_4(CH_2Cl)_2$. Stine[153] has described the chlorination of p-xylene in sunlight at 100° C. to yield p-xylylene dichloride, which is then hydrolyzed and nitrated to furnish various explosive substances. It is interesting to note that nuclear chlorinated xylenes may also be further chlorinated in the side chains by photochemical chlorination at 120° C. In this way trichloro-m-xylene yields di(dichloromethyl)-trichlorobenzene.[154]

The products of the chlorination of some of the higher benzene homologues at their boiling points (and usually in daylight) in the absence of catalysts are given in Table 133.

TABLE 133.—*Products of Chlorination of Higher Benzene Homologues.*

The photochemical chlorination of the higher alkylbenzenes in the absence of catalysts leads to the production of side-chain substituted derivatives almost exclusively even in the cold. Thus o-, m-, and p-xylenes yield the corresponding xylyl chlorides and xylylene dichlorides under these conditions, and m-xylene also gives some chloro-m-xylene.[158] Ethylbenzene in the cold in the presence of sunlight absorbs 1 mole of chlorine to form α-chloroethylbenzene[159] but further chlorination produces α,α-dichloroethylbenzene together with some nuclear substituted products.[160]

As in the case of toluene, chlorination of the higher alkylbenzenes in the presence of the usual halogen carriers leads predominantly to the formation of nuclear substituted derivatives even in the presence of sunlight or at the boiling point of the hydrocarbon. Nuclear substitution has been effected by many investigators by using iodine as a catalyst in the cold.[161] Iron has also been used.[162]

Nuclear substitution products are also obtained by heating the alkylbenzenes with the usual chlorinating agents in the absence of chlorine. Thus sulphuryl chloride chlorinates ethylbenzene in the nucleus in the presence of aluminum chloride to yield 4-chloro-1-ethylbenzene besides other products.[163] m-Xylene reacts with sulphuryl chloride at 160° C. to yield 4-chloro-m-xylene. In the presence of aluminum chloride 1,3-dimethyl-4-sulphonyl chloride is formed. By heating p-xylene with the double salt $2NH_4Cl . PbCl_4$, Seyewetz and Biot[164] obtained 2-chloro-p-xylene. An important exception to the general rule is phosphorus pentachloride. Thus, Colson and Gautier[165] found that by heating phosphorus pentachloride with o-, m-, and p-xylenes at 190° C. products were obtained containing up to four chlorine atoms substituted in the side chains.

THE BROMINATION OF THE HOMOLOGUES OF TOLUENE

Although a good deal of work has been carried out on the bromination of the higher benzene homologues a detailed discussion of the results cannot be given here. In brief, however, it may be said that the influence of various factors on the relative distribution of substitution in the nucleus and side chains respectively is almost identical with that observed in chlorination reactions. Diffused or direct sunlight and temperatures around the boiling point of the hydrocarbon promote substitution in the side chain and darkness and low temperatures yield nuclear substituted derivatives. The influence of catalysts such as iodine, or aluminum halides, is to promote substitution in the nucleus exclusively even under conditions which normally favor side chain substitution.

Chapter 33

Production of Alcohols by Hydrolysis of Alkyl Halides
Production of Esters

The alkyl halides, particularly the chlorides which may be manufactured relatively cheaply by direct chlorination of paraffin hydrocarbons, are possible raw materials for the production of monohydric alcohols of the aliphatic series. Not only secondary and tertiary alcohols but also primary ones, including ethanol and methanol, may be made by the hydrolysis of the appropriate alkyl chloride. This mode of synthesis of alcohols is therefore sharply differentiated from that involving the hydration of olefins which yields, except in the single instance of ethanol, secondary or tertiary alcohols only and cannot be used to make the simplest member, methanol.

The hydrolysis of alkyl chlorides to alcohols has usually been effected by treatment in the liquid phase with alkalies such as aqueous caustic soda, milk of lime or aqueous sodium carbonate, or in the gaseous phase by passing vaporized chloride over solid alkaline reagents or reagents capable of combining with, and fixing, hydrogen chloride. The reaction may be simply expressed as follows:

$$\underset{\textit{alkyl chloride}}{C_nH_{2n+1}Cl + M^IOH} \longrightarrow \underset{\textit{alcohol}}{M^ICl + C_nH_{2n+1}OH}$$

where M^I represents one atomic proportion of a monovalent element (or one-half atomic proportion of a divalent element).

The direct saponification of alkyl chlorides by steam in the vapor phase is known to proceed according to the reversible equation:

$$C_nH_{2n+1}Cl + H_2O \rightleftharpoons C_nH_{2n+1}OH + HCl,$$

but unfortunately, in general, the point of equilibrium even at elevated temperatures and in the presence of a large excess of steam appears to be well over toward the left. Accordingly, this method is of little value in the production of alcohols from alkyl chlorides but the reverse procedure may be employed successfully in many cases for producing alkyl halides from alcohols.

In the saponification of alkyl chlorides by alkalies to yield alcohols, it is necessary to control the conditions of the reaction, more especially the concentration of alkali and temperature, to minimize undesirable side reactions such as the elimination of hydrogen chloride to yield olefins according to the equation:

$$C_nH_{2n+1}Cl \longrightarrow C_nH_{2n} + HCl\ (\text{fixed})$$

Aliphatic ethers may also be produced by saponification under certain conditions.

Esters of aliphatic alcohols are obtained by heating alkyl halides with salts of the appropriate organic acids, the alkali or alkaline earth metal salts being most frequently employed. The reaction is exemplified by the conversion of amyl chloride into amyl acetate by heating with sodium acetate, thus:

$$C_5H_{11}Cl + NaOOCCH_3 \longrightarrow NaCl + C_5H_{11}OOCCH_3$$

The Conversion of Methyl Chloride into Methanol

Hydrolysis with Steam. The direct reaction of methyl chloride with steam in the vapor phase according to the equation:

$$CH_3Cl + H_2O \rightleftharpoons CH_3OH + HCl - 12 \text{ Cal.},$$

is a reversible process taking place with considerable heat absorption. Accordingly elevated temperatures should favor the hydrolytic process. Even at 350° C. and over in the presence of a large excess of steam the amount of methanol in equilibrium appears to be negligibly small. Application of the Nernst "approximation formula" to this equilibrium leads to a value for the equilibrium constant, $K_p = \frac{[CH_3OH]\,[HCl]}{[CH_3Cl]\,[H_2O]}$ of only about $2x10^{-4}$, at 350° C., showing that only relatively small amounts of methanol can be obtained even under equilibrium conditions. These theoretical considerations are completely substantiated by experimental results. For example Whiston[1] attempted to induce hydrolysis of methyl chloride with steam but found that only traces of methanol were produced. McKee and Burke[2] passed a mixture of steam and methyl chloride, in molar ratios varying from 1:1 to over 3:1 over a catalyst of pure silica at temperatures up to 350° C. but only traces of methanol and hydrogen chloride could be found in the products of reaction. Several other catalysts, including zirconium dioxide, anhydrous calcium chloride, anhydrous aluminum chloride and silica, were also tried but in every case only negligible quantities of methanol were produced.

Hydrolysis by means of Metallic Hydroxides. The reaction between alkyl halides and metallic hydroxides may be carried out either in the liquid phase using a solvent (in the case of methyl chloride this method of operation also involves the employment of pressure) or by passing the vapors of the alkyl halide over the heated solid hydroxides and condensing the alcohols so formed. The latter mode of procedure was employed by Dumas and Stas[3] in an attempt to produce methylene. By passing methyl chloride over hot potash lime, these investigators obtained potassium formate, potassium chloride, hydrogen and some methane. Similar results were obtained with solid sodium hydroxide and it was shown that the production of formates was due to the oxidation of the methanol initially formed.

Whiston[4] found that by repeated circulation of methyl chloride (without addition of steam) over calcium hydroxide at 300° C. the methyl chloride disappeared almost quantitatively. Although no experimental details or quantitative data were reported by Whiston, the presence of methanol and dimethyl ether was qualitatively demonstrated. An experimental and theoretical examination of the production of methanol by the passage of methyl chloride over heated metallic hydroxides was conducted by McKee and Burke.[5] Highly porous granular calcium hydroxide was an excellent material for effecting this reaction, but aluminum hydroxide proved unsatisfactory. On passing methyl chloride mixed with steam over granular calcium hydroxide at about 350° C. the methanol production was very high during the first few hours of the experiment. After a time, however, the reaction diminished due to the conversion of the surface layers of calcium hydroxide into calcium chloride, and eventually attained a low, but steady, value. The products of the reaction were mainly calcium chloride, methanol and dimethyl ether. The reactions involved together with the approximate thermal values are given in the following equations:

---

[1] *J.C.S.*, 1920, 117, 183.

[2] *Ind. Eng. Chem.*, 1923, 15, 682.

[3] *Ann.*, 1840, 35, 169; *Ann. chim. phys.*, 1840, (2), 73, 157; *J. pr. Chem.*, 1840, (1), 21, 377; see Gmelin, "Handbook of Chemistry," translated by Watts, Cavendish Society, London, 1852, 7, 288.

[4] *J.C.S.*, 1920, 117, 183.

[5] *Ind. Eng. Chem.*, 1923, 15, 682, 788.

$$2CH_3Cl + Ca(OH)_2 = CaCl_2 + 2CH_3OH + 3 \text{ Cals.}$$
$$2CH_3Cl + 2CH_3OH + Ca(OH)_2 = CaCl_2 + 2CH_3OCH_3 + 2H_2O + 9 \text{ Cal.}$$

The optimum temperature for this process was 350° C. By using fairly high rates of flow, thermal decomposition of the reacting gases may probably be reduced to under 2 per cent while the methyl chloride can be almost quantitatively converted into methanol and methyl ether. The relative amounts of the two products depend upon the relative partial pressures of methyl chloride and steam in the reacting gases.

Using equal partial pressures of methyl chloride and steam, yields of methanol and methyl ether in the ratio of 67 to 33 were obtained. This ratio is, however, increased in favor of methanol by the use of higher partial pressures of steam. If, for example, the partial pressures of steam and methyl chloride are in the ratio of 3:1, the resulting ratio of methanol to ether is 80:20, approximately. The use of a large excess of steam has the disadvantage that it reduces the percentage utilization of the calcium hydroxide. An endeavor was therefore made to effect the catalytic conversion of the dimethyl ether into methanol separately. This hydration process, namely, $(CH_3)_2O + H_2O \rightleftarrows 2CH_3OH - 3$ Cal., is a reversible reaction catalyzed by aluminum oxide at temperatures in the region of 350° C. McKee and Burke found that in order to convert 50 per cent of dimethyl ether into methanol in the presence of this catalyst at 350° C. about 8.5 volumes of steam per volume of ether are necessary in the reacting gases. Less steam is required, however, if the hydration is carried out in a number of successive stages. By heating gaseous methyl chloride in the presence of a dilute solution of caustic potash in a sealed tube at 100° C. for one week, Berthelot[6] obtained some methanol. Under these conditions, however, the hydrolysis was exceedingly slow.

Industrial Processes. Lacy[7] reported a method of hydrolyzing alkyl halides, and particularly methyl chloride, which consists in heating the halide in intimate contact with an alkaline solution to temperatures considerably above 100° C. and at a pressure above the vapor pressure of the alkaline solution. For example, a pressure vessel of 9 liters capacity, furnished with stirring devices, is half filled with milk of lime containing 15 per cent by weight of calcium hydroxide and heated to 190° C. (equivalent to 167 lbs. pressure). Methyl chloride is then introduced until the pressure attains about 260 lbs. per square inch and this pressure is maintained by regulating the supply of methyl chloride. After 15 minutes the reaction mixture is said to contain 7 per cent of methanol which can be removed by distillation. A similar process involving the heating of an alkyl halide with a basic compound at an elevated temperature or an increased pressure or both, has been described by Dill.[8] According to Szarvasy,[9] methanol is conveniently prepared by heating methyl chloride with an alkaline reagent at elevated temperatures and pressures of 20 to 24 atmospheres. For example, by heating 520 grams of methyl chloride, 3500 grams of water and 330 grams of calcium oxide in a horizontally rotating iron container to 140° C. for two hours, the pressure rising to about 20 to 24 atmospheres, 96 per cent of the theoretical amount of methanol is obtained. The walls of the reaction vessel become coated with the alkaline solution which prevents corrosion.

---

[6] *Compt. rend.*, 1857, 45, 916; *Ann. chim. phys.*, 1858, (3), 52, 101.

[7] British Patent 20,550, 1914; *J.S.C.I.*, 1915, 34, 575; U. S. Patent 1,253,055, Jan. 8, 1918; *Chem. Abs.*, 1918, 12, 702; both patents assigned to Roessler and Hasslacher Chemical Co.

The process of Riesenfeld[10] involves the intermediate formation of dimethyl ether by heating methyl chloride, under pressure in anhydrous alcoholic solution, with caustic alkalies. The dimethyl ether, so obtained, is subsequently hydrolyzed under pressure in the presence of a little free acid to yield methanol.

A method described by the Deutsche Petroleum A.-G.[11] involves passing gaseous methyl chloride countercurrent to a stream of a molten mixture of equimolecular quantities of sodium and potassium acetates at a temperature of 250° C. Methyl acetate and sodium and potassium chlorides are formed but the reaction must not be carried too far as the mixture becomes too viscous. The methyl acetate, which distils from the reaction vessels, is hydrolyzed with a solution of equimolecular quantities of sodium and potassium hydroxides to yield methanol and the mixed acetates of these metals, the latter being used again in the process. Increased pressures favor the formation of methyl acetate in this process. As an example it is reported that in 2½ hours, using 82 kilograms of sodium acetate and 98 kilograms of potassium acetate, 50 kilograms of methyl chloride can be converted into 30 kilograms of methanol, the yield being, therefore, over 90 per cent.

MacMullen and Gegenheimer[12] have developed a process of converting alkyl halides into alcohols, especially of methyl chloride into methanol, in which a mixture of the alkyl halide and steam (equimolecular proportions are said to be adequate) at a pressure of 175 to 200 lbs. per square inch is led over a contact mass of hydrated lime at 350° to 450° C., using a time of contact of 40 seconds or more. An apparatus for carrying out this process has been described by these workers,[13] in which two procedures can be adopted. In one, the mixture of methyl chloride and steam is passed through each of a plurality of conversion chambers, which are continuously charged with freshly hydrated lime at equal intervals of time. In another, the gaseous reaction mixture is passed successively through a series of conversion chambers containing progressively fresher hydrated lime and, as the lime in each chamber is consumed, the chamber is recharged with fresh lime and connected in at the other end of the series so that, in effect, the methyl chloride is contacted with the lime in countercurrent. A nearly complete conversion of the methyl chloride and consumption of lime is said to be thus effected.

Weber and Erasmus[14] described a method of treating a mixture of methyl chloride and methylene dichloride, produced by the controlled chlorination of methane, which consists essentially in forcing the mixture in gaseous form into a reaction vessel wherein it is heated under pressure with milk of lime. The methyl chloride is said to be hydrolyzed and the unattacked methylene dichloride is passed in gaseous form into a cooling apparatus where it is liquefied.

[14] U. S. Patent 1,565,345, Dec. 15, 1925; *Chem. Abs.*, 1926, **20**, 424; British Patent 227,475, 1925; *J.S.C.I.*, 1925, 784B; both patents assigned to T. Goldschmidt A.-G.

Carter and Coxe[15] reported a process for the hydrolysis of alkyl halides to alcohols, particularly methyl chloride to methanol, by heating under pressure with an aqueous alcoholic solution of an alkali (or alkaline earth) hydroxide at temperatures of about 100° C. The relative amounts of ether and alcohol produced in this hydrolytic process depend mainly upon the concentration of alcohol in the liquid. The experimental figures in Table 134, referring to the hydrolysis of methyl chloride in a methanol-water solution of calcium hydroxide, are advanced in support of this contention.

TABLE 134.—*Hydrolysis of Methyl Chloride by Calcium Hydroxide in Aqueous Methanol.*

Concentration of Methanol	Conversion	
	To Alcohol	To Dimethyl Ether
80	22.1	77.9
60	30.8	69.2
20	79.7	20.3
10	83.4	16.6
5	88.4	11.6

In order, therefore, to minimize the formation of ether during the hydrolysis it is proposed to keep the alcohol concentration in the reaction liquid at somewhat above 5 per cent but not exceeding 20 per cent. Starting with a 5 per cent methanol solution, for example, the hydrolysis of methyl chloride may be carried on until the concentration of the methanol rises to 10 to 15 per cent when the process is stopped. A considerable excess of alkali over that required for reaction is advantageous. For example, 100 pounds of methyl chloride are added to a solution of 150 pounds of sodium hydroxide in 100 gallons of 5 per cent aqueous methanol in an autoclave, and the mixture is heated at 100° C. until reaction is complete (about 1 hour). Sodium chloride, methanol, and some methyl ether are produced.

McKee's process[16] for the conversion of methyl chloride into methanol consists in mixing this gas with an equal volume of steam and passing it over an alkaline-earth hydroxide, especially calcium hydroxide, at 350° to 375° C. in an aluminum tube. The aqueous solution obtained by cooling the issuing gases affords methanol, free from acetone, and some dimethyl ether. The yield of methanol may exceed 70 per cent of the theoretical under the above conditions.

Silica or porous dioxides of the silica group have been suggested by Lloyd and Kennedy[16a] as catalysts for the production of alcohols or phenols from alkyl or aryl chlorides by reaction with steam at 550° to 850° C.

Methanol is a colorless liquid, boiling about 66° C., miscible in all proportions with water and most organic solvents. Until recent years the sole method for its large scale production was by the destructive distillation of wood. However, an increasingly important method of manufacture is by the catalytic high pressure reduction of carbon monoxide in the presence of a catalyst.[16b] This synthetic method yields a very pure methanol which is rapidly displacing the somewhat impure product obtained by wood distillation. Although methanol finds extensive application as a solvent for varnishes, lacquers and celluloid products,

its main use is as a chemical intermediate notably for the production of formaldehyde (a substance used in vast quantities in the manufacture of synthetic resins and as a disinfectant) and as a methylating agent in industrial organic synthesis. A possible important application of methanol is as a constituent of motor fuels and as an anti-freeze in automobile radiators. Methanol vapor is stated to be definitely toxic.

PRODUCTION OF ESTERS AND ETHERS FROM METHYL CHLORIDE

The process of the Deutsche Petroleum A.-G.[17] involving the intermediate production of methyl acetate by passing methyl chloride countercurrent to a stream of a molten mixture of sodium and potassium acetates at 250° C. has already been discussed. According to Carter and Coxe,[18] methyl acetate may be produced by heating methyl chloride with sodium acetate in the presence of water and a solvent for the methyl chloride, such as alcohol, in an autoclave at 100° C. The reaction is said to be rapid with a nearly theoretical yield, and is also applicable to the production of other methyl esters and of esters derived from higher alcohols, i.e., by interaction with higher alkyl halides.

Methyl acetate has been utilized to some extent as a substitute for acetone in certain of its applications as solvents. It is a good solvent for cellulose nitrate and for various resins but is readily hydrolyzed.

The production of *ethers* from alkyl halides, such as methyl or ethyl chloride, was reported by Carter and Coxe [19] to be readily effected by heating such alkyl halides under pressure in the presence of an alcohol and an alkaline compound such as caustic soda or potash. The formation of methyl ethyl ether from methyl chloride, ethanol and caustic soda is said to take place readily at 100° C. in an autoclave, sodium chloride being deposited.

CONVERSION OF ETHYL CHLORIDE INTO ETHANOL AND ITS DERIVATIVES

Little work appears to have been done on the hydrolysis of ethyl chloride to ethanol by steam in the vapor phase, in contact with alkaline hydroxides, or in the liquid phase. Aqueous potash slowly converts ethyl chloride into ethanol on heating but quantities of *ether* are obtained by heating concentrated alcoholic potash and ethyl chloride at 100° C. in a sealed tube.[20] By passing ethyl chloride over soda-lime at 350° C., Nef [21] obtained a 30 per cent conversion into ethanol. At the same time some sodium acetate, methane and hydrogen were formed. The first reaction can be represented as

$$CH_3CH_2Cl + NaOH \longrightarrow NaCl + CH_3CH_2OH$$

In attempting to explain the formation of the other products it was suggested that ethyl chloride first undergoes an ethylidene dissociation, such as

$$CH_3CH_2Cl \longrightarrow CH_3CH< + HCl$$

Both of these latter substances then react with the alkali; the hydrogen chloride yielding salt and water, and the ethylidene group (or radical) yields an acetate and hydrogen. There is also the possibility that some alcohol would be formed as an intermediate oxidation product of the ethylidene group by the alkali. Decomposition of the sodium acetate yields methane and hydrogen together with sodium carbonate.

[21] *Ann.*, 1899, **309**, 126; 1901, **318**, 1; *J.A.C.S.*, 1904, **26**, 1549.

According to Müller-Cunradi [22] ethyl chloride may be converted into ethanol by passing it in the presence of excess of steam over a heated contact material, which does not combine with hydrochloric acid. For example, a mixture of ethyl chloride and 10 times its weight of steam, passed at 250° C. over active charcoal impregnated with 5 per cent of zinc sulphate, undergoes practically quantitative conversion into ethanol. The point of equilibrium in the reversible gaseous reaction, $C_2H_5Cl + H_2O \rightleftarrows C_2H_5OH + HCl$, has not apparently been determined at the temperature mentioned above, but, by analogy with the case of the hydrolysis of methyl chloride with steam at elevated temperatures, it is doubtful whether the equilibrium is favorable to this process. The velocity of the reaction

$$C_2H_5OH + HCl \longrightarrow C_2H_5Cl + H_2O$$

in the liquid phase at 110° C. was investigated by Kilpi.[23] The rate of reaction between hydrochloric acid and the alcohol increased more rapidly with the temperature than that of the opposing reaction between ethyl chloride and water.

A process for the manufacture of dialkyl ethers from alkyl halides and in particular of *diethyl ether* from ethyl chloride has been described by Lacy,[24] who proposed to effect this conversion by passing ethyl chloride over heated granular calcium oxide at elevated temperatures. The reaction which is said to occur, namely:

$$2C_2H_5Cl + CaO \longrightarrow (C_2H_5)_2O + CaCl_2,$$

is highly exothermic, and, in order to control the process, Lacy suggested diluting the ethyl chloride vapors with ethane. Thus, a mixture of 1 volume of ethyl chloride and 4 volumes of ethane is passed over granular, or powdered, calcium oxide at 250° to 450° C. The resulting gaseous mixture is led through a cooler, compressed to 10 atmospheres and finally cooled to —20° C., whereby the diethyl ether is separated in the liquid state.

The production of diethyl ether by reaction of ethyl chloride under pressure with ethanol in the presence of an alkaline compound was reported by Carter and Coxe,[25] who also produced *ethyl esters,* such as ethyl butyrate, by heating ethyl chloride under pressure with a sodium salt of an organic acid in the presence of dilute alcohol.[26]

HYDROLYSIS OF HIGHER ALKYL HALIDES, ESPECIALLY CHLORIDES, TO ALCOHOLS

The applicability of vapor phase hydrolysis to alkyl halides of higher molecular weight is greatly reduced, mainly because of their greater tendency to undergo disruptive decomposition into an olefin and a halogen acid, according to the reaction: $C_nH_{2n+1}X \rightarrow C_nH_{2n} + HX$. This decomposition is perhaps the greatest difficulty associated with the hydrolysis of alkyl halides to alcohols, especially with chlorides, which are more difficult to hydrolyze than the bromides and iodides.

[26] U. S. Patent 1,459,971, June 26, 1923; assigned to Karpen and Bros.; *Chem. Abs.,* 1923, 17, 3033.

The alkyl iodides are much more readily hydrolyzed than the other halides but this fact is of little industrial value since the iodides cannot be produced by direct iodination of hydrocarbons. The matter is also further complicated by the great differences in ease of hydrolysis of the primary, secondary and tertiary halogen derivatives of the homologues of ethane. As a rule, the tertiary compounds are fairly readily hydrolyzed and the primary are the most difficult to convert into alcohols. The two extremes of behavior are exemplified by the *tertiary iodides,* which undergo extensive hydrolysis even in the presence of warm water, as contrasted with the *primary chlorides,* which require heating with strong caustic alkali solutions to temperatures of 150° C. or above to effect appreciable hydrolysis.

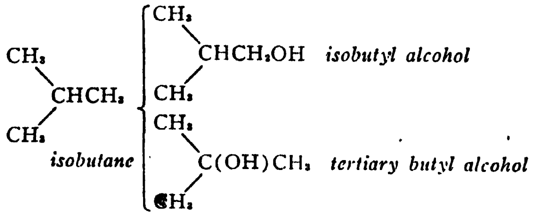
On account of the comparative high price of the bromine compounds and of the difficulty of producing iodine derivatives directly from paraffin hydrocarbons, it appears that only the alkyl chlorides are worthy of attention as commercial raw materials for the manufacture of alcohols. Our knowledge of the hydrolysis of the higher alkyl chlorides is almost entirely restricted to the chlorinated pentanes and isopentanes, which have been extensively investigated during the last few years. As far as is known, practically no investigations have been carried out on the hydrolysis of the monochlorides derived from propane, n-butane, and isobutane but such conversions would appear to offer some commercial possibilities.

Propane is known to yield both of the possible monochlorides on chlorination at elevated temperatures. Of these, 2-chloropropane may be expected, by analogy with the chloropentanes, to be more readily hydrolyzable (to isopropyl alcohol) than the primary chloride. No data are available to show what conditions are necessary for effecting these hydrolyses.

In a similar way n-butane is capable of yielding both a primary and a secondary chloride which might be hydrolyzed to n-butanol and secondary butanol respectively, and isobutane can form only a primary and a tertiary chloride, but no secondary. The monochlorides derived from isobutane should thus be capable of yielding a primary alcohol (isobutyl alcohol) and tertiary butanol. Here again the conditions necessary for successful operation have not been specifically described although they are apparently similar to those used with the amyl chlorides.[27] The various alcohols which might be produced in this manner from propane and the butanes are the following:

$$\underset{\textit{propane}}{CH_3CH_2CH_3} \left\{ \begin{array}{ll} CH_3CH_2CH_2OH & \textit{n-propyl alcohol} \\ CH_3CHOHCH_3 & \textit{isopropyl alcohol} \end{array} \right.$$

$$\underset{\textit{n-butane}}{CH_3CH_2CH_2CH_3} \left\{ \begin{array}{ll} CH_3CH_2CH_2CH_2OH & \textit{n-butyl alcohol} \\ CH_3CHOHCH_2CH_3 & \textit{secondary butyl alcohol} \end{array} \right.$$



---

[27] E.g., Ayres, Canadian Patent 278.537, 1928; *Chem. Abs.*, 1928, 22, 2753.

CONVERSION OF MONOCHLOROPENTANES TO AMYL ALCOHOLS

In considering the hydrolysis of the various monochloro-derivatives of pentane and isopentane to the corresponding amyl alcohols, attention must be drawn to the sharply differentiated properties of the three principal types of monochlorides under these conditions. When the rates of hydrolysis of the three types of monochlorides by hot water alone are compared, it is found that whereas the tertiary compounds are appreciably hydrolyzed, the secondary are more slowly attacked, and the primary chlorides show no tendency to undergo hydrolysis. On the other hand, the order of reactivity of the chlorides is reversed in their reactions with salts of organic acids in homogeneous solutions at, say, 180° C. In this case, the primary chlorides readily react to form esters, the secondary chlorides rather less rapidly and tertiary chlorides do not form esters under such conditions but tend to yield amylenes. During the hydrolysis of amyl chlorides either by water alone or by alkalies or aqueous solutions of alkali salts of the higher fatty acids, considerable quantities of amylenes are formed by elimination of hydrogen chloride according to the reaction $C_5H_{11}Cl \rightarrow C_5H_{10} + HCl$. The velocity of this decomposition increases rapidly with rising temperature and becomes appreciable at temperatures at which the velocity of hydrolysis is sufficiently great to give good yields of amyl alcohols. The production of amylenes is most rapid from the tertiary chlorides, less from secondary chlorides, and least from primary chlorides. According to Ayres,[28] the rates of decomposition of the three classes of amyl chlorides into amylenes and hydrogen chloride at 180° C. are as follows:

	Decomposition per Min. Per Cent
Primary	0.08
Secondary	0.65
Tertiary	3.70

As the temperature is reduced below 180° C. the ratio of rate of decomposition of secondary chlorides to rate of esterification remains the same but the rate of hydrolysis is not reduced nearly so rapidly as the rate of decomposition. On the other hand, the tertiary chlorides are readily hydrolyzed by water even at 100° C., at which temperature the tendency to decompose is relatively slight. Accordingly fairly low temperatures favor good yields of alcohols from secondary and tertiary chlorides. The primary chlorides are more difficult to hydrolyze and require higher temperatures and a catalyst.

According to Ayres, the rates of hydrolysis of primary, secondary and tertiary amyl chlorides in the presence of water alone are as given in Table 135.

TABLE 135.—*Rate of Hydrolysis of Amyl Chlorides in Water.*

	Agitated with Water at 80° C.	Heated in Colloidal Contact with Water at 180° C.

Primary	0.00	0.00

---

[28] *Ind. Eng. Chem.*, 1929, 21, 899.

Although the presence of alkali or dilute acid does not accelerate the rate of hydrolysis, addition of the former material removes the hydrochloric acid formed from the sphere of the reaction and so displaces the equilibrium

$$C_5H_{11}Cl + H_2O \rightleftharpoons C_5H_{11}OH + HCl$$

to the right. It will be noted that the rate of hydrolysis of the primary chlorides is very low even at 180° C. so that it becomes necessary to hasten this reaction in order to obtain the primary alcohols on a commercial scale. The solution of this problem has been achieved by taking advantage of the high velocity of esterification of primary chlorides in the presence of alkali salts of certain fatty acids. In practice it appears only necessary to have present in the reaction mixture a quantity of a fatty acid together with an excess of aqueous alkali. Under these circumstances the primary chloride is first esterified and the ester so formed is immediately hydrolyzed to the alcohol. The hydrolysis of primary chlorides to alcohols by alkali is thus hastened by the addition of fatty acids. For this purpose oleic and stearic acids are especially valuable because, by virtue of the colloidal characteristics of their salts, they facilitate intimate contact between the amyl chloride and the hydrolyzing medium.

Previous to the work of Ayres and his collaborators, Essex, Hibbert and Brooks[29] investigated the hydrolysis of mixtures of monochloropentanes (primary and secondary) by means of aqueous solutions of alkalies, at temperatures of 190° to 300° C. and at pressures of 240 to 6000 lbs. per square inch. The yield of amyl alcohols obtained was practically the same with sodium carbonate as with sodium hydroxide but sodium acetate gave a higher yield than either under the same conditions. Besides amyl alcohols, amylenes and quantities of diamyl ether (not exceeding about 8 per cent) were obtained. By heating 213 grams of chloropentane with 740 cc. of 25 per cent sodium hydroxide for 8½ hours at 250° C. under a pressure of 1200 lbs. per square inch, the yield of amyl alcohol was 20.5 per cent, and a maximum yield of 28 per cent was obtained using 580 cc. of alkali at 210° C. under a pressure of 3300 lbs. per square inch. These results show the difficulty of this hydrolysis.

Summarizing, it may be said that the hydrolysis of amyl chlorides by aqueous alkali in the liquid phase is a matter of some difficulty, requiring fairly high temperatures (150° C. or over). The primary chlorides are most difficult to hydrolyze and the tertiary chlorides least so. On the other hand, the tertiary chlorides have the greatest tendency to decompose into amylene and hydrogen chloride, an undesirable transformation, and the primary chlorides are most stable in this respect. In order to reduce the temperature necessary for the hydrolysis of the difficultly hydrolyzable primary compounds, the addition of soaps of high molecular weight fatty acids (oleic and stearic acids) has been found highly advantageous. The soap not only acts as an esterifying agent, yielding a readily hydrolyzable ester, but also promotes intimate contact of reagents.

THE LARGE SCALE PRODUCTION OF AMYL ALCOHOLS

The large scale manufacture of these alcohols has been described by Ayres[30] and by Clark.[31] The mixture of n- and iso-pentanes, employed in this process, is obtained by the low temperature distillation of natural gas gasoline. The chlorination of such a mixture has been previously discussed in Chapter 30. The mixture of monochlorides, derived from n- and iso-pentanes and containing six isomeric compounds, is subjected to hydrolysis by the action of 30 per cent aqueous caustic soda in the presence of a catalyst (sodium stearate or oleate). These soaps accelerate the hydrolysis of the more difficultly hydrolyzable primary chloride and favor the process generally by assisting emulsification and intimate contact of reactants. The operation of mixing and digesting chlorides, aqueous caustic solution and oleate, and distilling off the alcohols and amylenes was first conducted as a batch process[32] but the steps were later made continuous by joining two digesters, maintaining one full all the time, continuously circulating between the two, and distilling from the second, partly filled. Amyl chloride and aqueous caustic soda are continuously pumped into a hot emulsion of amyl alcohol and water circulating rapidly through a digester, from which are continuously withdrawn two products, namely (1) a saturated salt solution which is returned to electrolytic cells for the manufacture of chlorine and caustic soda; and (2) a vapor consisting principally of mixed amyl alcohols. This vapor is separated by a train of fractionating columns into five components: (a) amyl chloride, which is returned for hydrolysis; (b) amylenes which are hydrated to (secondary and tertiary) alcohols; (c) diamyl ether; (d) amyl alcohol fractions which are cut for special purposes; and (e) a mixture of amyl alcohols marketed as a pyroxylin lacquer solvent under the name of "Pentasol."

The actual temperature used in the hydrolysis of amyl chlorides is not definitely stated but it is probably in the neighborhood of 150° C. It is obviously essential for good yields of amyl alcohols from the three types of chlorides, exhibiting such markedly different behavior on hydrolysis, to choose such operating conditions that, on the one hand, even the difficultly attacked primary chlorides are hydrolyzed with sufficient speed, and on the other hand, the velocity of decomposition of the tertiary chlorides (into amylene and hydrochloric acid) is still relatively low. As with many other chemical processes it became necessary to effect a compromise between two opposing factors. No method of operation can effect complete hydrolysis of the mixture of amyl chlorides and it is a matter of the greatest difficulty to remove the last traces of them from the hydrolyzed alcohols. Thus several hours digestion of amyl alcohol containing 1 per cent of amyl chloride with 5 per cent of metallic sodium only reduces the amyl chloride content to about 0.3 per cent. Fortunately a very satisfactory separation of amyl chlorides and alcohols may be effected by fractional distillation in the presence of water. The chlorides and alcohols form a three-component constant boiling mixture with water, the distillate from which separates on cooling into two layers, an aqueous layer containing alcohol in solution and a non-aqueous layer containing 20 per cent of alcohols and 80 per cent of chlorides.

OTHER METHODS FOR THE PRODUCTION OF AMYL ALCOHOLS

Hibbert, Essex and Brooks[33] described a method of making a material similar to fusel oil containing amyl and hexyl alcohols by hydrolysis of the monochlorides of pentanes and hexanes obtained by the chlorination of a gasoline distillate boiling between 25° and 75° C. The hydrolysis is effected by subjecting the mixed amyl and hexyl chlorides to the action of alkali or alkali carbonate solution under a pressure of 1000 to 4000 lbs. per square inch at temperatures of

[32] Ayres and Haabestad, U. S. Patent 1,691,426, Nov. 13, 1928; *Brit. Chem. Abs.* **B**, 1929, 11; Canadian Patent 286,076, 1929; *Chem. Abs.*, 1929, 23, 1417; British Patent 241,889, 1925; *Brit. Chem. Abs.* **B**, 1927, 859; all patents assigned to B. A. S. Co.

[33] U. S. Patent 1,214,919, Feb. 6, 1917; assigned to Gulf Refining Co.; *Chem. Abs.*, 1917, 11, 1019.

180° to 280° C. A pressure of 3000 lbs. per square inch and a temperature of 220° C. are recommended to give a 40 per cent yield of synthetic fusel oil. The pressure may be attained either by the application of heat alone or by the addition to the charge of a light volatile liquid such as ordinary ether. These high pressures are said to increase materially the yields of alcohols but considerable quantities of alkyl chlorides are always converted into olefins, i.e., amylenes and hexenes. It has been proposed to convert these olefins into (secondary and tertiary) alcohols by absorption in commercial sulphuric acid d 1.86 (at 0° C.), followed by dilution and distillation.

A second, and indirect, method of hydrolysis of amyl and hexyl chlorides consists, according to the same workers, in heating under a pressure of 300 lbs. per square inch or more at 170° to 250° C. with sodium acetate, either with or without a solvent. A mixture of the corresponding amyl and hexyl acetates together with a mixture of olefins is formed. The acetates may be readily hydrolyzed to the corresponding alcohols by the usual methods.

A process of Brooks and Essex [34] for the manufacture of amyl alcohols and other high boiling monohydric alcohols from the corresponding monochlorinated paraffins, consists in heating the chloride under pressure with a mixture of methyl alcohol and a formate. A mixture consisting of a metallic chloride, methyl formate, and the desired amyl or other alcohol is produced. For example, 1 gallon of monochlorinated pentane (or homologous paraffin hydrocarbon) mixture, 3 to 4 gallons of methyl alcohol and 6 pounds of commercial dry sodium formate are introduced into a suitable pressure vessel, which can be rotated. The mixture is heated in this sealed container to about 160° C. for about 6 hours. The methyl formate produced in the reaction may be continuously removed through a weighted valve but this is unnecessary. By retaining the methyl formate in the reaction mixture the progress of the operation may be followed by readings on a pressure gauge, the end of the reaction being indicated by no further increase of pressure. The reaction mixture is then cooled and separated from the insoluble salts, consisting mainly of sodium chloride. Distillation of the salt-free liquid yields first methyl formate (boiling point 32° to 33° C.), then methyl alcohol (boiling 66° to 67° C.) and finally a mixture of amyl and other high boiling alcohols. The methyl formate is hydrolyzed by caustic alkali to methyl alcohol and an alkali formate, both of which are used again.

The hydrolysis of amyl and hexyl chlorides to the corresponding alcohol by first converting them into readily hydrolyzable esters of stearic acid (or other non-corrosive fatty acid of high-boiling point) has been suggested.[35] Stearic acid and solid caustic soda are heated together in a jacketed vessel at 200° to 240° C., and when all excess water has been expelled, a mixture of monochlorinated pentanes and hexanes is introduced at the bottom of the vessel. Part of the halogenated hydrocarbon mixture reacts with the sodium stearate forming esters of stearic acid, another portion is converted into olefins, and the rest distils unchanged. The volatile products are condensed and separated by a reflux cooler maintained at the requisite temperature. The stearic ester in the reaction vessel is cooled to 150° C., treated with sufficient caustic soda to replace the alkali which has reacted with the chlorides, heated again to 200° to 240° C., and the resulting alcohols are distilled off with a little water or steam.

Ayres [36] described a process of producing monohydric alcohols containing 4 or 5 carbon atoms by chlorination of n-butane and n-pentane followed by hydrolysis of the alkyl chlorides with aqueous alkali. The resulting alcohols are purified from chlorides by extraction with water. The hydrolysis of mixed amyl chlorides is also accomplished by heating with aqueous alkali and a substantially water-insoluble organic acid in a closed vessel at 150° C. The organic ester produced is heated in a closed vessel at the same temperature with further quantities of amyl chlorides, and aqueous caustic soda and the amyl alcohols produced are separated by fractionation.[87]

Zinc oxide has also been suggested as a base for the hydrolysis of amyl chloride to amyl alcohol.[87a]

PRODUCTION OF AMYL ESTERS FROM CHLOROPENTANES

The classical method of preparation of alkyl esters of organic acids by the direct combination of an alkyl halide with the anhydrous salt of an organic acid has been applied by a number of workers to the production of amyl esters from monochlorinated pentanes. Some data on this type of reaction have been supplied by Ayres.[88] The comparative figures are given in Table 136 for the rates of esterification of the primary, secondary and tertiary amyl chlorides by potassium acetate in glacial acetic acid solution at 180° C.

TABLE 136.—*Rates of Esterification of Amyl Chlorides with Potassium Acetate at 180° C.*

	Esterified per Min. Per Cent
1-Chloropentane	3.17
1-Chloro-2-methylbutane	3.17
4-Chloro-2-methylbutane	1.20
Secondary amyl chlorides	0.60
Tertiary amyl chlorides	0.00

The figures in Table 136 reveal the fact that the primary chlorides are much more readily esterified than secondary chlorides. Dry esterification (in the absence of water) of tertiary amyl chloride does not yield an ester but only trimethylethylene. The above rates of reaction are approximately doubled for a temperature rise of 10° C. and are of the same order with the potassium, sodium, or calcium salts of acetic, butyric, oleic, and stearic acids provided the salts are in molecular contact with the amyl chloride. This problem of intimate contact is simplified in the case of the higher fatty acids, the salts of which serve to emulsify the reaction mixture. According to Ayres, the esterification of secondary amyl chlorides in the absence of water yields about 48 per cent of the ester but in the presence of water the yield varies from 65 per cent at 180° C. to almost theoretical at 100° C. As in hydrolysis, the yields are reduced by decomposition of these chlorides into amylene and free hydrogen chloride. This decomposition is greatest in the case of the tertiary, and at a minimum with primary chlorides. The formation of amylenes from amyl chlorides is, fortunately, not accelerated by moisture, caustic soda, amyl alcohol and esters or fatty acids.

Among the earlier studies of the conversion of amyl chlorides into acetates, that of Brooks, Smith and Essex[89] is of interest. A mixture of chlorinated pentanes, boiling between 95° and 140° C. and containing about 90 per cent of (mixed) monochlorides, was acetylated by heating under pressure with sodium acetate and acetic acid in the presence of a solvent (alcohol, acetone, or amyl acetate). Yields of amyl acetate varying from 55 per cent to 63 per cent of the theoretical were obtained by heating the reaction mixture for 5 to 9 hours at 195° to 200° C. under a pressure of 180 to 230 lbs. per square inch, though at the same time quantities of amylenes were always produced.

[89] *J. Ind. Eng. Chem.*, 1918, **10**, 511.

Koch and Stallkamp[40] have described a method of esterification of amyl chlorides in which the tendency of these amyl chlorides to decompose into amylenes and hydrogen chloride is said to be suppressed by the introduction of activated charcoal as a catalyst,[41] The esterification is carried out by mixing the amyl chloride along with 65 to 75 parts by weight of fused and ground sodium acetate and 1 to 2 parts of solvent in a steel-jacketed, agitator-equipped autoclave, which is then heated to 400° to 450° F. (pressure, 200 to 250 lbs. per sq. in.) for about 8 hours. The esterified product is distilled directly from the autoclave through a condenser into a washer where it is washed and neutralized with sodium carbonate solution, and again distilled to yield the following fractions:

Fraction 1, boiling up to 82° C., Amylenes, pentanes, etc.
Fraction 2, boiling 82° to 120° C., Unconverted amyl chloride and some esters.
Fraction 3, boiling 120° to 175° C., Amyl acetate.

The amyl acetate recovered in fraction 3 had the following properties: d 0.88; color, none; moisture, none; acidity, 0.196 per cent as acetic acid. It compared favorably with the technical grade of amyl acetate.

The influence of the addition of activated charcoal to the reaction liquid is clearly brought out by the figures in Table 137 of yields of ester obtained in comparative experiments with and without the addition of charcoal.

6 hours 40 min.	29.2	8 hours 15 min.	83.2
7 hours 20 min.	35.4	8 hours	78.3

Yields of amyl acetate as high as 90 per cent of the theoretical were obtained by Dobryanski and Gurevich[42] by heating amyl chlorides (obtained by the photochemical chlorination of a fraction of Krasnodar aviation gasoline, boiling 31° to 38° C.) with dry sodium acetate at 230° C. in sealed tubes for 4 to 8 hours.

According to Clark,[43] it is better to produce amyl esters by direct esterification of the alcohols resulting from the hydrolysis of amyl chlorides than by direct esterification of the chlorides. Since the tertiary alcohol cannot be directly esterified by the use of ordinary reagents, this alcohol is first removed from the mixture of amyl alcohols, which are then acetylated in a kettle at 125° C. in the presence of sulphuric acid as a catalyst. The crude esters are neutralized with soda ash and purified by fractionation. The production of mixed amyl phthalates by direct esterification of "pentasol" with phthalic anhydride was described by

Jaeger.[44] The product, boiling at 190° to 205° C. at 10 mm., is colorless or slightly yellow after rectification and is a solvent and plasticizer.

OTHER METHODS FOR THE PRODUCTION OF AMYL ESTERS

Masland[45] reported that good yields of amyl acetate may be obtained by heating a mixture of equal weights of monochloropentanes and acetic acid together with sufficient sodium acetate to combine with all the chlorine present. Acetic acid of 70 per cent concentration or higher may be employed. The reactants are heated in a sealed pressure container to a temperature of 180° C. or higher and under a pressure of about 250 lbs. per square inch. The period of heating may vary from 2 to 12 hours, longer periods being required with lower temperatures. The products consist of amyl acetate together with quantities of unsaturated hydrocarbons. The same worker[46] also suggested that the process can be modified so that the reaction mixture, consisting of amyl (or hexyl) chlorides, sodium acetate, and acetic acid (of concentrations down to 70 per cent) is subjected to a preliminary heating at 150° C. and 100 lbs. per square inch pressure for several hours. This treatment results in the production of olefins from the more readily decomposable chlorides. The olefins so formed are removed as far as possible by distillation, and the residual reaction mixture is then heated to 180° C. or higher at 250 lbs. per square inch pressure, at which time the main esterification takes place.

Kaufler[47] stated that the esterification of amyl chlorides by means of sodium acetate is greatly facilitated by the employment of sodium acetate prepared in a highly porous and bulky condition. By heating 100 parts by weight of amyl chloride, 72 parts of this grade of sodium acetate and 6 parts of glacial acetic acid under pressure for 12 hours at 195° to 210° C., a yield of 65 parts by weight of amyl acetates, boiling at 120° to 146° C., is obtained. The efficiency of esterification is enhanced by the addition of catalysts, such as copper salts, to the reaction mixture. Using quantities of reactants identical with those given above but with the addition of 3 parts by weight of copper acetate, the same yield of amyl acetates was obtained by operating at a lower temperature and for a shorter time, e.g., by heating at 170° to 180° C. for 8 hours.

Sparre[48] described a process for the manufacture of a nitrocellulose solvent by the acetylation of a mixture of mono- and di-chlorinated paraffin hydrocarbons (pentanes and hexanes) with sodium acetate and acetic acid. The composition of the solvent mixture obtained in this manner was approximately 35 per cent of olefins, 5 per cent of chloro-olefins, 50 per cent of monoacetates and 10 per cent of diacetates.

A process of Essex and Brooks[49] for the manufacture of amyl and similar esters from monochlorinated petroleum fractions involves heating the dry monochloride mixture with an equal weight of dry fused alkali salt of a fatty acid. The reaction is carried out in an autoclave at a temperature of about 200° C., and in the presence of a solvent such as acetic acid or preformed ester. For making esters of acetic acid, the sodium, potassium, or calcium salts of this acid may be employed while, if other esters are desired, such as formates, butyrates, propionates, benzoates, etc., the corresponding alkali salts may be substituted. The period of reaction depends mainly upon the temperature employed, the use of higher temperatures rendering possible the employment of shorter reaction periods. Suitable times of reaction are 20 hours at 150° C., 5 hours at 200° C., and 2 hours at 220° C. For the manufacture of amyl acetate, good yields are secured by using 100 parts of a mixture of equal parts of chloropentane and sodium acetate, 64 parts of glacial acetic acid and 64 parts of amyl acetate and effecting the reaction at 200° C. for 5 hours under pressure in a rotating autoclave.

For the *purification* of synthetic amyl acetate prepared from chlorinated pentanes, Essex and Humphrey [50] recommended heating it with metallic sodium and then washing with water. The relatively small amounts of chloro-compounds (which are objectionable since they reduce the solvent properties) cannot be removed by heating with metallic magnesium or with the zinc-copper couple. The amount of sodium required for this purification step is that equivalent to the combined chlorine present and ordinarily does not exceed 1 per cent or so of the weight of material. Thus by refluxing 125 parts by volume of a synthetic amyl acetate with 1 per cent of metallic sodium for 2 hours, followed by cooling, dilution with water, separation and drying over calcium chloride, a product was obtained of better odor and considerably enhanced solvent properties as compared with the original ester. This procedure is said to be equally applicable to the purification of amyl alcohol, amyl formate, and other amyl esters synthesized from chloropentanes. Another method for the purification of amyl acetate containing chlorohydrocarbons has been proposed by Oberfell and Boyd,[51] who made use of the solubility of amyl acetate in sulphuric acid, in which the impurities are not soluble. The purification therefore consists in fractionally distilling the esterified chlorohydrocarbons to remove olefin hydrocarbons formed during the reaction and then treating the residue with sulphuric acid. The latter dissolves amyl acetate and similar esters, leaving the other constituents unaffected. The two layers are separated and the amyl acetate is recovered from its solution in sulphuric acid either by dilution with water or by wet steam distillation.

For the manufacture of amyl acetate from chloropentane Oberfell and Boyd [52] recommended esterification in the presence of sodium or potassium sulphate which they believe minimizes the decomposition of the chloropentane into amylenes. By heating a charge of 100 parts (by weight) of chloropentane, 72 parts of fused alkali acetate, 0.5 parts of acetic acid, and 1 part of sodium or potassium sulphate in a mechanically stirred acid-resisting autoclave under pressure at a temperature of 195° C. for 8 to 14 hours, a 65 per cent yield of amyl acetates, boiling at 120° to 148° C., is obtained. The presence of more than a trace of water in the alkali acetate is stated to be detrimental, since it leads to increased formation of amylenes.[53] The esterified product may be removed from the autoclave by distillation under pressure. Another catalyst which is employed to suppress partly the undesirable decomposition reaction resulting in the formation of olefins and to increase the yield of ester is activated carbon, such as "batchite" or "dorsite."[54] Yields of about 75 per cent of the theoretical amount of amyl acetate are obtained by heating a mixture of chloropentane, sodium acetate and activated carbon, particularly batchite, with or without the addition of acetic acid, at 250° to 450° F. and a pressure of 200 to 225 lbs. per square inch in an autoclave provided with a mechanical stirring device.

[53] This is apparently contradictory to the results obtained by Ayres (previously noted). These two conclusions, however, can be reconciled if it is assumed that the reaction between amyl chloride and alkali acetate is facilitated by the small amount of acetic acid acting as a mutual solvent. Water would tend to throw out the amyl chloride from the acetic acid-potassium acetate solution and slow up the esterification rate while olefin formation proceeds unchecked, hence giving a lower yield of acetate. Under the conditions mentioned by Ayres, the sodium oleate and amyl chloride mix in all proportions and water does not throw out the amyl chloride. (Hass, private communication.)

Carter and Coxe[55] suggested a procedure for the manufacture of esters in which a halogenated paraffin hydrocarbon is heated under pressure at 100° C. with a metallic salt of an organic acid in the presence of water and a solvent for the halogenated hydrocarbon, such as alcohol. The production of amyl esters as intermediate products in the hydrolysis of amyl chlorides (especially primary compounds) by heating a substantially water-insoluble fatty acid, amyl chloride, and aqueous caustic soda in a closed vessel at 150° C. is described by Ayres and Haabestad.[56]

PROPERTIES AND USES OF THE SYNTHETIC AMYL ALCOHOLS AND THEIR ESTERS

The amyl alcohols find very extensive application, especially in the form of their esters, as solvents for cellulose nitrate in the production of pyroxylin lacquers. Despite the many new solvents available for cellulose nitrate, amyl acetate still holds a high position in this respect. Until the discovery of the synthetic processes, outlined above, the main source of amyl alcohols was the so-called fusel oil which constitutes a by-product of the alcohol fermentation industries Ordinary fusel oil contains two amyl alcohols, both of which are primary (3-methylbutanol and 2-methylbutanol) as well as other primary alcohols including n-propanol, isobutanol, and n-hexanols. On the other hand the synthetic amyl alcohols from petroleum pentanes contain not only primary, but also secondary alcohols and a tertiary alcohol, the relative proportions of these alcohols depending mainly upon the method of chlorination and the conditions of hydrolysis. The process described by Ayres[56a] and Clark[56b] produces six, out of the possible eight, isomeric amyl alcohols. Of these, three are primary; two, secondary; and one, tertiary. This mixture of isomers possesses the following approximate composition: 50 per cent primary isoamyl alcohols, 25 per cent of primary n-amyl alcohol, and a residue of 25 per cent consisting of secondary and tertiary alcohols. The physical properties of these six amyl alcohols are listed in Table 138.

TABLE 138.—*Physical Properties of Amyl Alcohols.*

Amyl Alcohol	Dry B.P., ° C.	d_{20}^{20}	Aqueous Azeotrope B.P., ° C.
Pentanol-1	138	0.817	95.5

[56b] *Loc. cit.*

Synthetic amyl alcohol is not a solvent for cellulose esters or cumaron but dissolves ester gum, elemi, mastic, shellac, and other resins, but only partly in the case of dammar, and is miscible with castor and linseed oils. Its main application is in the form of its esters.

By far the most important of the amyl esters is the acetate, though the formate and propionate have also been used to a lesser degree. A grade of synthetic amyl acetate, which has been marketed under the name of "Pentacetate," consists of a mixture of esters derived from three primary and two secondary amyl alcohols. Tertiary amyl alcohol, though produced in the synthesis from pentanes, cannot be esterified by ordinary means. "Pentacetate" meets the following specifications:

Color	Water white
d_{20}^{20}	0.860–0.870
Acidity	Less than 0.03% as acetic acid
Non-volatile at 100° C.	Less than 0.02%
Water content	None
Halogen content	None
Petroleum hydrocarbons	None
Weight per gallon	7.2 lbs.
Distillation	100% above 126° C.
	95% above 130° C.
	75% above 135° C.
	25% above 140° C.
	End point not above 155° C.

The mixture of synthetic isomeric amyl acetates has solvent properties almost identical with that manufactured from fusel oil and the tolerance of a nitrocellulose solution for toluene is about the same as that of pure amyl acetate and secondary butyl acetate but not as high as that of n-butyl and ethyl acetates. Data on tolerance of nitrocellulose solutions to hydrocarbons, viscosities of nitrocellulose solutions, evaporation rates and solubility of resins in the synthetic amyl acetate have been supplied by Wilson and Worster,[57] and demonstrate the essential similarity of the properties of this solvent with those of amyl acetate derived from fusel oil.

Amyl acetate is an excellent solvent for cellulose nitrate, and like synthetic amyl alcohol can be used as a solvent for a number of resins. It is not a solvent for cellulose acetate. Pentacetate has been stated to possess a slight, though not dangerous, toxicity.[58]

Of the other amyl esters, *amyl formate,* which is also a solvent for cellulose nitrate and a number of resins, has been used instead of amyl acetate for special applications, including those involved in the manufacture of leather-cloth and of non-splintering glass. It lacks the disagreeable odor of amyl and n-butyl acetates and hence is preferable to these solvents for upholstery work. *Amyl propionate* possesses a milder odor and slower rate of evaporation than the acetate and has been used for brushing lacquers where lower evaporation rate is desired. Some of the amyl esters are finding application in the manufacture of synthetic fruit essences and perfumes and for such purposes the synthetic amyl esters should prove valuable raw materials. The main utilization of amyl esters, however, is in the manufacture of lacquers.

PRODUCTION OF HIGHER ALCOHOLS FROM HIGHER ALKYL HALIDES

So little work has been carried out on the hydrolysis of monochlorinated paraffins of more than five carbon atoms that it is profitless to enter into any discussion of their possible applications. So far the aliphatic alcohols of more than five carbon atoms have not been of as great industrial value as the butyl and amyl alcohols. When these higher alcohols are required in sufficient quantities for special purposes a number of synthetic methods are available for their production from the lower alcohols and also from carbon monoxide and hydrogen. The production of some of the hexanols from monochlorinated hexane can apparently be brought about in a manner analogous to that used for the hydrolysis of the amyl chlorides. A *hexyl ester* was prepared by Pelouze and Cahours [59] by direct esterification of a monochlorinated petroleum hexane fraction while a *heptyl ester* was similarly obtained by Schorlemmer [60] from a chlorinated petroleum heptane. These products were in all probability mixtures of isomers but their preparation shows the possibility of extending the processes, previously described, to higher members of the series.

Of considerable interest is the possibility of producing *glycerol,* the alcohol of all edible fats, from petroleum hydrocarbons. Both propylene dichloride and allyl chloride have been suggested as starting materials for this synthesis. Thus, McElroy [61] converted propylene, or gaseous mixtures containing propylene, to glycerol by first treating it with chlorine to obtain propylene dichloride, followed by further chlorination to 1,2,3-trichloropropane, a liquid boiling at 158° C. The latter chlorination may be carried out either in the liquid phase in the presence of iodine and light, or in the vapor phase in the presence of a catalyst, such as bone-black. The 1,2,3-trichloropropane is then hydrolyzed by heating under pressure with aqueous sodium bicarbonate solution or it may be heated with sodium acetate solution to furnish acetins which are subsequently hydrolyzed. The process may be varied by first producing the propylene chlorohydrins which are then subjected to chlorination either in the presence of glacial acetic acid or a saturated solution of sodium phosphate and phosphoric acid. The resulting dichlorohydrin is then hydrolyzed to glycerol.

A process of Essex and Ward [62] involves the conversion of allyl chloride into glycerol dichlorohydrin by treatment with hypochlorous acid, followed by hydrolysis of this product to glycerol. For example, a mixture of 225 parts of allyl chloride and 4000 parts of an aqueous solution containing 215 to 220 parts of sodium hypochlorite is cooled and vigorously stirred while carbon dioxide is introduced into the solution until a test shows only a trace of hypochlorous acid. The flow of carbon dioxide is discontinued and the stirring stopped and a little less than 400 parts of sodium carbonate are added. The reaction mixture is then boiled under reflux for 7 hours, after which time the yield of glycerol in the resulting liquid is said to be 82 per cent of the theoretical.

Chapter 34

Miscellaneous Reactions of Halogen Derivatives of Paraffins and Cycloparaffins

Because of the great number of known halogenated derivatives of the paraffin and cycloparaffin hydrocarbons and the great variations in their chemical reactivity it is possible, in a discussion of this type, to list only a few of the more important chemical reactions of those derivatives which are likely to become commercially available. The chlorine derivatives alone are worthy of serious notice since bromine and iodine compounds are too expensive for large scale application. From a technical point of view the monochlorinated paraffins, or alkyl chlorides, are by far the most important, mainly because they can be used in chemical synthesis, for example as alkylating agents, and also because of their relative ease of preparation in a pure condition.

MISCELLANEOUS REACTIONS OF THE ALKYL HALIDES

The normal order of chemical reactivities of the alkyl halides is as follows: the iodides are generally more reactive than the bromides; the chlorides are least reactive. This generalization is, however, only true for one particular type of alkyl halide since constitutive influences play an important rôle in determining chemical reactivity. In most chemical processes, the primary halides are less reactive than the secondary compounds while the tertiary products undergo some reactions with amazing facility. The tertiary halides, though, are incapable of taking part in some of the reactions exhibited by the other two classes; for example, they do not react with salts of organic acids or with alcoholic ammonia to yield esters and amines respectively but, under the influence of these reagents, are transformed in large measure to the corresponding olefin.

The halogen atom in alkyl halides is often replaceable by another halogen atom merely by heating with certain metallic halides. For example, n-propyl iodide is partly converted into the corresponding chloride by the action of mercuric chloride. Many other examples of this interchange of halogens have been noted.

In the following pages a few of the more important reactions of the alkyl halides are briefly discussed, attention being concentrated more especially on the readily available alkyl chlorides. This account is not to be considered by any means exhaustive but it will serve to indicate some of the obvious applications, both actual and potential, of these compounds in chemical technology. Among the more interesting, and valuable, reactions of the alkyl halides, the following may be mentioned:

(1) Production of olefins and hydrogen halides by the reaction

$$C_nH_{2n+1}X \longrightarrow C_nH_{2n} + HX.$$

(2) Reaction with alkali alcoholates or phenates to yield ethers, thus:

$$C_nH_{2n+1}X + NaOR \longrightarrow C_nH_{2n+1}OR + NaX,$$

where R = alkyl or aryl group.

(3) Condensation with alcoholic ammonia or with amines to yield alkylamines.

$$C_nH_{2n+1}X + NH_3 \longrightarrow C_nH_{2n+1}NH_2 + HX.$$

(4) Condensation with hydrocarbons, or certain derivatives of hydrocarbons, under the influence of Friedel-Crafts condensing agents to furnish alkylated derivatives; as for example:

$$C_nH_{2n+1}X + C_6H_6 \xrightarrow{AlCl_3} C_nH_{2n+1}C_6H_5 + HX.$$

The use of trialkyl or triaralkyl borates has been proposed in place of the halides generally employed in this type of condensation.[1]

(5) Replacement of halogen by certain acid radicals, such as —CN, —SH, and others through interaction with salts of these acids.

$$C_nH_{2n+1}X + KCN \longrightarrow C_nH_{2n+1}CN + KX$$

$$C_nH_{2n+1}X + KSH \longrightarrow C_nH_{2n+1}SH + KX$$

$$C_nH_{2n+1}X + AgNO_2 \longrightarrow C_nH_{2n+1}NO_2 + AgX$$

(6) Interaction with metallic magnesium to yield Grignard compounds capable of being utilized in numerous syntheses.

$$C_nH_{2n+1}X + Mg \longrightarrow C_nH_{2n+1}MgX.$$

An industrial application of the Grignard synthesis is the preparation of lead tetraethyl from the halogen derivatives of ethane. In one procedure ethyl chloride, dissolved in ethyl ether, is treated with lead chloride and magnesium turnings. After treatment with water and sodium hydroxide, the ether is removed by distillation, and the lead tetraethyl recovered by steam-distillation.[1a]

The most technically important reactions of the alkyl chlorides, namely hydrolysis to alcohols and interaction with metallic salts to furnish esters, have already been discussed in detail in Chapter 33.

THE DECOMPOSITION OF ALKYL HALIDES INTO OLEFINS

The alkyl halides are decomposed to yield olefins and hydrogen halides according to the reaction, $C_nH_{2n+1}X \rightarrow C_nH_{2n} + HX$, by the action of chemical reagents, such as alkalies or alkali salts of organic acids, as well as by the action of heat with or without catalytic influence. The production of olefins during the hydrolysis of alkyl halides by alkalies, as in the production of alcohols, occurs most readily in the case of the tertiary halides and least so in the case of the primary compounds. Dechlorination of the chlorinated hydrocarbon may be effected by the action of hot alkalies in aqueous or alcoholic solutions but the reaction yields ethers and alcohols as well as olefinic hydrocarbons.[2] Organic bases can be used also for dechlorination, for example, Fortey[3] was able to obtain cyclohexene by heating chlorocyclohexane with quinoline.

The production of olefins from alkyl halides under the influence of heat, with or without catalysts, is a reversible process in certain instances such as ethylene, propylene and tertiary olefins, in which the point of equilibrium in the reaction, $C_nH_{2n+1}X \rightleftarrows C_nH_{2n} + HX$, is displaced towards the right-hand side of the equation with rising temperature.[3a] Accordingly low temperatures favor the production of alkyl halides from olefins,[4] while higher temperatures favor the production of olefins from these halides. In general the alkyl iodides are most readily decomposed by heat (especially the tertiary iodides) and the chlorides least so. Methyl chloride is the most resistant of the alkyl halides to thermal decomposition but pyrolysis is quite noticeable at about 500° C. The products consist of hydrogen chloride, carbon, methane, and other hydrocarbon gases.[5] In contrast to the thermostability of methyl chloride, the compound methyl iodide, though the most stable alkyl iodide, undergoes some decomposition at about 270° C. yielding methane, ethylene, and iodine.[6]

[1] Kaufmann, French Patent 720,034, 1931; *Chem. Abs.*, 1932, 26, 3803.

[1a] Daudt, U. S. Patent 1,798,593, March 31, 1931; assigned to E. I. duPont de Nemours and Co., Inc.

[2] Nef, *Ann.*, 1899, 309, 128; 1901, 318, 1.

[3] *J.C.S.*, 1898, 73, 941.

Ethyl chloride was found by Nef[7] to be decomposed at 510° to 530° C. in the presence of pumice to yield 55 per cent of ethylene, while at 560° to 600° C. 76.8 per cent of ethylene was produced. The marked catalytic influence of the chlorides of the divalent elements (nickel, cobalt, iron, cadmium, lead, and especially barium) on the decomposition of alkyl chlorides into olefins at temperatures as low as 260° C. was shown by the work of Sabatier and Mailhe.[8] Brooks[9] obtained quantitative yields of ethylene and propylene from ethyl and propyl chlorides respectively by the catalytic influence of barium chloride on pumice at 400° to 450° C.

The decomposition of the propyl chlorides into propylene and hydrogen chloride has been studied by a number of workers. Sabatier and Mailhe[8] obtained good results with barium chloride, or other divalent metallic chlorides, at 260° C., but the catalyst tended to become gray in color because of the simultaneous polymerization of some of the olefins. According to Senderens,[10] alumina is an excellent catalyst for the decomposition of propyl and isobutyl chlorides at temperatures above 250° C. For example, propyl and isobutyl chlorides gave, with alumina as catalyst, at 350° C. a 97 per cent yield of propylene and 95 per cent of isobutylene, respectively.

The pyrolysis of 1- and of 2-chlorobutane both in the absence and in the presence of a catalyst (calcium chloride) has been investigated by Weston and Hass.[11] In the absence of catalysts the decompositions of 1-chlorobutane (at 550° C.) and of 2-chlorobutane (at 500° C.) were found to be homogeneous gaseous reactions. 1-Chlorobutane yielded butene-1 as the only product, while 2-chlorobutane on decomposition yielded a mixture of butene-1, *cis*-butene-2 and *trans*-butene-2. At 450° C. and in the presence of the catalyst both of the chlorobutanes were decomposed into mixtures of principally the *cis*- and *trans*-butene-2, together with a small proportion of butene-1. At still lower temperatures (400° C. and 250° C.) almost no butene-1 was formed by the decomposition of 2-chlorobutane. With both of the chlorobutanes the percentage of decomposition was observed to increase with increasing times of exposure to the heated reaction zone. It was not determined whether the butenes rearranged in the presence of the catalyst or whether the catalyst induced decomposition with formation of the two butene-2 compounds directly from the chlorobutanes.

[3a] The kinetics of the decomposition of alkyl halides in the gas phase at 300° to 400° C. has been studied by Lessig (*J. Phys. Chem.*, 1932, **36**, 2325; *Chem. Abs.*, 1932, **26**, 5000).

[4] An account of the production of alkyl halides from olefins is given in Chapter 12.

As previously mentioned in Chapter 33, Ayres[12] observed the following percentage decomposition of various amyl chlorides in the liquid phase at 180° C.

	Decomposed per Min. at 180° C. Per Cent
Primary chlorides	0.08
Secondary chlorides	0.65
Tertiary chloride	3.70

It is evident that the decomposition of the tertiary chloride is considerable at 180° C., though it is inappreciable at 100° C. According to Ayres the formation of amylenes from the amyl chlorides is not accelerated by moisture, caustic soda, amyl alcohols or fatty acids and the only amylene formed in an alkaline hydrolysis of an amyl chloride is that derived from the purely thermal decomposition of the chloride.

Faragher and Garner[13] studied the catalytic production of olefins from chlorinated hexane, isohexane, cyclohexane, and heptane. They found that the stability of the monochloro-derivatives at a given temperature decreased with increasing molecular weight, at least up to about 7 carbon atoms in the chain. The following catalysts were tried at temperatures of 150° C. and over: alumina, unglazed porcelain, and porcelain impregnated with barium chloride. Of these catalysts, alumina was the most efficient, but all three lost their activity rapidly because of the poisoning by the decomposition of the hydrocarbons. The employment of temperatures higher than 200° C. resulted in a more complete decomposition of the chloro-compound, a fact which is well illustrated in Table 139, which gives experimental results showing the iodine numbers of products from the catalytic decomposition of chloroheptane at temperatures of 150° C. to 400° C. in the presence of various contact materials. The theoretical iodine number for a heptene is 260.

TABLE 139.—*Iodine Numbers of Condensates from the Catalytic Decomposition of Chloroheptane.*

Temp. ° C.	Unglazed Porcelain	Alumina	Unglazed Porcelain and Barium Chloride	Pyrex Glass
150	100	—	—	—
200	127	198	178	52.5
250	192	238	187	64
300	260	254	170	83
400	265	250	180	181

The condensates obtained in the experiments of Faragher and Garner readily yielded fairly pure olefins on fractionation. This method of removing hydrogen chloride from a chloro-compound is recommended by these workers. No indications of the extent of isomerization occurring during the reaction are given but, at the higher temperatures at any rate, considerable rearrangement must have occurred. Moreover, the rapid poisoning of the catalyst is an obvious disadvantage of this and similar methods. For the production of trimethylethylene from isoamyl chloride, isoprene from chloroisoamylene, and butadiene from dichlorobutane, Müller-Cunradi and Ober[13a] suggested a catalyst of titanium dioxide at 300° to 500° C. under atmospheric or reduced pressure.

The observation of Faragher and Garner that the tendency of decomposition of the alkyl chlorides increases with increasing molecular weight is in agreement with the results of Schaarschmidt and Thiele [14] on the production of fatty acids from paraffin. It was found that chlorine can be quantitatively removed from (mono-) chloro-derivatives of paraffin merely by heating the chloroparaffin at about 300° C. The resulting olefin, however, possessed a much lower iodine value than that obtained by the action of alcoholic alkali, a result indicating that the olefin, initially produced, had undergone partial cyclicization. Similar observations were made by Gardner and Bielouss [15] on the chlorinated paraffins of 17 or more carbon atoms. These chloro-compounds could be completely dechlorinated by heating to about 250° C. without the aid of catalysts but the products showed much lower iodine numbers than required by theory, again showing that partial transformation of the olefins to cyclic hydrocarbons had taken place under the influence of heat. The work of Gardner and Bielouss was directed toward the application of the olefinic compounds produced by thermal decomposition of chlorinated high molecular weight paraffins, as drying oils. The reactions of these hydrocarbons with several reagents were also investigated. At temperatures ranging from —5° to +20° C. sulphuric acid combined with a small proportion of the unsaturated hydrocarbons in the product to yield alkylsulphuric acids, which could be hydrolyzed to alcohols. The principal action of sulphuric acid was the almost complete polymerization of the unsaturated hydrocarbons. With sulphur monochloride, in amounts varying from 10 to 30 per cent of the hydrocarbons, the formation of hard and brittle products took place. When treated with this same reagent (sulphur monochloride) but in the presence of 10 to 15 per cent tung oil, rubber-like substances were obtained, which were similar in appearance to some of the so-called vulcanized oils. The use of concentrated nitric acid resulted in the polymerization of these hydrocarbons.

While some unsaturated hydrocarbons can be esterified by organic acids, Gardner and Bielouss failed to obtain such esters from their product on treatment with either acetic acid for 8 to 10 hours at 120° to 130° C. or with abietic acid for 6 to 8 hours at 200° C.

Gardner [16] has also described a procedure for the dechlorination of chlorinated petroleum products by heating the chlorinated oil to temperatures of 210° C. or higher in the presence of high-boiling materials, such as soya-bean oil, castor oil, and paraffin wax. The unsaturated hydrocarbons may be recovered by vacuum distillation and are said to be useful in the manufacture of varnishes.

According to Gardner,[17] these unsaturated hydrocarbons, or dechlorinated oils, may be used together with sulphur and rubber to produce tough molded articles, which can be vulcanized. The addition of fillers or pigments, such as zinc oxide, barium sulphate or lampblack, can be made also. Tire-treads, shoe soles, laminated waterproof fabrics or coatings for paper, are examples of the types of uses. Shiffler, Holm and Miller [17a] dechlorinated distillates containing combined chlorine formed as a result of cracking with aluminum chloride, by heating them at 150° C. under pressure in the presence of ferrous sulphide or calcium oxide.

Polychlorinated paraffin hydrocarbons may be converted to either saturated

or unsaturated products by means of alkalies. When the halogenated hydrocarbons, containing more than 8 carbon atoms and not more than 9 chlorine atoms per molecule, are boiled under a reflux apparatus with solutions of sodium hydroxide or carbonate, dechlorination is effected with the formation of saturated substances. In this procedure catalysts such as copper salts or the oxides or hydroxides of iron or zinc may be employed. On the other hand, by heating chlorinated hydrocarbons with milk of lime under pressure at 150° to 160° C. unsaturated hydrocarbons possessing the characteristics of drying oils are obtained.[18]

If in place of refluxing the chlorinated hydrocarbons with solutions of sodium hydroxide or carbonate the reaction is carried out under pressure, then light-colored viscous oils are the result. These oils are probably unsaturated monohydric alcohols and may still contain halogens.[19]

Monochloro-derivatives of the Cycloparaffins. Faragher and Garner reported that monochloro-cyclohexane was much more readily decomposed than the alkyl chlorides of 6 and 7 carbon atoms and this rule also applies to the higher chlorinated derivatives. The ease with which the chlorinated cycloparaffins decompose to yield cyclic olefins and hydrochloric acid was employed by Thiele[20] in making drying oils from kerosene containing considerable proportions of cycloparaffins. Chlorinated kerosene is acidified with acetic acid and then treated with metallic zinc. The cleavage of hydrogen chloride from various mono- and dichlorocyclohexanes by the use of catalysts, such as barium chloride or alumina, has been proposed by Schmidt, Hochschwender and Eichler.[21]

ISOMERIZATION PHENOMENA AMONG ALKYL HALIDES

Many alkyl halides, when heated either in the liquid or gaseous phases, exhibit a marked tendency to isomerize to a more stable isomer. The general trend appears to be for primary halides to isomerize to secondary which in turn possess a disposition to be transformed to tertiary compounds whenever possible. There is little doubt that this isomerization reaction takes place by the intermediate production of an olefin,[22] so that the conversion of n-propyl bromide into isopropyl bromide may be represented as follows:

$$\mathrm{CH_3CH_2CH_2Br} \longrightarrow (\mathrm{CH_3CH{=}CH_2 + HBr}) \longrightarrow \mathrm{CH_3CHBrCH_3}$$

According to Brunel,[23] n-propyl bromide when heated in the liquid phase for 1 hour at 262° C. is converted to the extent of about 22 per cent into the iso-form, while in the gaseous phase at the same temperature a conversion of over 34 per cent was observed after 2 hours. The reverse process, conversion of isopropyl bromide into the n-bromide, takes place at 260° C. though very much more slowly. In the gaseous phase at 360° C. an equilibrium is ultimately set up in which the ratio of iso- to n-bromide is 73:27; quantities of hydrogen bromide and propylene are also present.[24] In a similar way, isobutyl bromide may be isomerized to the tertiary bromide to the extent of 72 to 74 per cent by heating at 140° C.

for 15 hours,[25] while the tertiary bromide may be partially reconverted to the isobutyl bromide by heating to temperatures of 180°-260° C. for several hours. At 237° C. in the liquid phase the equilibrium appears to correspond to a mixture of 73 per cent tertiary and 27 per cent of isobutyl bromides, but in the gaseous phase at 280° C. the equilibrium mixture contains 90 to 91 per cent of the tertiary form.[26]

A number of transformations of amyl bromides have been studied in some detail by Michael and Leupold,[27] who found that the tertiary compound is the most stable variety. Nevertheless tertiary amyl bromide, when heated in the liquid state at 184° C. for 30 minutes, underwent a 7 per cent conversion to active amyl bromide (1-bromo-2-methylbutane) and about 12 per cent to 3-bromo-2-methylbutane, so that here again an equilibrium appears to exist in which the tertiary compound is always in excess.

REACTION OF MONOCHLORINATED PARAFFINS AND CYCLOPARAFFINS WITH AMMONIA AND AMINES

The primary and secondary alkyl halides may be condensed with ammonia (and amines) to furnish alkylamines, but this condensation is not applicable to tertiary halides which yield olefins on treatment with ammonia. The reaction with ammonia, which is usually effected by heating the halide with an alcoholic ammonia solution, leads to the production of mono-, di-, and tri-alkylamines as well as of quaternary ammonium salts, though conditions can be often arranged so that a preponderance of one product is obtained. By heating an alcoholic ammonia solution of ethyl chloride in sealed tubes at 100° C., Groves[28] noted the formation of ethylamine together with some diethylamine and triethylamine. The reaction was further investigated by Hofmann,[29] who showed that, besides the three amines already noted, tetraethylammonium chloride is also formed under certain conditions. The yields of the various products depend mainly upon the relative proportions of the reactants. The several stages of the condensation between ethyl chloride and ammonia may be summarized by the following reactions:

$$C_2H_5Cl + NH_3 \longrightarrow C_2H_5NH_2 + HCl$$
$$C_2H_5Cl + C_2H_5NH_2 \longrightarrow (C_2H_5)_2NH + HCl$$
$$C_2H_5Cl + (C_2H_5)_2NH \longrightarrow (C_2H_5)_3N + HCl$$
$$C_2H_5Cl + (C_2H_5)_3N \longrightarrow (C_2H_5)_4NCl$$

According to Henning,[30] the ethylation of ammonia and other amines by means of ethyl chloride can readily be effected by heating the reactants together for 4 hours in an autoclave at 100° C. and under about 150 lbs. pressure.

Examples of the alkylation of ammonia by means of alkyl chlorides are very numerous. Malbot[31] reported the formation of mono- and di-isopropylamines by heating isopropyl chloride with ammonia. When alkyl halides are treated with a solution of sodamide in liquid ammonia, two concurrent reactions take place resulting in the formation of alkylamines and olefin hydrocarbons. These processes are exemplified by the case of the condensation of ethyl chloride with sodamide, which may be represented in the following manner:[32]

$$C_2H_5Cl + NH_2Na \longrightarrow NaCl + C_2H_5NH_2$$

and

$$C_2H_5Cl + NH_2Na \longrightarrow NaCl + NH_3 + C_2H_4$$

On the other hand, when alkyl chlorides are treated at —40° C. with ammonia and an alkali metal (i.e., a metallic ammonium compound) primary amines and paraffin hydrocarbons are formed according to the typical reactions:[33]

$$CH_3Cl + 2NH_3Na \longrightarrow CH_4 + NH_2Na + NaCl + NH_3$$
$$RCl + NH_3Na \longrightarrow RNH_2 + NaCl$$

The alkylation of aliphatic and aromatic amines can similarly be effected by heating an alkyl halide with the amine. The condensation of n-propyl chloride with ethylamine to furnish ethylpropylamine and ethyldipropylamine has been described by Comanducci and Arena.[34] The alkylation of aromatic amines by means of alkyl chlorides is exemplified by the condensation of 1-chlorobutane with o- and p-toluidines, a reaction investigated by Reilly and Hickinbottom.[35]

Groggins and Stirton[35a] studied the effect of catalysts on the reaction of aqueous ammonia with halogenated compounds and observed that the activity of the catalyst depends upon the type of organic compound and that a small proportion of water catalyzes the reaction. For example, ethylene dichloride can be reacted with aqueous ammonia at 110° C. to form ethylenediamine without the use of a catalyst, though copper, or some other metal following hydrogen in the electrochemical series, is necessary in the reaction of ammonia with compounds containing a halogen attached to the phenyl nucleus, such as chlorobenzene, 4-chloro-2-phenylanthraquinone, and chlorobenzoylbenzoic acids. They also noted that the addition of ammonium nitrate or oxidants, such as potassium chlorate, to the copper compounds increased the yield and purity of the resulting amine. This was especially true in the amination of compounds containing the halogen attached to the phenyl nucleus. Contrary to the conclusions of Hale and Britton[35b] in their work on aniline, Groggins and Stirton found that the presence of metallic copper is not necessary when copper compounds are used as catalysts, nor is it advantageous to keep the copper catalyst in a reduced state.

That ammonolysis is brought about by the activity of ammonia and not by the base ammonium hydroxide is concluded by Groggins and Stirton on the basis of the following observations: Ammonolysis may be carried out in the vapor phase with anhydrous ammonia or in the liquid phase with anhydrous ammonia dissolved in an inert diluent. The properties of the system, ammonia-water, are those of a typical mixture. No ammonolysis takes place when equivalent amounts of ammonium salts are substituted for the ammonia. Colorimetric studies in sealed glass tubes show that the p_H of aqueous ammonia decreases with rising temperature and that this decrease is more rapid when ammonium salts are added.

Salts of diguanidine derivatives of the higher molecular weight paraffin hydrocarbons may be prepared by the reaction between α,β-dihalogen derivatives of these hydrocarbons and guanidine in warm alcohol solutions.[36]

[35] *J.C.S.*, 1918, **113**, 974.
[35a] *Ind. Eng. Chem.*, 1933, **25**, 42, 169, 274.
[35b] U. S. Patent 1,607,824, Nov. 23, 1926; *Brit. Chem. Abs.* **B**, 1927, 101; Reissue 17,280, Apr. 23, 1929; assigned to Dow Chemical Co.

The manufacture of nitrogen-containing compounds of the higher paraffins is described by the I. G. Farbenindustrie A.-G.[37] Halogenated derivatives of the paraffin hydrocarbons of more than 8 carbon atoms are heated with ammonia in aqueous or alcoholic solution, or with agents yielding ammonia, e.g., ammonium carbonate or urea, with or without the addition of copper compounds as catalysts. The heating is best carried out under increased pressure. These compounds can be sulphonated to give emulsifying agents.[37a]

Substances which may be employed as wetting, cleansing, tanning or dispersing agents can be prepared by the condensation of halogenated paraffin hydrocarbons, containing more than nine carbon atoms, with amines or substituted amines.[38] For example, paraffin wax (m.p. 46° to 50° C.) is chlorinated until a 25 per cent increase in weight is obtained. The chlorinated hydrocarbon is made to react at 180° C. with 2-hydroxyethylamine, and the resulting product is esterified at 50° to 60° C. with chlorosulphonic acid. This procedure yields a substance which may be used as a wetting agent. A leather-softening agent is obtained as the result of the reaction between chlorinated brown-coal tar oil (b.p. 200° to 300° C.) and n-butylamine, while chlorinated paraffin oil (b.p. 150° to 300° C.) and p-aminophenol unite to give a dispersing agent.

The amines generally are stronger bases than ammonia, and readily form salts with both organic and inorganic acids. This is particularly true of the alkylamines derived from paraffin hydrocarbons having about 6 or less carbon atoms in the molecule. As a rule the solubility of such amines in water decreases with the number of alkyl groups attached to the nitrogen atom. For a given series of amines having the same hydrocarbon radical the primary amine is the most soluble, the secondary less so, and the tertiary amine the least soluble. In addition to being fairly strong bases the amines are also solvents for many organic substances.[39]

Production of Ethers from Monochlorinated Paraffins

Alkyl halides can be condensed with sodium alcoholates or alkali salts of phenols to form ethers, the reactions being:

$$RX + NaOC_nH_{2n+1} \longrightarrow ROC_nH_{2n+1} + NaX$$
$$RX + NaOC_6H_5 \longrightarrow ROC_6H_5 + NaX$$

The second reaction, namely, the formation of arylalkyl ethers, is of great industrial importance in the dye industry and is effected more readily than the first reaction. In general, it is sufficient to heat the alkyl halide with an alkaline solution of the phenol under pressure. Ethyl chloride is used extensively for the ethylation of certain phenols employed in the preparation of hydroxyazo dyes whereby the fastness of these dyes to alkalies is greatly increased. An example of a dye which is stabilized to alkalies by the introduction of an ethyl group in a phenolic OH group is Chrysophenine G, which is obtained by the condensation of diazotized diaminostilbene-sulphonic acid with two molecules of phenetol

(ethyl phenyl ether). According to Henning,[40] most industrial ethylations of hydroxylic compounds by means of ethyl chloride can be accomplished by heating in an autoclave under 160 lbs. pressure at about 100° C., but this has been contested by Callan.[41]

Dispersing, emulsifying or softening agents may be obtained by the sulphonation or halogenation of the ethers derived from chlorinated high molecular weight paraffin hydrocarbons, that is, those containing 9 or more carbon atoms per molecule, and polyhydric alcohols or phenols or naphthols.[42] As an example, chlorinated petroleum hydrocarbons may be etherized with the monosodium derivative of ethylene glycol and the resulting ether, which contains a hydroxyl group, then esterified with chlorosulphonic acid at 40° to 50° C.

The reaction between alkyl chlorides and alkali phenoxides is capable of extension to the higher members of the series of alkyl chlorides, so that high molecular weight ethers, some of which may have industrial applications, can be produced. Bosshard and Strauss [43] described the production of a phenoxyparaffin, a soap-like mass of melting point 60° C., by heating a monochlorinated solid paraffin with phenol, potassium carbonate, and a solvent under reflux. This phenoxyparaffin can be sulphonated to a semi-solid fat-like substance soluble in water which can be used in the tanning industry. The production of α- or β-naphthoxyparaffins, from the chloroparaffin and alkaline α- or β-naphthols respectively, can be similarly effected.

Carbohydrate ethers have been prepared by reacting alkyl halides, such as ethyl chloride, with a mixture of cellulose and a metallic hydroxide in suspension in an organic liquid.[43a]

NUCLEAR ALKYLATION OF AROMATIC COMPOUNDS BY MEANS OF ALKYL HALIDES

The alkyl chlorides may be used for the introduction of alkyl groups into the aromatic nucleus. Not only may aromatic hydrocarbons be readily alkylated by treatment with an alkyl chloride in the presence of a suitable condensing agent, but the process can also be extended to the alkylation of phenols, aromatic ketones, and other compounds. The condensing agent most frequently employed is anhydrous aluminum chloride but other anhydrous metallic halides can also be employed in some cases. These processes belong to the series of synthetic reactions usually designated by the names of their discoverers, Friedel and Crafts.[44] The reactions proceed more readily in the case of the bromides than with the chlorides while tertiary compounds appear to undergo this process with particular ease. A large number of nitrated tertiary butyl aromatic compounds having strong musk-like odors, were prepared by the aid of this reaction.[45]

An important peculiarity of this process of alkylating aromatic hydrocarbons is that the alkyl group frequently undergoes an isomerization reaction during the process of alkylation and presumably under the powerful catalytic influence of the anhydrous metallic halide. Thus n-propyl bromide reacts with benzene to furnish mainly an isopropylbenzene, while n-butyl bromide condenses to furnish a secondary butyl product. Treatment of benzene with (primary) isobutyl chloride in the presence of aluminum chloride leads to the production of tertiary butylbenzene together with some isobutylbenzene.[46] Numerous other examples of such isomerization phenomena during this condensation might be cited. Schmidt, Ernst and Lange[46a] formed alkylnaphthalenes by heating naphthalene with monochlorinated compounds, such as chloromethane or chloroethane at 160° to 180° C. under pressures as high as 45 atmospheres in the presence of zinc chloride or oxide.

Phenols may similarly be alkylated by treatment with an alkyl chloride in the presence of anhydrous aluminum chloride. In this way 4-tertiary butyl-β-naphthol may be prepared from β-naphthol and tertiary butyl chloride.[47] The alkylation of phenols by alkyl halides in the presence of anhydrous ferric chloride has been studied by a number of investigators.[47a] Linner[47b] prepared p-tertiary-butylphenol by passing isobutylene through a solution of phenol in carbon tetrachloride containing aluminum chloride in suspension and a small proportion of tertiary butyl chloride. The reaction is initiated by the alkyl chloride and the hydrogen chloride liberated combines with the isobutylene to form additional alkyl chloride to continue the reaction. 4-Hydroxytetraphenylmethane results by the reaction of triphenylmethyl chloride and phenol in the presence of aluminum chloride.[47c]

The alkylation of aromatic hydrocarbons by means of the higher alkyl chlorides has led to the use of these chlorides in the production of synthetic lubricating oils of value for blending with natural petroleum lubricants to lower their pour point. Thus a synthetic lubricating oil possessing these pour-reducing properties has been produced by condensing a monochlorinated paraffin wax with a solid aromatic hydrocarbon, such as naphthalene, at low temperatures and in the presence of aluminum chloride as a condensing agent.[48]

DOUBLE DECOMPOSITION OF SALTS OF INORGANIC ACIDS WITH ALKYL HALIDES

Production of Nitriles. The reaction of primary and secondary alkyl halides with metallic cyanides results in the formation of nitriles according to the reaction:

$$RX + MCN \longrightarrow RCN + MX$$

(M = monovalent element, such as Na, K, etc.)

The nitriles, so produced, may be made the starting point for a large number of syntheses of valuable organic chemicals, including aliphatic acids, amines, amides or alcohols. Despite the fact that the reaction has been known for many years, it is surprising to find that it has been very little studied. The reaction of a number of alkyl chlorides with potassium cyanide to yield nitriles by heating them in aqueous alcoholic solution was studied by Lieben and Rossi.[49] Adams and Marvel[50] succeeded in producing valeronitrile from butyl bromide and sodium cyanide under similar conditions.

Later Hass and Marshall[51] reported the synthesis of caproic acid by the hydrolysis of amyl cyanide. The optimum conditions for the production of the latter compound by the interaction of sodium cyanide and 1-chloropentane were determined. The best yields of amyl cyanide (68 to 70 per cent of the theoretical) were obtained by refluxing 1 mole of the chloride with a slight excess of sodium cyanide (1.1 moles) in aqueous ethanol solution for 48 hours or longer. A solvent consisting of 80 per cent ethanol and 20 per cent of water is suitable for this purpose. These yields were very greatly improved by the addition of sodium iodide to the reaction mixture, the increased yields being due to the intermediate production of the more reactive amyl iodide according to the scheme:

$$C_5H_{11}Cl + NaI \longrightarrow C_5H_{11}I + NaCl$$
$$C_5H_{11}I + NaCN \longrightarrow C_5H_{11}CN + NaI$$

By refluxing an equimolecular mixture of amyl chloride and sodium iodide with a 10 per cent excess of sodium cyanide in 80 per cent ethanol-water for 24 hours, a 90 per cent yield of crude n-amyl cyanide was obtained.

The hydrolysis of n-amyl cyanide was readily effected by warming it with an equimolecular amount of 67 per cent sulphuric acid for 30 minutes when caproic acid was obtained in excellent yield.[52] Aliphatic nitriles are said to be readily hydrolyzed to acids by treatment with 90 per cent phosphoric acid at 150° to 220° C.[53]

On attempting to apply their method for the preparation of nitriles to the secondary and tertiary amyl halides, Hass and Marshall found that the secondary amyl chlorides and bromides gave comparatively low yields of nitriles (about 30 per cent), while the tertiary chlorides or bromides gave no nitriles whatever.

This method of nitrile production can be applied to other primary alkyl chlorides with excellent yields. In the case of the lower boiling chlorides, such as butyl chloride, it is best to use superatmospheric pressure, for which purpose iron autoclaves are quite suitable.

Alkyl chlorides may be condensed with alkali hydrosulphides to yield mercaptans; with alkali sulphides to furnish sulphides or thioethers; and with a number of other metallic salts of various acids to yield the corresponding alkyl esters. Generally the reaction is more difficult to effect in the case of the chlorides than with the other halides, and in the laboratory the more reactive iodides are most frequently employed for such syntheses.

Keller[53a] suggested the preparation of sulphurized hydrocarbon derivatives by reacting halogenated higher aliphatic hydrocarbons with hydrosulphides, sulphides or polysulphides, under such condition that the chlorine is replaced completely or only in part by sulphur-containing groups. For example, trichlorinated hard paraffin wax is heated with a potassium hydroxide solution of hydrogen sulphide under pressure at 140° C., the products being insecticides.

The manufacture of ethyl mercaptan from ethyl chloride has been carried out on a considerable scale. Ethyl mercaptan is employed as a raw material in the synthesis of *sulphonal*, a very widely used hypnotic drug. This synthesis is effected by condensing ethyl mercaptan and acetone together in the presence of a catalyst, such as zinc chloride, with the production of a mercaptol, which is readily oxidized to the corresponding sulphone, or sulphonal.[54] The series of reactions is represented as follows:

---

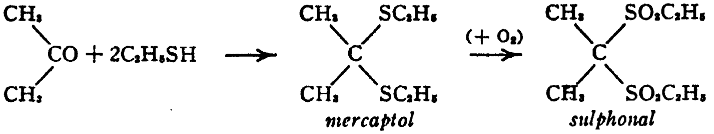
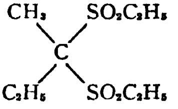
$$C_2H_5Cl + KSH \longrightarrow \underset{\textit{ethyl mercaptan}}{C_2H_5SH} + KCl$$

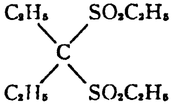


mercaptol *sulphonal*

Two other drugs of the same class may also be synthesized from ethyl mercaptan, namely trional and tetronal, having the following structural formulas:



trional



tetronal

Reaction of the Alkyl Chlorides with Magnesium

When alkyl halides are treated in anhydrous ethereal solution with pure magnesium ribbon direct combination takes place with the production of magnesium alkyl halide, the so-called Grignard reagent. These magnesium compounds are of great value in organic syntheses since they readily combine with a number of substances such as aldehydes, ketones, carbon dioxide and many others with the formation of new products. On a laboratory scale the more reactive alkyl magnesium iodides are generally employed, and little use has been made of the chlorides. However, the action of metallic magnesium on a few alkyl chlorides has been investigated. For example, tertiary butyl chloride readily combines with magnesium at 5° to 15° C. to yield a Grignard compound but at a higher temperature there is a tendency for decomposition to occur with the formation of isobutylene and isobutane, according to the reaction:[55]

$$2C_4H_9Cl + Mg \longrightarrow MgCl_2 + C_4H_{10} + C_4H_8$$

This disruptive process is even more pronounced at much higher temperatures. When isobutyl chloride is heated with magnesium for several hours at 260° C., the products consist of hydrogen, diisobutyl and a solid material.[56] It appears, however, that stable Grignard compounds can be prepared from alkyl chlorides in dry ethereal solution in the presence of a catalyst such as iodine or magnesium iodide. Schmalfuss[57] reported the preparation of a reactive Grignard reagent by passing gaseous methyl chloride into dry boiling ether containing finely divided magnesium and one or more catalysts. Organo-magnesium compounds may likewise be prepared from chlorinated aromatic hydrocarbons. For example, a Grignard compound results on heating magnesium with chlorobenzene to 160° to 170° C. Such products condense with ethylene oxide, ethylene chlorohydrin, ketones, aldehydes, or esters, to yield alcohols. The compound mentioned condenses with ethylene oxide to form β-phenyl alcohol.[57a]

[54] Baumann, *Ber.*, 1886, **19**, 2805.
[55] Bouveault, *Compt. rend.*, 1904, **138**, 1108.
[56] Spencer and Crewdson, *J.C.S.*, 1908, **93**, 1821.
[57] German Patent 374,368, 1922; *J.S.C.I.*, 1923, **42**, 1202A.

The reaction of isopropyl magnesium bromide and allyl bromide yields, according to Risseghem,[57b] a mixture of 4-methyl-1-pentene and a more volatile product.

Grignard compounds are of little value industrially because of their high cost. However, Zelinski[58] has described a process of preparing the higher fatty acids by decomposing the Grignard compounds of higher monochlorinated hydrocarbons with carbon dioxide. The crude petroleum is chlorinated, the product is dissolved in anhydrous ether and the solution treated with magnesium. Solution of the magnesium is accelerated by the addition of a catalyst, such as iodine, methyl iodide, aluminum salts or hydrogen chloride. Into the cold ethereal Grignard reagent is passed a stream of carbon dioxide. The Grignard compound is thereby decomposed with the production of the magnesium salt of a fatty acid according to the reaction:

$$2RMgCl + 2CO_2 \longrightarrow (RCOO)_2Mg + MgCl_2,$$

where R represents a hydrocarbon residue. The fatty acids, so produced, are then liberated from the magnesium salts by treatment with dilute acid.[59] It is understood that this process, though of considerable scientific interest, is not economically practicable owing to the high cost of the magnesium which cannot be recovered as such. Nevertheless, in the production of some compounds, such as lead tetraethyl, organic metallohalides appear to be indispensable. Tetraethyl lead (tetraethyl plumbane) was prepared from (1) ethyl iodide and lead-sodium,[59a] (2) zinc diethyl and lead chloride,[59b] and (3) ethyl magnesium bromide and lead chloride.[59c] These methods have been modified later for application on an industrial scale. In several methods,[59d] lead-sodium alloys are heated together with ethyl halides, and in others[59e] magnesium ethyl halides are caused to react with lead chloride in the presence of a catalyst such as an alkyl iodide.[59f]

The Grignard reagents produced from the monohalogenated cycloparaffins exhibit a similar order of reactivity to those derived from straight chain components.

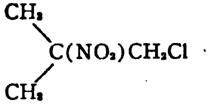
The relation between aromatic, tetraethyl lead, and octane equivalents and their determination, and the characteristics of gasolines and the amounts of added tetraethyl lead are discussed by Sachanen and Tilicheyev, *Chemistry and Technology of Cracking*, translated by Boehtlingk, Brown and Steik, Chemical Catalog Co., Inc., New York, **1932**, 213-217.

OTHER REACTIONS OF THE ALKYL CHLORIDES AND MONOCHLORINATED CYCLOPARAFFINS

A number of alkyl chlorides can be readily nitrated by dilute nitric acid to furnish nitro-derivatives. For example, Konovalov prepared a chloronitroisobutane of the structure



$$(CH_3)_2C(NO_2)CH_2Cl$$

by nitration of isobutyl chloride at 70° to 100° C. The production of resinous or viscous oils, which may be used in varnish or pyroxylin compositions, has been described by Bielouss.[60] The procedure consists in chlorinating a mineral oil distillate of the paraffin type, specific gravity not less than 0.882, until about 20 per cent by weight of chlorine has been absorbed. The chlorinated oil is then nitrated, employing a mixture of nitric and sulphuric acids, at temperatures below 55° C.

According to Schrauth,[61] carboxylic acids may be made by fusing monochlorinated petroleum fractions with alkalies at 200° to 300° C. in such a manner as to avoid high pressure. The temperature is at first maintained at 200° to 230° C. and later raised to 300° C. The products obtained after 6 to 9 hours contain dry, odorless soaps soluble in hot water, with good lathering properties. The excess of alkali may be neutralized with mineral acid and the fatty acids extracted by means of steam or water. Hydrogen is evolved during the fusion. Under these conditions, cetyl chloride is said to be converted into palmitic acid. It appears probable that this reaction proceeds through the intermediate formation of an olefin which then combines with the alkali with the production of an alkali salt of a fatty acid and evolution of hydrogen. The series of reactions may be represented as follows:

$$RCH_2CH_2Cl \longrightarrow RCH{=}CH_2 + (HCl)$$
$$RCH{=}CH_2 + NaOH + H_2O \longrightarrow RCH_2COONa + 2H_2$$

Fatty acids are said to result also on heating olefins with water and alkali hydroxides, phenolates, naphthenates or other weak-acid salts, to 360° C. under pressures of about 46 atmospheres.[62] Sodium propionate may be formed from propylene in this manner, and from 2 liters of ethylene measured at 20° C. at 25.5 atmospheres were obtained 71.5 grams of acetic acid. In carrying out the process, for example, 200 grams of water, 65 grams of sodium hydroxide and 46 grams of ethylene are heated in an autoclave in the presence of an inert oil for 1 hour at 360° C. under a pressure of 25 atmospheres. The products consist of 40 grams of gasoline and 81 liters of a gas containing 65.4 liters of hydrogen and 72 grams of acetic acid.

The later discovery that the lower alkyl chlorides can be condensed with carbon monoxide to furnish carboxylic acid chlorides according to the reaction

$$CH_3Cl + CO \longrightarrow CH_3COCl$$

---

[60] U. S. Patent 1,519,017, Dec. 9, 1924; assigned to H. A. Gardner.

[61] Schrauth, German Patent 327,048, 1914; *J.S.C.I.*, 1921, 40, 227A.

[62] Bataafsche Petroleum Maatschappij, British Patent 355,866, 1930, *Brit. Chem. Abs.* B, 1932, 56; German Patent 560,907, 1930; *Chem. Abs.*, 1933, 27, 1006; French Patent 690,935, 1930; *Chem. Abs.*, 1931, 25, 1259.

would appear to offer a definite technical method of application of these alkyl chlorides in the synthesis of numerous organic products. According to Frolich and Wiezevich,[63] this reaction proceeds, in the case of methyl chloride, at 700° to 800° C. with an efficiency of over 75 per cent, though the conversion per single passage is limited. A number of catalysts for effecting this combination have been mentioned by Steinhäuser.[64] These include boric acid, phosphoric acid, or an alkali borate or phosphate.

Oxygenated organic compounds are said to result from the action of carbon monoxide on low-molecular weight hydrocarbons, their monochlorides or ethers in the presence of anhydrous aluminum chloride.[64a] From butyl chloride and carbon monoxide a product of the formula $C_6H_{10}O_2$ was obtained.

REACTIONS OF DICHLORINATED PARAFFINS AND CYCLOPARAFFINS

The constitution of the dichloro-compounds produced by the substitutive chlorination of paraffins and cycloparaffins is known only in a relatively few cases. This fact limits the utility of any comprehensive account of the reactions of dichlorinated paraffins and cycloparaffins from the viewpoint of the industrial application of such substances. Only a few of the obviously important reactions of these compounds will therefore be discussed. The 1,2-dichloro-compounds, or olefin dichlorides, are treated in Chapter 20.

Under the influence of light, asymmetric-dichloroethylene ($CH_2:CCl_2$) yielded a completely saturated polymer, the molecular weight of which corresponded to about 50 to 100 original molecules.[64b] When heated to above 120° C. the polymer charred and liberated hydrogen chloride. A mixture of hydrocarbons resulted on heating 1.5 grams of the polymer with 1 gram of red phosphorus and 7 grams of 70 per cent hydriodic acid. Extraction of the hydrocarbon mixture with boiling benzene gave a soluble fraction having a melting point of about 111° C., which corresponded to about $C_{100}H_{202}$, and an insoluble portion melting at 116° to 117° C. and corresponding to $C_{160}H_{322}$. Further purification by distillation with soda-lime and extraction with ether resulted in the resolution of two hydrocarbons melting at 74° to 75° C. ($C_{36}H_{74}$) and 95° C. ($C_{60}H_{122}$), respectively. Reduction of the polydichloroethylene with zinc dust and acetic acid in a stream of hydrogen chloride furnished a polymer $(C_2HCl)_x$. When heated with aniline for 14 days polydichloroethylene yielded an almost completely halogen-free benzene-soluble product $(CH_2.C{=}NC_6H_5)_x$. Sodium methoxide or ethoxide, trimethylamine, pyridine, or quinoline, however, failed to completely eliminate the chlorine from the polymer.

Perhaps the most important property of the dihalogen derivatives is their decomposition with the formation of diolefins and loss of two molecules of hydrogen chloride, according to the scheme:

$$C_nH_{2n}Cl_2 \longrightarrow 2HCl + C_nH_{2n-2}$$

This decomposition can be brought about by the action of alkalies or by purely thermal means. Very frequently the process can be cut short at the intermediate stage, i.e., with the production of a monochlorinated olefin. Thus, ethylene dichloride can be converted into vinyl chloride[65] by passing through a pumice-filled tube at 600° C., while at higher temperatures acetylene becomes the main product.

[63] *Ind. Eng. Chem.*, 1931, **24**, 13.

[64] German Patent 561,399, 1928; *Chem. Abs.*, 1933, **27**, 1007; U. S. Patent 1,911,589, May 30, 1933; *Chem. Abs.*, 1933, **27**, 3950; British Patent 308,666, 1928; *Brit. Chem. Abs.* **B**, 1930, 808; all patents assigned to I. G. Farbenindustrie A.-G.

[64a] Hopff, German Patent 512,718, 1927; *Chem. Abs.*, 1931, **25**, 1258; Hopff and Dunkel, German Patent 568,129, 1928; *Chem. Abs.*, 1933, **27**, 2691; both patents assigned to I. G. Farbenindustrie A.-G

[64b] Staudinger and Feisst, *Helv. Chim. Acta*, 1930, **13**, 832; *Chem. Abs.*, 1931, **25**, 487.

For the elimination of hydrogen chloride from various chloro-derivatives of hexane and heptane by thermal treatment in the presence of various contact materials, such as unglazed porcelain alone or treated with barium chloride, Faragher and Garner[66] found that the dichloro-compounds were less satisfactory than the monochlorides. There was much more extensive decomposition and greater difficulty in separating all the chlorine from dichloro-compounds. Table 140 shows the yields and iodine values of the products obtained by Faragher and Garner on decomposing a dichlorohexane, d^{20}_{0} 1.067, at various temperatures in the presence of the above catalysts.

TABLE 140.—*Decomposition of Dichlorohexane.*

Catalyst	Temp. ° C.	Yield Per Cent	Condensate	
			d^{20}_{4}	Iodine No.
Unglazed porcelain alone	350	75	0.874	188
	400	95	0.896	160
	450	90	0.875	176
	500	—	0.876	170
Unglazed porcelain + $BaCl_2$	200	88	0.996	64
	300	88	0.942	123
	400	84	0.920	142

(The theoretical iodine number for a hexadiene is 620.)

In the course of their work on the production of drying oils from higher molecular weight petroleum hydrocarbons, Gardner and Bielouss[67] observed that the dissociation point of the polychloro-compounds, derived from these hydrocarbons, lies between 120° C. and 250° C. and that practically complete dechlorination can be effected by heating them to 250° C. without the aid of any other agents. Here again, however, the iodine numbers of the resulting hydrocarbons were always considerably lower than the calculated values, probably on account of cyclicization.

The dichloro- and trichloro-derivatives of cyclohexane were found by Faragher and Garner to be more readily decomposed than the chlorides of the paraffin hydrocarbons. Thermal treatment of a dichlorocyclohexane, of d^{20}_{0} 1.179, gave products of the following iodine numbers (Table 141) when subjected to the action of unglazed porcelain and alumina, respectively, at various temperatures. The theoretical iodine number of the expected dihydrobenzene is 317.

TABLE 141.—*Decomposition of Dichlorocyclohexane.*

Temperature ° C.	Iodine Number of the Products	
	Unglazed Porcelain	Alumina
200	113	132
250	146	167
300	175	170
400	188	117

---

[65] Böeseken and Bastet, *Rec. trav. chim.*, 1914, 32, 184; Baxter, Edwards and Winter, British Patent 363,009, 1930; assigned to Imperial Chemical Industries, Ltd.; *Brit. Chem. Abs.* B, 1932, 331.

[66] *J.A.C.S.*, 1921, 43, 1715.

[67] *Ind. Eng. Chem.*, 1922, 14, 619.

Decomposition of a trichlorocyclohexane (d^{20}_{0} 1.266) at 250° C. in the presence of unglazed porcelain furnished a 10 per cent yield of benzene, determined by conversion into m-dinitrobenzene.

One of the earlier contemplated uses of the above reactions was for the production of certain conjugated diolefins, such as isoprene, capable of being polymerized to rubber-like products. Graul, Hanschke and Webel[68] described the preparation of isoprene and similar diolefins by treatment of dichlorinated derivatives of pentane and hexane with catalysts, such as alumina and barium chloride at elevated temperatures and under reduced pressure.[68a] Schmidt, Hochschwender and Eichler[69] also eliminated hydrogen chloride from mono- and dichlorocyclohexanes by thermal treatment in the presence of catalysts. Chlorination of a fraction of Caucasian petroleum of boiling point 68° to 73° C. is said to yield a dichloro-methylcyclopentane which may be resinified to a glassy solid, almost devoid of color, by heating with zinc chloride in glacial acetic acid.[70]

The chlorine atoms in di- and poly-chlorinated paraffins may be substituted by hydroxyl, alkoxy-, cyano-, acetoxy-, phenoxy-, amino-, and other groups using reactions similar to those employed in the case of the monochlorides. Under some conditions, however, while one chlorine atom is replaced by another group, a second chlorine atom is eliminated in the form of hydrogen chloride so that an unsaturated product is obtained.[71] Bosshard and Strauss[72] have described the conversion of a dichloroparaffin, melting point 40° to 60° C., and obtained by the chlorination of paraffin wax, into a *phenoxychloroparaffin* by heating it with phenol and potassium carbonate.

The manufacture of certain *nitrogenous derivatives of the higher paraffin hydrocarbons* has been described by the I. G. Farbenindustrie A.-G.[73] Halogenated derivatives of paraffins of more than 8 carbon atoms are heated with ammonia in aqueous or alcoholic solution preferably under pressure. Instead of ammonia, substances capable of yielding this compound may be used, such as ammonium carbonate or urea, together with a catalyst, such as copper or a copper compound. Methods have also been proposed[74] for making *sulphonated derivatives of higher paraffin hydrocarbons.* These higher paraffins (above C_8H_{18}) are halogenated to introduce more than two halogen atoms per molecule and the halogenated products are treated with aqueous or alcoholic solutions or suspensions of alkali or alkali carbonates, and finally with a sulphonating agent in the presence or absence of a diluent (carbon tetrachloride) or of compounds which assist the reaction (e.g., fatty acids or their anhydrides or chlorides). Wetting agents have also been prepared by condensing glycol with chlorinated petroleum in the presence of sodium or with piperidine or p-aminophenol in the presence of copper.[74a]

[74a] I. G. Farbenindustrie A.-G., French Patent 709,626, 1931; *Chem. Abs.*, 1932, **26**, 1403.

The products obtained by heating poly-chlorinated paraffin hydrocarbons of more than 8 carbon atoms, with alkalies in aqueous or alcoholic media, best under pressure and in the presence of catalysts, are said to be mainly unsaturated hydrocarbons containing one or more hydroxyl groups. These products are reported to be valuable as greasing and lubricating agents in the leather and textile industries. They may be sulphonated to produce wetting and emulsifying agents.[75]

Curme and Lommen[76] obtained ethylenediamine by treating dichloroethane with a large excess of ammonia. Aliphatic diamines may also be prepared by a similar reaction using one or more oxides or salts of such metals as copper and zinc, capable of forming complexes with the diamine, under heat and pressure.[77] By reacting dichloroethane with an excess of aniline at 115° C. in the presence of a small proportion of water and a large amount of NN′-diphenylethylenediamine, Morton[78] obtained aromatic derivatives of 1,2-diaminoethane, melting at 65° C.

Chapter 35

Extraction of Nitrogen Compounds from Petroleum

In coal oil and shale oil there are present aromatic compounds of nitrogen which can be identified with comparative ease. Their analytical constants of identification have long been established. This, however, is far from being true in the case of the nitrogen compounds of petroleum for here are presented an astonishing variety of nitrogen bodies of unknown structure many of which, according to present indications, fall into the class of hydroaromatics.

The study of this array of hydroaromatic bases opens to chemists a new domain of great scientific interest and possible practical value. For hydroaromatic bases are closely allied to the alkaloids. To change hydroaromatic bases to alkaloids it is only necessary to make a proper placement of oxygen in the molecule.

Further, indications point to the presence in petroleum of bases containing naphthene rings of 5 carbon atoms, particularly polycyclic compounds composed of naphthene and aromatic or hydroaromatic nuclei. Following a common practice in referring to naphthenic acids these naphthene compounds of nitrogen may be designated naphthenic bases. In due course there may be expected an appropriate correlation between naphthenic bases and their corresponding hydrocarbon relatives.

The nitrogen content of petroleum oils is rather low; in most instances being about 0.1 per cent or less.[1] The two extremes however seem to be represented by American oils. The Pennsylvania oils have the lowest nitrogen content, 0.008 per cent having been reported,[2] and the California oils [3] contain the highest percentage of nitrogen. Japanese and South American oils also appear to have a nitrogen content considerably higher than the average. Paraffin base oils, like those from Pennsylvania, which show such a small nitrogen content, can probably be considered as practically nitrogen-free or as containing only a trace of nitrogen, as such nitrogen determinations are well within the experimental error of the analysis. Poth, Armstrong, Cogbrun and Bailey [4] in their investigation of the nitrogen content of a large number of California crude oils found the maximum quantity to be about 0.82 per cent. On the assumption that the average molecular weight of the nitrogen compounds was represented by the formula $C_{10}H_{13}N$, which was admitted to be probably low, Mabery has suggested that the percentage of nitrogen in an oil should be multiplied by 10 to give the percentage of nitrogen compounds.

By distillation *in vacuo* of nitrogen bases extracted with sulphuric acid from California petroleum, Mabery [5] obtained several fractions, which corresponded in analyses and molecular weights with the following: [6]

---

[1] Gurwitsch-Moore, "Scientific Principles of Petroleum Technology," D. Van Nostrand Co., Inc., New York, 1932, 170.

[2] Beilby, *J.S.C.I.*, 1891, **10**, 120.

[3] Mabery, *J.S.C.I.*, 1900, **19**, 502, reported 2.39% nitrogen in some California oils.

[4] *Ind. Eng. Chem.*, 1928, **20**, 83.

[5] *Loc. cit.*

[6] There appeared to be some doubt as to the number of hydrogen atoms in the molecule. Mabery and Wesson (*J.A.C.S.*, 1920, **42**, 1015) stated that the final main fractions, obtained by distillation at 50 to 90 mm. pressure, were as here given.

B.P. °C.	Formula	B.P. °C.	Formula
130–140	$C_{12}H_{17}N$	223–225	$C_{15}H_{19}N$
197–199	$C_{13}H_{15}N$	243–245	$C_{16}H_{19}N$
215–217	$C_{14}H_{19}N$	270–275	$C_{17}H_{21}N$

The bases dissolved in acids to form salts which could be easily decomposed. Crystalline precipitates could be formed with platinum chloride though the platinum content was about 2 per cent lower than the calculated value. Neither the picrates nor oxalates were well-defined salts. The only product which could be identified from oxidation with chromic acid was a small quantity of acetic acid, which was obtained from the bases containing methyl side chains. With potassium permanganate in neutral or alkaline solution a part of the nitrogen was evolved as ammonia, while in acid solutions all of the nitrogen was evolved as nitrogen. The bases formed quaternary salts when heated with ethyl iodide. While no definite structures could be given for any of the bases, the evidence seemed to indicate the existence of a tetrahydroquinoline ring as a part of the molecule, and also a benzene ring.

Later Mabery and Wesson[7] oxidized some of these fractions with neutral potassium permanganate and obtained oxidation products which could be separated into alcohol-soluble and alcohol-insoluble portions. The alcohol-insoluble portions were dissolved in hot water, from which insoluble silver salts were obtained. Their analyses led Mabery and Wesson to believe them to be the tetra-silver salts of pyridine pentacarboxylic acid.[8] This conclusion appeared to be confirmed when the corresponding barium salt on dry-distillation yielded a distillate whose principal component was pyridine. From the soluble portions of the oxidation products, silver salts were separated, the analyses of which indicated them to be di-silver salts of methylpyridine tetracarboxylic acid.

Oxidation of the fractions with permanganate failed to yield appreciable quantities of aliphatic acids; the small quantities which were formed possessed the properties of the lowest molecular weight acids, acetic and propionic. These facts would tend to argue against the presence of any side chains of considerable length in the molecule.

Oxidation with chromic acid followed by the dry distillation of the calcium salt yielded a product which, from the melting point of its picrate,[9] was probably β-methylquinoline. On the assumption that the compound formed during the distillation of the calcium salt was β-methylquinoline then this would indicate the formation of β-methylcarboxyquinoline (by oxidation) as this substance is known to be resistant to oxidation, in certain instances, before disruption of the quinoline molecule takes place.

On treating the bases with reducing agents, such as tin and hydrochloric acid, zinc and acetic acid, sodium amalgam and alcohol, not only was the nucleus hydrogenated, but the nitrogen was reduced from the tertiary to the secondary state. The latter condition was indicated by the formation of a nitroso-amine when the reduced base was treated with nitrous acid.

When dissolved in organic solvents and treated with either bromine or iodine the original bases apparently formed addition compounds, as well as substitution products. These same bases also reacted with phthalic anhydride in the presence of anhydrous zinc chloride to form phthalones, while fuming sulphuric acid converted them to sulphonated compounds. Platinic chloride reacted with the bases to form chloroplatinates, though on attempting to recrystallize these salts from hot water, decomposition was noted. Attempts to break the nitrogen ring, using von Braun's method,[9a] that is, benzoylation of the base followed by treatment with phosphorus pentachloride, yielded negative results.

---

[7] *J.A.C.S.*, 1920, 42, 1014; *Chem. Abs.*, 1920, 14, 1831.

[8] On attempting to prepare the free pyridine carboxylic acids from their salts Mabery and Wesson reported (*J.A.C.S.*, 1920, 42, 1021) that "only semi-liquid or amorphous products were obtained, however, in place of the acids." Hantzsch (*Ann.*, 1882, 215, 62) reported that after evaporation of a concentrated solution of pyridine pentacarboxylic acid to a syrupy consistency on a water bath the liquid slowly solidifies to a mass of microscopic crystals on cooling. He also emphasized the difficulty of obtaining salts of this acid free of potassium. Weber (*Ann.*, 1887, 241, 15-16) stated that by the decomposition of the silver salt, free of potassium, with hydrogen sulphide he was able to obtain pyridine pentacarboxylic acid with 3 molecules of water from an aqueous solution. It is possible therefore that Mabery and Wesson were not working with the pure acids.

[9] No other method for the identification of this product was reported.

From the results of their work Mabery and Wesson drew the following conclusions. (1) These bases consist principally of alkylated quinolines or isoquinolines.[10] (2) Three alkyl groups are united to the α, β, and γ-carbon atoms of the nitrogen ring. In the lowest member of the series, $C_{12}H_{13}N$, these three side chains must be methyl groups since the quinoline radical accounts for 9 carbon atoms. (3) Phthalone formation[11] requires a $—CH_2$ or $—CH_3$ group in the α- or γ-position in the nitrogen ring. (4) The non-formation of high molecular weight aliphatic acids as oxidation products indicated that none of the side-chains were over 4 carbon atoms in length. (5) The other reactions, such as those with halogens, with reducing agents, with fuming sulphuric acid, etc., also conform with these conclusions.

It is also pointed out by Mabery and Wesson that "all of the fractions of the series of bases represent mixtures which can be fairly well separated into stages as regards molecular weights, but are difficult to separate into individual substances. The facts cited in experimental evidence for the character of the compounds represents what might be expected from a mixture of quinoline and possibly isoquinoline derivatives, a small part more, a small part less highly alkylated than the average, and containing perhaps a small percentage of hydrogenated nuclei or of pyridine derivatives."

Bailey,[12] however, points out that very little or practically none of the nitrogen compounds in crude oils can be extracted with dilute acid, indicating that such compounds are of a non-basic character. The distillates from such crude oils, however, contain nitrogen compounds which are basic, together with compounds which are inert toward acids. These basic compounds no doubt result from the decomposition of more complex substances during distillation, and generally the higher the temperature of distillation the greater the nitrogen content of the distillate.

The complexity of these nitrogen compounds is also shown by the fact that exhaustive fractionation of kerosene (California) bases boiling from 180° to 335° C. failed to yield any component in a pure form. Furthermore, that a number of basic compounds was present in each fraction was indicated by the fact that picrates which separate in a crystalline form were not obtained (except from one fraction boiling around 276° C.). However by extracting with a buffered acid solution, and then fractionally precipitating by the addition of sodium hydroxide, it was possible to concentrate several products which yielded crystalline salts, and were apparently in a pure form.

That the failure to isolate pure substances by fractional distillation was not due to the formation of constant boiling mixtures is indicated by the following consideration. So far fractional distillation has yielded a mixture of products which, at atmospheric pressure, boil within a range of a few degrees. Also the fractional distillations have been carried out at low pressures, to avoid decomposition of the nitrogen bases, and it is not improbable that with the use of a reflux column it is possible to separate bases in the fractions with components boiling within a range of two degrees. In fact from one fraction of bases two compounds having the formula $C_{12}H_{18}N$ and boiling at 280.6° C. and 278.9° C. (both at 746 mm.), respectively, and also the substance $C_{16}H_{25}N$ boiling at 278.2° C., have been obtained in pure conditions. The residual bases, after the removal of these three compounds, boiled at a constant temperature.

[9a] *Ber.*, 1904, **37**, 2818.

[10] *Cf.*, Mabery's earlier views concerning the structure of these bases (*J.S.C.I.*, 1900, **19**, 505).

[11] Bailey (private communication) has reported that the hydroaromatic base, $C_{16}H_{25}N$, obtained from a petroleum distillate condenses with phthalic anhydride exactly as quinaldine does. As this base is not a quinoline derivative, phthalone formation apparently, therefore, cannot be taken as indication of the structure of the molecule.

[12] Poth, Armstrong, Cogburn and Bailey, *Ind. Eng. Chem.*, 1928, **20**, 83; Poth, Schulze, King, Thompson, Slagle, Floyd and Bailey, *J.A.C.S.*, 1930, **52**, 1240.

While these basic nitrogen compounds are extracted by the sulphuric acid used in refining,[13] the isolation of such compounds from the acid extract would prove expensive and seriously interfere with plant routine. There is also the possibility of sulphonation, oxidation or polymerization of the nitrogen compounds by the acid. Bailey and his co-workers therefore used the sulphur dioxide extract obtained by the Union Oil Company of California in the refining of kerosene distillates by the Edeleanu process. Sulphur dioxide acts merely as a solvent, and, after its recovery, the residue contains the nitrogen bases mixed with a large quantity of hydrocarbon oil. From this residue the nitrogen bases were extracted with dilute sulphuric acid and the water-insoluble bases obtained by the addition of sodium hydroxide.[14] In this manner 50 liters of water-insoluble bases were obtained from 150 barrels of residue. These bases contained a small amount of hydrocarbon oil and from 0.3 to 0.6 per cent of sulphur.

A number of the individual nitrogen bases have been isolated and several identified. The preparation and properties of the latter will be described briefly.

The first of the nitrogen compounds to be identified was 2,3,8-trimethylquinoline,[15] which comprises about 18 per cent of the fraction boiling at 276° to 277° C., at atmospheric pressure. The other compounds which have been isolated from this same fraction are the isomeric compound $C_{12}H_{18}N$, and the base having the formula $C_{16}H_{25}N$. The separation of 2,3- as well as 2,4-dimethylquinoline from the fraction boiling around 265° C. has also been announced. These are well-known synthetic products which had not been obtained previously from a natural source.

One method of isolating the 2,3,8-trimethylquinoline was by dissolving the fraction in 50 per cent acetic acid and then precipitating it as the picrate. Mixed with this is the picrate of the substance $C_{16}H_{25}N$; in contrast to the former, it is readily soluble in both benzene and alcohol, and separation of these two picrates was therefore easily effected. Another method of isolation was by means of its acid sulphate. This was obtained by treating the particular fraction with 50 per cent sulphuric acid. Associated with this sulphate is a small quantity of the sulphate of another base, $C_{12}H_{18}N$. This latter compound, not yet identified, is an odorless solid, melting at 43° C. and boiling at 278.9° C. (748 mm.).

To prepare the free base either the picrate or the sulphate is heated with ammonium hydroxide, and the base separates as an oil. The base is then dissolved in ether, the solution washed and the ether allowed to evaporate. Recrystallization from 50 per cent alcohol yields crystals melting at 55° to 56° C. and boiling with partial decomposition at 280° C. (at 747 mm.).

Proof of the structure of this new base was confirmed through its synthesis, from tiglic aldehyde and o-toluidine in the presence of hydrochloric acid.[16] Derivatives of the synthetic product, such as the sulphate, hydrochloride, nitrate, and picrate, as well as a number of its metallic salts such as those with platinum and gold chlorides, were found to be identical with those prepared from the kerosene base.

---

[13] Campbell (U. S. Patent 1,907,318, May 2, 1933; *Chem. Abs.*, 1933, 27, 3601), for example, decolorized hydrocarbons by extraction of the bases with sulphuric acid.

[14] See also, Ihrig, U. S. Patent 1,671,721, May 29, 1928; assigned to S. E. Campbell and to Associated Oil Co.

[15] King and Bailey, *J.A.C.S.*, 1930, 52, 1245.

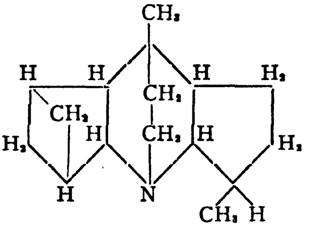
[16] *Cf.* Rohde, *Ber.*, 1887, 20, 1911.

Other reactions also confirmed the structure of the base. Its failure to react with methyl iodide to form the quarternary ammonium salt indicated steric hindrance due to substituents in the 2 and 8 positions. The presence of methyl groups at the 2 and 3 positions was indicated by the fact that the base condensed with two and not three molecules of formaldehyde. Oxidation of this base with chromic acid, followed by distillation over soda-lime yielded the well-known 2,3-dimethylquinoline. This was further evidence of the presence of methyl groups in the 2 and 3 positions. Similarly oxidation of the formaldehyde derivative yielded a dimethylquinolinic acid, which in turn on distillation from soda-lime yielded 3,8-dimethylquinoline. The synthesis of this new quinoline, by Bailey and King, from o-toluidine, propinoic aldehyde and methylal is further proof of its structure.

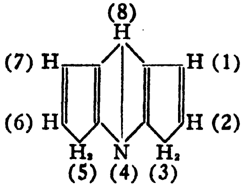
It is of interest to note that an examination of the different distillation fractions failed to reveal any case of optical activity.

The hydroaromatic base of the formula $C_{16}H_{25}N$ is of unusual interest because it represents a new type of nitrogen compound of the cyclopentane type and is probably the forerunner of structurally similar bases occurring in petroleum distillates. The base $C_{16}H_{25}N$ is obtained from the picrate by decomposing with ammonium hydroxide,[17] washing well with water, and drying in a current of air at 100° C. As a final purification the product can be distilled at low pressures (10 to 15 mm.). The substance is a colorless, odorless, optically inactive oil, which is only very slightly soluble in water but soluble in the usual organic solvents. It boils at 278.2° C. at 746 mm. pressure, and has the following physical constants: d_4^{20} 0.9391 and n_D^{20} 1.5129.

The structure assigned to this compound[18] is



This compound is therefore a derivative of the substance,



---

[17] Thompson and Bailey, *J.A.C.S.*, 1931, 53, 1002.

[18] This formula, and also formulas (1) and (II) for products obtained by the action of nitric acid on this base, give a better interpretation than the ones formerly assigned (*J.A.C.S.*, 1931, 53, 1002) because of the fact that the $C_{16}H_{25}N$ base behaves as a completely saturated molecule. Private communication from Dr. Bailey. See also Armendt and Bailey, *J.A.C.S.*, 1933, 55, 4145.

for which the name pyrindacine has been adopted. The systematic naming of the compound $C_{16}H_{25}N$ would therefore be decahydro-3,8-dimethyl-5,7-methano-4,8-ethanopyrindacine. In view of the large number of bases which occur in petroleum distillates it is possible that the product $C_{16}H_{25}N$ is one of a series of naphthene compounds of nitrogen, or naphthenic bases.

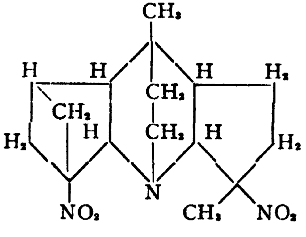
This compound $C_{16}H_{25}N$, is unusually stable toward permanganate in both neutral and alkaline solutions, and also toward oxidation with chromic acid in sulphuric acid solution. It is, however, quite readily attacked by permanganate in an acid solution. It can also be oxidized by fuming sulphuric acid with the evolution of sulphur dioxide when the mixture is heated just above 200° C. Its reaction with hot nitric acid (specific gravity 1.260) yielded several products which were of aid in establishing its structure, and which are discussed a little later.

As it is a basic compound it forms the usual salts such as the hydrochloride, nitrate, acid sulphate and picrate, as well as metallic salts such as those with platinic chloride, mercuric chloride and zinc chloride. Heated with methyl iodide it yields quantitatively the methiodide derivative. Results thus far obtained indicate that it can be neither hydrogenated nor dehydrogenated.

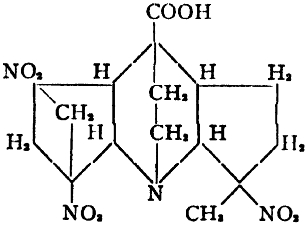
Both the naphthenic base ($C_{16}H_{25}N$) and 2,3,8-trimethylquinoline form loose addition products with bromine, though their behavior is slightly different. The *naphthenic base,* when dissolved in chloroform, excess bromine added, and the chloroform evaporated, yields a red, oily residue. The addition of picric acid to an alcohol solution of the residue yields the picrate of the original base. When treated with bromine water the naphthenic base forms a viscous, red-brown gum soluble in glacial acetic acid, and which is converted to the original base by sodium hydroxide solution. Both of these reactions indicate a loose combination of the bromine with the base. The *2,3,8-trimethylquinoline,* when dissolved in chloroform and bromine added, immediately yields a light yellow needle-like product. This crystalline product is converted to the original compound when treated with a solution of sodium hydroxide.

An unusual property of a saturated hydrocarbon is the nitration of methylcyclopentane with the formation of a mono-nitro derivative. Here the reactive hydrogen is joined to the tertiary carbon in the five-membered ring. Under similar conditions the $C_{16}H_{25}N$ base yields a dinitro compound, $C_{16}H_{23}(NO_2)_2N$, which suggests that two cyclopentane complexes are involved in this reaction. (See formula I.)

(I)

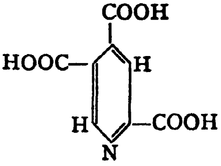


(II)



A second product of the action of nitric acid on the naphthenic base has the composition $C_{16}H_{20}O_8N_4$. Titration showed this substance to be a mono-basic acid, due to the oxidation of the methyl in position 8 to a carboxyl, and three nitro groups entering the molecule are tentatively assigned to positions 3, 5, and 7, respectively.

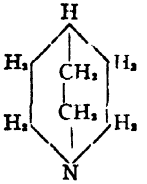
Another product of the nitric acid reaction is berberonic acid, identified by comparison with berberonic acid prepared by oxidation of the alkaloid berberine with nitric acid.[18a] The formation of this acid under similar conditions from



berberonic acid

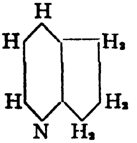
an alkaloid and from the hydroaromatic base[4] must be accepted as a proof that the nitrogen in both compounds is present in a six-membered ring.

There are certain interesting structural relationships between the pyrindacine base and other natural products. One of its ring nuclei is quinuclidine,



and the same complex has been established as present in the alkaloids, quinine and cinchonine.

The cyclopentane ring with a methylene bridging as pictured in the formula of the naphthenic base brings out a structural analogy in this part of the molecule with the newly discovered bi-cyclic naphthenic acids.[19] The isolation of the aromatic base, 5,6-dihydropyrindine



from shale oil,[20] along with its subsequent synthesis,[21] strengthens the claim of the pyrindacine structure of the $C_{16}H_{25}N$ base.

Later, Perrin and Bailey [22] developed a method for the separation of aromatic from non-aromatic bases which they term "cumulative extraction". The resolution is dependent on the solubility of the hydrochlorides of non-aromatic bases as compared with a lesser solubility of aromatic base hydrochlorides in chloroform or ethylene dichloride. Accordingly the bases are dissolved in an excess of 1 :1 hydrochloric acid and the solution is extracted with the organic solvent. The aqueous layer, which contains a high concentration of aromatic base hydrochlorides, is extracted several times with chloroform, and the chloroform layer with water. The process is controlled by refractive index determinations. For the separation of aromatics from small amounts of non-aromatics the bases may be converted in acetone solution to sulphates. The aromatic sulphates separate from this solvent in crystalline form.

[21] Thompson and Bailey, *J.A.C.S.*, 1931, **52**, 1002.

[22] *J.A.C.S.*, 1933, **55**, 4136.

By employing the method of cumulative extraction, Perrin and Bailey[22] isolated 2,4,8-trimethylquinoline, and Lake and Bailey,[23] 2,8-dimethylquinoline from the kerosene bases. 2,4,8-Trimethylquinoline was obtained from an extraction of a fraction of the bases of boiling point 273° C. Its hydrochloride is readily soluble in water and the sulphate in acetone; it was separated from the accompanying 2,3,8-trimethylquinoline by use of these solvents. The picrate, which crystallized from alcohol in slender rectangular plates with melting point 193° C. was isolated. The phthalone of 2,4,8-trimethylquinoline was formed by heating the base with phthalic anhydride for three hours at 200° C., dissolving the melt in concentrated sulphuric acid and pouring it onto crushed ice. The phthalone crystallized from alcohol in yellow microscopic needles melting at 282° C.

The isolation of 2,8-dimethylquinoline was accomplished by cumulative extraction of a 253° to 256° C. fraction of kerosene bases. From 6420 cc. of bases, 285 cc. of aqueous solution was obtained, which represented 4.6 per cent of the initial material. This was evaporated to a small volume and chilled. The smeary mixture was washed with a small amount of cold acetone and the residue recrystallized from alcohol. The yield of practically pure hydrochloride was 32 grams (0.4 per cent). Derivatives prepared were the acid sulphate, perchlorate, mercuric chloride salt and phthalone.

Biggs and Bailey,[24] continuing the investigation, isolated 2,4- and 2,3-dimethylquinoline by extraction with sulphur dioxide. Sulphur dioxide forms addition compounds with both aromatic and non-aromatic bases; some of these compounds are fairly stable whereas others dissociate rapidly at room temperature. A partial separation of the bases was accomplished by taking advantage of this difference in reactivity. After a sulphur dioxide separation of a fraction of kerosene bases of boiling point 263° to 267° C., one portion of the bases was treated with an alcoholic solution of picric acid. The precipitant was washed with alcohol, and leached with hot glacial acetic acid. 2,4-Dimethylquinoline picrate separated in long orange-colored needles and was then recrystallized from 95 per cent alcohol. A product melting at 194° C. was obtained. It was found to be identical with 2,4-dimethylquinoline, synthesized according to a method by Fischer.[25]

The picrates difficultly soluble in glacial acetic acid were recrystallized from that solvent. Microscopic hexagonal prisms melting at 231° C. were formed. This base, liberated from the picrate, proved identical with 2,3-dimethylquinoline synthesized by a method of Eliasberg and Friedländer.[26] It is a white crystalline solid melting at 67° C. and boiling at 273° C. (750 mm.).

Armendt and Bailey[27] investigated the fraction of kerosene bases within the boiling point range 215° to 216° C. They isolated a base $C_{13}H_{21}N$ by fractional crystallization of picrates. The base was a colorless oil, with not unpleasant odor, insoluble in water and miscible in all proportions with common organic solvents. Its melting point was 24.5° C.; boiling point, 225.6° C. at 750 mm. The mercuric chloride, the chloroplatinate, acid-sulphate, and picrate were prepared. The base was not identified, however. Its reactions and behavior were compared with the base $C_{16}H_{25}N$, previously mentioned, described by Thompson and Bailey.[28] Neither of these bases could be hydrogenated or dehydrogenated and prolonged heating with alkaline permanganate had no oxidizing effect. Although the $C_{16}H_{25}N$ compound reacted with methyl iodide, the methiodide of $C_{13}H_{21}N$ was not formed under similar conditions. The following formula was selected provisionally for the compound $C_{18}H_{21}N$:

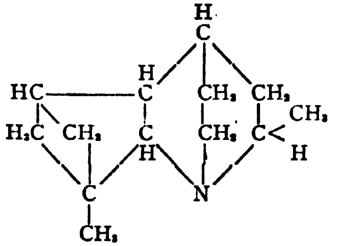
[28] *Loc. cit.*



It is certain that petroleum distillates, and this applies especially to California petroleum, contain a host of hydroaromatic bases. Bailey is of the opinion that many of them are of the pyrindine or pyrindacine type and that they will be found to differ from one another in the state of saturation, in the position of double bonds, in the number and position of side-chains and in the nature of bridging in the ring nuclei. In any event, it is highly probable that the importance of the cyclopentane complex, i.e., naphthenic structure, will be brought into greater prominence as the true nature of the petroleum hydroaromatic bases is revealed.

Just why *hydroaromatic* bases should come from petroleum and be absent in coal, shale and bone distillates is a puzzle for which no explanation so far has been offered. Furthermore, it is of interest to note that none of the *aromatic* bases, so far encountered in the investigation of kerosene bases by Bailey and his co-workers, has been obtained previously from any other natural source.

In spite of the satisfactory interpretation of the reactions of the base $C_{16}H_{25}N$ by means of the structure assigned, there are still several other trinuclear cyclic arrangements possible. In the absence of the synthesis of this base absolute proof of the structure presents a very difficult problem in orientation.

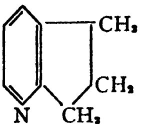
Nitrogen compounds belonging to the pyridine series have been isolated by Eguchi[29] from one fraction obtained on the distillation of Fushun (Japanese) shale tar. No primary or secondary bases were found and only traces of pyrroles.

The crude shale tar was separated into the following fractions: 3 per cent boiling up to 200° C.; 25 per cent from 200° C. to 250° C.; 27 per cent from 250° C. to 300° C.; 23 per cent from 300° C. to 350° C.; and 22 per cent residue. On extraction with 30 per cent sulphuric acid 106 liters of the fraction boiling from 220° C. to 250° C. yielded 3550 cc. of bases. Of these bases a fraction of 1965 grams, boiling up to 200° C., was further separated into 56 fractions, and the nitrogen bases separated from the various fractions by means of the addition compounds formed with mercuric chloride. Identification was obtained by oxidizing the compounds to their corresponding carboxylic acids, and also by comparison of their physical properties with those of synthetic materials. The fraction boiling from 128° to 130° C. yielded 2-methylpyridine; that boiling from 143° to 144° C. gave 2,6-dimethylpyridine; the one boiling from 158° to 160° C. yielded both 2,4-dimethyl- and 2,6-methylethyl pyridine; while 2,4,6-trimethylpyridine was obtained from the fraction boiling between 170° and 172° C.

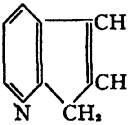
---

[29] *Bull. Chem. Soc. (Japan)*, 1927, 2, 176; *Chem. Abs.*, 1927, 21, 3196; *Brit. Chem. Abs.* **B**, 1927, 696.

Later Eguchi[30] devised a method for the separation of various methyl pyridines based on the carefully controlled fractional precipitation with picric acid and the purification of the various picrate fractions. Applying this method to the various low-boiling fractions of nitrogen bases from the Fushun shale tar he was able to obtain a series of pyridine derivatives particularly rich in α- and γ-alkyl derivatives. The majority of these were methyl derivatives, though from the last fraction boiling at 200° to 202° C. a new base called pyrindane



was obtained. Bailey,[31] however, has suggested the name pyrindine for the compound



and according to his system of nomenclature pyrindane would become 5,6-dihydropyrindine (*cf.* pyrindacine). The synthesis of 5,6-dihydropyrindine, using cyclopentanone as the initial material, was accomplished later by Thompson[32] and further confirmation of the structure, as suggested by Eguchi, was thus obtained.

Likhushin[32a] removed as much as 0.26 per cent of nitrogen compounds from oil and acid separated from acid sludge. The nitrogen compound separated from the sulphuric acid had the composition: 51.33 per cent carbon, 6.42 per cent hydrogen, 2.49 per cent nitrogen and 41.87 per cent sulphuric acid. Another oil, yellow in color and with a pyridine-like odor, which was separated by steam distillation of the neutralized acid, contained 81.95 per cent carbon, 10.12 per cent hydrogen and 8.40 per cent nitrogen. This latter oil was believed to consist of a mixture of pyridine and quinoline compounds.

The extraction of nitrogen bases from other petroleum distillates and their industrial application has also been suggested. For example, the crude gasoline obtained from the first distillation of petroleum oil is extracted with 25 per cent sulphuric acid, and after separation of the acid and distillate the former is made alkaline and distilled. The nitrogen bases thus obtained after distillation can be used as one of the components of insecticides.[33] The same use can be made also of such bases obtained from the sulphur dioxide extract obtained in the refining of heavier distillates,[34] such as kerosene. The bases obtained from California gas oil by acid extraction followed by steam distillation of the extract are further purified by redistillation or treatment with oxidizing agents. Lubricating oils are said to be improved by the addition of 1 per cent of such bases.[35] As they are added in such small quantity their effect is possibly that of an antioxidant, or inhibitor; as a large group of nitrogen compounds, particularly the organic base type, are known to inhibit the autoxidation of lubricating oil. (See Chapter 40.)

Orelup [35a] observed that nitrogen bases from oil shale residues can be used to stabilize cracked petroleum distillates.

Still another use for these nitrogen bases is as inhibitors in pickling solutions. Voorhees [36] has prepared a pickling acid from the sludge obtained in the treating of light distillates such as cracked gasoline or kerosene. The sludge is diluted with water to a concentration of about 35 to 40 per cent sulphuric acid; the acid is then removed from the tarry material which separates and is deodorized by steaming. Afterwards this acid can be diluted to the proper concentration for pickling, usually about 6 per cent, and used alone or it can be mixed with pure acid and the mixture used as a pickling solution. As basic nitrogen compounds, such as quinolines, isoquinolines and acridines, are known to be inhibitors in the pickling process there is little doubt that some basic nitrogen compounds remain in the acid obtained from sludge and these are the active inhibitors. Later, Voorhees [37] described the recovery of such bases from cracked petroleum oils and their use in baths for pickling metals.

Chapter 36

Oxidation of Petroleum Hydrocarbons. General Considerations. Use of Air, Oxygen or Ozone

The wide variety of oxidation products of petroleum hydrocarbons and their production is a problem of great economic importance. As an illustration of the possibilities in this field, Egloff and Schaad[1] calculated from the amounts of the various paraffin hydrocarbons in commercial fuel gases that 2×10^{12} cubic feet per year of methane, ethane, propane and butane are available for conversion into oxidation products. The alcohols that could be made from such a quantity of gases would total billions of gallons. In addition to alcohols, other substances such as aldehydes or acids, could be made also by oxidation. As previously pointed out, alcohols are being made from the unsaturated gaseous hydrocarbons obtained in cracking operations.[2] These unsaturated hydrocarbons are absorbed in sulphuric acid to form the acid esters which, by hydrolysis, yield alcohols.

The oxidation of petroleum wax to produce high molecular weight acids has received a considerable measure of research and commercial attention. These acids may be converted to fats by esterification with glycerol or glycol. They may be used also in the manufacture of candles and soaps. Furthermore, if the oxidation of wax is not carried completely to the acid stage, intermediate products resembling true waxes are obtained. Such compounds present marked industrial possibilities.

Acids have been made by the oxidation of high-boiling distillates. Such acids appear to be mixtures derived not only from straight-chain or paraffinic but from cyclic hydrocarbons as well. Other products which have been made by the vapor phase oxidation of some of the petroleum fractions are various solvents and oxidized kerosene. For instance, a liquid having a high solvent power for naphthalene has been so prepared.[3] Hydroxy-acids and unsaponifiable oxidized oils have been prepared by liquid and vapor phase oxidation. The utilization of the hydroxy-acids as starting materials for the manufacture of cheap varnish gums or paint film substitutes and of the unsaponifiable oxidized oils for lubricating greases has been suggested.[4]

Artificial asphalts are made by the blowing of heavy pitch-like residues obtained on the distillation of certain crude petroleum oils with air or other oxidizing gases.[5] The changes which take place during such an operation are obviously too complex to be well understood. Hausman[6] states that it is essential to have raw materials containing hydrocarbons which, after cracking and polymerization, help in the formation of asphalts. He is of the opinion that even crude oils containing paraffin wax can be used for the production of asphalt.[7] The lower boiling hydrocarbons present in blown asphalts can be removed by distillation, particularly with steam or under reduced pressure.[8] The subject of asphalt manufacture, however, is one of almost unlimited extent and no attempt to review it will be made here.[9]

GENERAL CONSIDERATIONS

Petroleum hydrocarbons can be oxidized in either the liquid or vapor phase, the determining factor in a large measure being the type of hydrocarbon which is being treated. For hydrocarbons which are normally gases or low boiling liquids, vapor phase oxidation is almost universally used. For paraffin wax and heavy oils, liquid phase oxidation is used to better advantage. The temperatures employed vary from about 120° to 150° C. for liquid phase oxidation, to cover 500° C. for some vapor phase oxidation processes. Similarly, the pressures used cover a wide range.

The most generally used oxidizing agent is air, though pure oxygen or ozone is sometimes substituted for it. The oxides of nitrogen, particularly the dioxide, either alone or mixed with air or oxygen, are also employed occasionally. In some processes these oxides appear to act only as catalysts, though in others they serve as actual oxidizing agents.

When oxygen or air is used as the oxidizing agent the products include alcohols, aldehydes, ketones, and acids. Further oxidation eliminates the carboxyl group, yielding carbon dioxide and a molecule containing one less carbon atom. With unsaturated hydrocarbons oxidation is often accompanied by a rupture of the molecule at the double bond.

Two general theories have been offered for the mechanism of oxidation: the hydroxylation and the peroxide theories. According to the first theory, each hydrogen atom attached to a carbon atom is successively hydroxylated by the reacting oxygen. The second theory assumes that the oxygen and the hydrocarbon first form a peroxide, or moloxide (see Chapter 37) which is the active oxidizing agent. Experimental evidence has indicated that peroxide formation takes place with both saturated and unsaturated hydrocarbons. Peroxides of saturated hydrocarbons, however, apparently have not been isolated, but peroxides of unsaturated hydrocarbons have been obtained. They play an important rôle in the autoxidation of various petroleum distillates.

Ozone seems to react with saturated hydrocarbons in a manner similar to that of oxygen. With unsaturated compounds, however, it forms ozonides of definite composition, the ozone attaching itself to the molecule at the double bond. Decomposition of these ozonides is accomplished by heating or by hydrolysis, the resulting products usually being aldehydes or ketones.

As an oxidizing agent nitrogen dioxide reacts rather slowly with saturated hydrocarbons, forming monobasic acids, which can then be further oxidized. The oxidation proceeds eventually to oxalic acid and carbon dioxide. Simultaneously the nitrogen dioxide is reduced to nitric and nitrous oxides and ultimately to nitrogen.[10] The reactions are generally more easily effected with branched-chain than with straight-chain hydrocarbons. With olefinic hydrocarbons there are immediately formed the unstable isomeric nitrosates and pseudonitrosites, the formation often being accompanied by the polymerization of the olefin. With benzene in the cold, nitrogen dioxide slowly forms picric acid, and toluene is converted to trinitrotoluene. At the same time, toluene forms some nitronitrite compounds which may be decomposed by alkalies to yield various nitrocresols. In the presence of metallic salts such as aluminum or ferric chlorides, benzene forms addition products with nitrogen dioxide which can be decomposed by water.

Electrolytic oxidation of petroleum hydrocarbons has been investigated to a limited extent.[11] The hydrocarbons are not conductors and must therefore be thoroughly emulsified with some electrolyte.[12] Low yields of products are usually obtained. Electrolytic oxidation and reduction appear to be more applicable to aromatic hydrocarbons, though even here these same objections hold.[13] Frequently with aromatics it is difficult to control the course of the reaction.

Other methods of oxidation are also available, though they probably have not been used to any great extent in commercial practice. Unsaturated compounds can be oxidized with neutral or alkaline solutions of potassium permanganate. This results in the addition of hydroxyl followed by the formation of acids, the latter step resulting in a rupture of the molecule at the double bond. Although saturated hydrocarbons are not generally oxidized under these conditions, nevertheless this reagent does attack them if they are mixed with unsaturated compounds.[14] Saturated hydrocarbons which contain tertiary carbon atoms appear to be oxidized in the presence of unsaturated hydrocarbons more readily than those containing secondary or primary carbon atoms.

The use of chromyl chloride as an oxidizing agent has been suggested. Etard[15] found that hexane from an American petroleum could be oxidized to yield a chlorohexyl ketone. Schulz[16] investigated the oxidizing effect of this reagent on various fractions of a Boryslaw oil but, although reaction products were obtained, no definite compounds were isolated. Generally the higher the specific gravity of the fraction, the greater was the yield of oxidized products. From the highest boiling fraction he obtained a small quantity of a substance which reacted with Fehling's solution and also reduced ammoniacal silver nitrate solution. All the oxidation products reacted with nitric acid to yield oily, noncrystallizable acids.

Petroleum hydrocarbons can be oxidized by passing their vapors over oxides of metals which are reducible or which exhibit more than one valence state. In this manner, Piotrowsky and Jakubowicz[17] increased the olefin content of various fractions of Boryslaw crude oil by treatment with manganese dioxide at 550° to 600° C. The fraction boiling between 50° and 150° C. was completely converted to unsaturated hydrocarbons.

Oxidation processes are generally aided by the presence of metals, metallic oxides, or their salts. Catalysts vary greatly in the way they influence the

oxidation of hydrocarbons. The specific catalysts suggested for a particular oxidation will be mentioned. Nevertheless, a few have been proposed for general oxidation reactions of hydrocarbons. Frazer,[18] for example, recommended finely divided porous manganese dioxide prepared by treating a manganese compound with cold nitric acid. Chromium-mixed catalysts obtained by heating salts such as basic zinc ammonium chromate, zinc tetrapyridine dichromate, and manganese ammonium chromate [19] have likewise been used for similar purposes, as well as ruthenium,[20] magnesium, nickel, molybdenum or tungstic oxides,[21] aluminum, tin, zinc, iron, cobalt, or nickel borates or phosphates treated with halogen, or halogen acids.[22]

Krauch [23] made the following partial general classification of catalysts: Carbon chains are split by vanadium, molybdenum, tungsten, uranium and their oxides. Copper, nickel, sulphur and selenium tend to promote dehydrogenation. Iron, though it lowers the cracking temperature and favors the dehydrogenation of both aromatic and hydroaromatic compounds, also promotes condensation reactions. Aluminum, which has been previously activated by treating it with solutions of certain metallic salts, often effects cleavage of the molecules at temperatures as low as 100° to 180° C. Aluminum chloride and boron trichloride, because of their polymerizing effect on olefinic hydrocarbons, are good catalysts for the manufacture of lubricating oils.[24] Antiknock compounds, such as lead tetraethyl and iron carbonyl, are classed as negative catalysts.

In this chapter are discussed some of the more general methods for the oxidation of petroleum hydrocarbons. Processes for the manufacture of specific compounds or for the oxidation of definite types of petroleum hydrocarbons are discussed in subsequent chapters.

OXIDATION OF GASEOUS HYDROCARBONS

Walter [25] obtained formaldehyde by the oxidation of 1 volume of natural gas, containing principally methane, with 5 volumes of air and 2 volumes of steam. Similarly, formaldehyde was obtained also from ethylene and air; a large excess of ethylene was required to prevent the occurrence of explosions. A number of metals and metallic oxides were employed as catalysts: platinum, iridium, silver, palladium, uranium, vanadium, manganese, copper, cobalt, nickel, thorium, titanium and tungsten; lead oxide either alone or mixed with aluminum oxide or calcium oxide; molybdic acid and thallium oxide, both of which were rather volatile and not easily separated from the products of the reaction; mercury and arsenic, though volatile also, could be easily separated from the reaction products.

According to Clancy,[26] a catalyst for the oxidation of methane may be prepared by heating the cyanamides of copper or silver to a temperature of 250° to 350° C. in the presence of the ferrocyanide or ferricyanide of bismuth, calcium, cerium, cobalt, vanadium or molybdenum.

Sabatier and Mailhe[27] found that hydrocarbons of both the methane and ethylene series could be oxidized with air or oxygen at low temperatures in the presence of metallic oxides to yield aldehydes and acids. The oxidations were somewhat difficult to control because of the explosions which took place when the temperature of the catalyst reached the point of incandescence. Ethane can be oxidized to yield acetaldehyde. As a general rule, however, the resulting aldehyde contains one less carbon atom than the original hydrocarbon. From ethane, for example, was obtained mainly formaldehyde and from butane, propionic aldehyde. Acids are also formed, usually with fewer carbon atoms than the original hydrocarbon. Ethane, though it yields some acetic acid, is oxidized principally to formic acid.

The oxidation of hydrocarbons (such as those which occur in natural or refinery gases) chiefly to alcohols takes place in the presence of catalysts, under pressures of 1500 to 3500 pounds per square inch and at temperatures of 350° to 600° C., according to Young.[28] The quantity of oxygen in the gas mixture should be low, not exceeding 15 per cent. Numerous catalysts can be used in this process, as for example, manganese, silver wire, platinum foil, cobalt-plated copper wire, chromium-nickel alloy, and vanadium pentoxide powder. Beall[29] oxidized natural gas hydrocarbons with air by subjecting the mixture to a pressure of 300 to 1250 pounds per square inch and temperatures of 180° to 216° C. Platinum sponge or nitrogen oxides are employed as catalysts. The products are a mixture of aldehydes, ketones, acids and alcohols.

Oxygenated compounds are reported to be obtained when a mixture of methane and steam, together with carbon dioxide, hydrogen, or oxygen, is passed over metallic catalysts at 200° to 500° C., under pressures up to 500 atmospheres or more.[30] The oxygenated compounds so produced, which may be varied according to gaseous mixture used, are alcohols, aldehydes, ketones, and acids. Among the catalysts which can be used are zinc, magnesium, calcium, aluminum, chromium, manganese, vanadium, molybdenum, titanium, iron, cobalt, nickel and rare earths, or their compounds such as sulphides, arsenides, phosphates, silicates or borates. The catalysts may also contain various chromates, tungstates or molybdates. The apparatus may be of copper, or lined with copper, or made of steel containing vanadium, manganese, nickel or cobalt.

In a process developed by the I. G. Farbenindustrie A.-G., the catalytic oxidation of gases and vapors containing hydrocarbons of low molecular weight such as those obtained in the destructive distillation of coal yields acetic acid and its homologues, ketones, aldehydes, and alcohols together with propylene, butylene, butadiene and other olefins.[31] The hydrocarbon gases are mixed with gases such as carbon dioxide, steam or air, which supply oxygen for the reaction, and the mixture is subjected to a temperature of 500° to 800° C. in the presence of catalysts. These catalysts include manganese dioxide, vanadium oxide, the oxides of molybdenum, chromium, aluminum, and the carbonates of the alkali and alkaline earth metals. The olefins obtained in this process may be polymerized to substances of high molecular weight, for example, lubricants, or polymerization products which are either plastic or elastic.

Burke and Fryling[32] effected selective oxidation of hydrocarbons in the absence of a catalyst. They state that the temperature must be carefully controlled, being kept at a point where only partial oxidation takes place and any hydrogen or carbon monoxide present are unaffected. This temperature is generally about 350° C. An aluminum reaction chamber is employed (aluminum having no catalytic action), and a pressure of more than 300 pounds per square inch is maintained.

OXIDATION OF LIQUID HYDROCARBONS IN THE VAPOR PHASE

Reactions which occur in the oxidation of hydrocarbons in the vapor phase are very sensitive to temperature, time of contact, pressure and proportion of constituents in the reaction zone.[33] Continuous recirculation is advantageous in processes of this kind. Marek[34] observed that aliphatic hydrocarbons require lower temperature, shorter contact time and lower oxygen concentration than aromatics. Increased pressures reduce the temperatures required for oxidation and stabilize the products but they also increase the possibility of explosion.

In carrying out the oxidation of hydrocarbons to alcohols, acids, aldehydes, and other products, Frolich[35] heated the mixture of air and hydrocarbon to temperatures between 350° and 700° C., at pressures between 70 and 250 atmospheres. Thus, in the oxidation of butane with air, a mixture of the two gases is passed through a chamber partly filled with nickel catalyst. The pressure is maintained at 160 atmospheres and the temperature at 430° C. The products consist of ethyl and propyl alcohols, acetic acid and esters, with smaller proportions of acetaldehyde and propionaldehyde, acetone, and methyl and butyl alcohols.[36] Similar methods have been proposed by Pugh, Tauch and Warren,[37] Lewis,[38] and Dearborn and Gray.[39] Low molecular weight organic acids or anhydrides such as acetic anhydride, can be mixed in as diluents to avoid danger of explosion.[40]

For the oxidation of gasoline vapors, Freund[41] employed an iron tube packed with petroleum coke (which had been previously ignited) and conducted the mixture of gasoline vapors and air through this tube at temperatures of 400° to 500° C. Two samples of gasoline were used: A Galician gasoline from Boryslaw crude oil (predominantly paraffinic in character), and a cracked gasoline (having a high content of unsaturated hydrocarbons) made from a crude oil obtained in the western part of the United States. Oxidation was found to increase with rising temperatures. It was also increased by prolonging the time of passage of the gases through the tube and by using a larger proportion of air in the gas mixture. With four successive passages of a given quantity of gasoline vapor through the tube at 400° C., about 30 per cent was converted into oxidation products, which included acids, phenols and other aromatic bodies, together with unsaturated compounds, esters, water and carbon dioxide. Under the same conditions the American gasoline, because of its unsaturated character, yielded a larger proportion of oxidation products than the Galician gasoline. A relatively large amount of acetic acid was found among the oxidation products of the American gasoline. Purely pyrolytic reactions were shown to take place by substituting nitrogen for the air, a larger proportion of unsaturated hydrocarbons being thus formed.

Employing a somewhat lower temperature (250° C.), Cândea[42] observed the formation of aromatic compounds when the vapors of Rumanian gasolines (which boiled up to 150° C.) and air were passed over a catalyst. Iron oxide (Fe_2O_3) appeared to be the best catalyst and the highest yield of aromatics obtained was 6.4 per cent. This reaction appears to be dehydrogenation, other examples of which are discussed in Chapter 39.

Results on the vapor phase oxidation of hydrocarbons have been reported by Shimose.[43] In his work he found that maleic acid (together with some carbon dioxide and formaldehyde) was the principal product of the oxidation of n-pentane, n-heptane, n-octane, 2-amylene, 2-isoamylene, diisoamylene and cyclohexane with air. The same substances were also obtained by the oxidation of gasoline vapors. The catalysts used were the oxides and salts of vanadium, molybdenum, uranium, chromium and manganese.

To obtain oxidation products from petroleum hydrocarbons with boiling ranges higher than those of gasoline, two general methods have been used: (1) the direct oxidation of the hydrocarbons in the vapor phase, and (2) the cracking of such hydrocarbons followed by the vapor phase oxidation of the lower-boiling products thus formed.

Walter[44] oxidized a petroleum distillate boiling above 300° C. by passing the vapors together with air and steam over a heated catalyst of copper deposited on asbestos. The products of the reaction were acetic acid and its homologues, and aldehydes.

James[45] produced aldehydes and aldehyde-acids by the passage of a mixture of hydrocarbon vapors and air through a heated reaction zone containing catalysts. The temperature of the reaction zone varied from 230° to 500° C., being determined by the type of petroleum distillate undergoing oxidation. Steam may be used as a diluent for the gas mixture. Catalysts used included the oxides of metals which are capable of exhibiting more than one valence state, as for example, molybdenum, vanadium, and uranium. In carrying out the process, the oil and air are both led into a heating and mixing vessel. The heated mixture of hydrocarbon vapors and air is then passed through a screen of the catalytic material and from there into a condenser. The time of contact of the vapors with the screen is of the order of 0.3 second.

For example, when a mixture of air and the vapors of a Pennsylvania petroleum fraction, 90 per cent of which distilled between 250° and 324° C., was conducted over a molybdenum oxide catalyst at a temperature of 310° to 320° C., the condensate was reported to consist of 28 per cent by volume of aldehydes and 46 per cent by volume of aldehyde-acids.[40] The portion of such condensates boiling up to 300° C. could be mixed with benzol, alcohol or gasoline and used as a motor fuel. The soaps obtained by extracting portions boiling above 300° C.

[46] James, U. S. Patent 1,697,653, Jan. 1, 1929.

with sodium or potassium hydroxide solutions exhibited detergent properties. The corresponding calcium and aluminum soaps were considered appropriate for water-proofing materials. The residue, after the alkali-extraction, contained alcohols, aldehydes and waxes and was said to be utilizable for a lubricant. Either before or after the removal of the aldehyde-acids with alkaline solutions, the product was stated to be thickened or resinified by dry hydrogen chloride, anhydrous zinc or calcium chloride, or phosphoric acids. These resinous substances were acidic in nature and could be converted into calcium or sodium soaps.[47]

The separation of the aldehydes and aldehyde-acids obtained in this process may be effected by converting the acids to salts, for example, the insoluble calcium salts.[48] After separation of the acids, the residual aldehydes and hydrocarbons can be returned to the system for further oxidation. Any unsaturated oxygenated product can be converted to the corresponding saturated compound by hydrogenation or halogenation.[49]

The operation of a plant for the oxidation of petroleum vapors on a commercial scale has been described by Bitler and James.[50]

Other methods have been suggested for the oxidation of petroleum vapors. For instance, Martin[51] oxidized the vapors by mixing them with oxygen and subjecting the mixture to the influence of ultraviolet light. The products, after being condensed, are stated to be usable as frothing agents. Egloff and Morrell[52] suggested conducting the mixture of hydrocarbon vapors and oxidizing gas through a heated zone in which the mixture is subjected to a high-potential electrical discharge under pressure. With some types of hydrocarbon vapors, the presence of aluminum chloride or ferric oxide promotes the reaction. The use of oxidizing gases such as air, oxygen, ozone and the oxides of nitrogen, leads to the production of oxygenated compounds such as alcohols, aldehydes, ketones and acids.

The second method of obtaining oxidation products from petroleum hydrocarbons, that is, cracking the distillate and then oxidizing the lighter products is exemplified by the processes developed by Ellis. In one procedure he[53] cracked kerosene, for example, at 800° to 900° C., under a pressure of 10 to 20 atmospheres, obtaining lighter products with a large content of aromatics. These lighter products, together with air possessing a constant moisture content, are passed over a catalyst kept at 300° to 400° C. Chromium oxide, vanadium oxide, molybdenum oxide, iron chromate and similar compounds supported on a carrier such as asbestos or pumice serve as catalysts. The volume of oxygen used is such that the oxygen content of the gas mixture is about 20 per cent, which is very much less than that required for complete combustion. The oxidation products are passed through an air condenser which allows separation of the higher boiling constituents, then through a scrubbing tower in which the water-soluble products are collected, and finally through oil scrubbers. The aqueous solution from the scrubbing tower contains not only monobasic acids such as acetic acid and its homologues, but also dibasic acids. When the kerosene, however, is cracked at slightly lower pressures (at 4 to 5 atmospheres) and the catalyst is maintained at slightly higher temperatures (400° to 500° C.) for example, in addition to organic acids there are also obtained aldehydes or aldehyde-acids.[54]

Ellis[55] found that the oxidation proceeds more slowly and can be controlled more readily if the hydrocarbon-air-water vapor mixture is cooled just before it enters the reaction chamber so that it comes in contact with the catalysts as a mist. This method of oxidation of hydrocarbon vapors, particularly those from cracking petroleum products, leads to the formation of aromatic derivatives, especially phthalic anhydride. The yield of the latter depends to a large degree upon the proportion of naphthenes present in the original oil. Extraction of the original oil with alcohols, sulphur dioxide, or other solvents at low temperatures makes it possible to separate many of the paraffin hydrocarbons. Such extracted oils, containing a higher proportion of naphthenes, give on oxidation a larger yield of aromatic derivatives.

With silver, copper, or aluminum, a temperature between that of black and dull red heat, (that is, slightly below 538° C.) aldehydes are the predominating reaction products.[56] Gases such as carbon dioxide can be used as well as air. Formaldehyde is the principal aldehyde formed, together with small quantities of acetaldehyde, acrolein and benzaldehyde. The small quantities of acids produced consist mainly of formic, propionic, benzoic, citraconic, maleic, and phthalic acids.

In oxidizing gaseous products which contain a large percentage of unsaturated compounds (20 per cent or more) obtained in the cracking of petroleum distillates, Ellis[57] found that, by carefully regulating the quantity of air used, it is possible to obtain monobasic acids such as acetic, propionic, and butyric. Increasing the quantity of air results in the production of oxalic, succinic, malic, maleic, and similar dibasic acids. During oxidation the temperature of the catalyst should be kept between 400° and 500° C. It is possible, however, to carry out the oxidation at lower temperatures provided the pressure is greatly increased.

In a process developed by Palmer[58] the oil or gas is first cracked to yield more active hydrocarbons, that is, unsaturated hydrocarbons. These are partly oxidized with steam, air, or oxygen in the presence of a catalyst (platinum or vanadium on asbestos) at 300° to 700° C. After the precipitation of tar, the products are recovered and partially separated in a series of condensers. Aldehydes appear to be the main oxidation products. The residual gases can be used for the production of carbon black.

Oxidation during cracking, however, can be made so extensive that carbon monoxide and dioxide, nitrogen and hydrogen result.[59] Thus, gas oil, when mixed with air and steam and cracked in the presence of an iron-chromium alloy, yields these gases. The greater part of the carbon monoxide is then oxidized to carbon dioxide by passing the gas mixture over a ferric oxide catalyst. The remaining carbon monoxide is oxidized by adding the requisite quantity of air and conducting the gaseous mixture over mixed oxides of iron and chromium capable of preferentially oxidizing the carbon monoxide. The carbon dioxide is removed with alkaline solutions and the resulting mixture of hydrogen and nitrogen can be used for the production of ammonia.[60]

[60] The production of hydrogen by the action of steam on saturated hydrocarbons is discussed in Chapter 10.

OXIDATION IN THE LIQUID PHASE

The methods for oxidizing liquid hydrocarbons may be grouped into three main divisions: (1) oxidation during distillation, (2) oxidation at high temperatures (about 400° C.) while keeping the liquid under pressure, and (3) oxidation at relatively low temperatures (about 200° C.) and under atmospheric or slightly increased pressure. The first two methods are, of course, applicable to nearly all types of distillates, but the last method can be used only with high-boiling distillates. Heat is evolved during the oxidation of the hydrocarbons.

LIQUID-PHASE OXIDATION DURING DISTILLATION

In the Dubbs[61] process, oil is heated in a still to a temperature somewhat lower than its boiling point and air is introduced through a perforated pipe near the bottom of the still. After the reaction has started, the heat generated is sufficient to maintain the temperature and cause distillation of the lighter hydrocarbons formed. This process is essentially a dehydrogenation, the temperature being so regulated that hydrogen of the hydrocarbon combines with the oxygen. If steam is introduced with the air, discoloration of the residue in the still is prevented to a large degree.

A similar process has been proposed by the Société Anonyme des Combustibles Industriels[62] for the oxidation of hydrocarbons such as coal tar, wood tar, and schist oils. Air enriched with oxygen or ozone can be used in the oxidation, the heat generated being sufficient for continuing the process. The distillates are said to be usable as lubricating oils. The temperature of distillation can be lowered, of course, by reduction of pressure.

The production of mineral frothing agents is accomplished by oxidizing petroleum distillates in the presence of carbon. Martin[63] passes the oil and air over heated coke or charcoal in a retort and condenses the vapors in a series of condensers. A temperature of 400° C. is used when the oxidation is carried out in the presence of coke, and 350° C. with charcoal. The oily product which separates in the condensers can be employed as a frothing agent. Steam or water is introduced at the beginning of the operation to minimize the danger of explosions. An excessive quantity must be avoided as the condensed oxidation products easily form emulsions with water which are difficult to separate.

In the process developed by Brewster[64] the oil is maintained at the conversion temperature (380° to 405° C.) under a pressure of 4 to 5 atmospheres and air is supplied to the still. The evolved vapors are passed through a stripping column in countercurrent heat exchange with incoming oil which is thus preheated. The condensed heavier fractions are returned to the still.

LIQUID-PHASE OXIDATION AT HIGH TEMPERATURES AND PRESSURES

An example of liquid-phase oxidation at high temperatures and pressures is the Penniman[65] process. Crude petroleum, or its distillates, is mixed with powdered coal, coke or peat, and then oxidized by passing air through a heated body of the material. With gas oil, for example, the oil is first heated in a still to 260° C. (500° F.) under a pressure of 20 atmospheres. On introduction of air the temperature rises to 385° to 400° C. (725° to 750° F.). The distillate obtained during oxidation separates on standing into an upper water-insoluble layer, an intermediate layer, and a lower aqueous solution of organic acids. Acids, phenols and aldehydes may be extracted (in that order) from the upper layer with solutions of sodium carbonate, sodium hydroxide and sodium bisulphite, respectively. The residue from the upper layer is washed with water, treated with sulphuric acid, and then distilled to yield a motor fuel. The residue is returned to the oxidation still. From the acid extract, alcohols can be obtained by diluting with water and distilling.

[64] U. S. Patent 1,694,092, Dec. 4, 1928; assigned to Standard Oil Co. of California; *Brit. Chem. Abs.* B, 1929, 234.

[65] British Patent 252,327, 1925; *Chem. Abs.*, 1927, 21, 1546. British Patent 255,020, 1925; *Chem. Abs.*, 1927, 21, 2793; British Patent 256,922, 1925; *Chem. Abs.*, 1927, 21, 3126; British Patent 257,886, 1925; *Chem. Abs.*, 1927, 21, 3123.

The lower aqueous layer obtained in the Penniman process contains acids (principally acetic) and aldehydes (largely acetaldehyde and propionic aldehyde) together with some ketones and alcohols. On distillation this layer yields acetaldehyde and a liquid which can be either added to a motor fuel to increase its antiknock properties or used as a solvent for shellac and other resins. The distillation residue, after treating it with sulphuric acid, is steam-distilled to obtain gums.

An examination of the aqueous distillate obtained in the oxidation of a Mid-continent gas oil distillate by air, using the Penniman process, was made by Swann, Howard and Reid.[66] The aqueous distillate was separated into several fractions which were examined individually. An estimate of the quantities of organic substances in the water layer, per 1000 pounds of gas oil oxidized, was as follows:

Acetaldehyde	5.5 lbs.	Ethyl alcohol Ethyl acetate	2 lbs.
Acetone Methyl acetate Methanol Dimethyl acetal	19 lbs.	Allyl alcohol	3.5 lbs.
		Acetic acid	7 lbs.

These quantities would, of course, vary considerably with different operating conditions. Aluminum chloride, or the oxides of manganese, lead, iron, chromium, vanadium, zinc, copper, or calcium may be used as catalysts.

In the Cross[67] process, the oil is heated to the conversion temperature and conveyed to a reaction chamber, the pressure being maintained at 400 to 750 pounds. On the introduction of air or other oxidizing gas into the reaction chamber a considerable rise in temperature results. From the reaction chamber the oil passes to a still kept under reduced pressure. The evolved vapors are then fractionated.

Luther and Wille[67a] proposed to eliminate the formation of resinous by-products in the oxidation of hydrocarbons in the liquid phase by stopping the reaction before oxidation is complete, removing the products by extraction with methyl alcohol, and continuing the oxidation of the residue.

A procedure in which heated air is passed through a nozzle into a low gravity oil, contained in a closed tank, has been developed by Persch.[68] The air is forced into the oil in such a manner that the oil is atomized. The low-boiling products formed are condensed, flow back into the tank, and promote contact between the gas and the particles of atomized oil. After the oil has been sufficiently acted upon, the low-boiling products are separated by distillation with a current of air. A breaking-down of the complex hydrocarbons and their recombination in different proportions is said to be the mechanism of this process, the oxygen of the air probably assisting in the rearrangement.

LIQUID-PHASE OXIDATION AT RELATIVELY LOW TEMPERATURES AND PRESSURES

The blowing of petroleum residues converts them into asphaltic products with high melting points and viscosities and of good ductility. In one process[69] high pressure air or steam or both is introduced into a still through a number of pipes extending to the bottom. The pipes are arranged in such a manner that a double circulatory motion of the residue in the still is obtained. Light volatile products which are formed are taken off at the top. The condensed vapors may be returned to the oil undergoing oxidation.[70] The residues from cracked distillates are oxidized under reduced pressure by steam or air-blowing at 300° C.[71] Bauer and Urman[72] report that if the hot products are treated with super-heated steam or an indifferent gas, directly after oxidation, an improvement in quality is obtained.

MacLachlan[73] oxidized petroleum residue or heavy hydrocarbons mixed with natural or prepared asphalt by continuously circulating oxidizing gases and resulting fumes through the charge. Small additions of air or other oxidizing gas are continually made to replace that used in the oxidation.

Rudigier[74] proposed the introduction of hot petroleum residuum, at a temperature of 215° to 225° C. (420° to 440° F.) into a tank. Air is admitted at the bottom of the tank through a perforated pipe. The temperature during oxidation rises to about 235° C. (456° F.). Any volatile products formed during oxidation are passed through a scrubbing tower and washed with a water spray. The wash water together with the entrained distillate is then run to a separator where the hydrocarbons are recovered.

Distillation of volatile products during oxidation can be prevented by mixing petroleum residuum with a high-boiling coal tar and oxidizing at low temperatures.[75] For example, the process can be started at 110° C. and finished at 220° C., the air being forced through the mixture at such a rate that all of the oxygen is absorbed. The operation can be made continuous by connecting several oxidation chambers in series so that any chamber can then be shut off, the charge withdrawn, and a fresh charge introduced.

For the production of materials with rubber-like properties, Kirschbraun[76] conducted petroleum residuum together with air through a long pipe coil in which the temperature is gradually increased from 200° to 350° C. It then passes into a receiving tank where, after agitation, the liquid oxidized asphalt is withdrawn.

An apparatus in which the oxidation of heavy oils and pitches may be effected has been described by Gevers-Orban.[77] It consists of a cylindrical horizontal tank fitted with a horizontal shaft provided with paddles. An inlet nozzle for admitting the oxidizing gas is placed at one end near the top of the tank, and a connection is provided at the other end for leading the exit gases to a condenser. Heat is applied externally. With a tank about half full of oil, the rotation of the paddles throws a spray of oil into the upper part. The oil is thus brought into intimate contact with the oxidizing gas. The more volatile constituents pass into the condenser and are recovered. As oxidation continues, the oil remaining in the tank becomes thicker.

Petroleum residues can also be oxidized by causing the material to flow through a series of three cylindridal receivers countercurrent to a stream of air or air containing oxygen or ozone.[78] No external heat is required inasmuch as oxidation proceeds with the generation of heat, which may be conserved by passing the gas directly from one receiver into another. With a partial vacuum, the latent heat of evaporation alone is sufficient to effect both dehydration of the tar and distillation of low-boiling hydrocarbons. The substances carried away by the gases can be condensed by passing them into cold tar or into vessels immersed in cold tar which is later treated.

Turek[79] found that tars or pitches which could not be used satisfactorily for the manufacture of artificial asphalts by blowing with air or oxygen were rendered adaptable if mixed with phenolic tars in such proportions that the resulting mixture had a phenol content of 12 to 24 per cent. This mixture can be oxidized with heated air in the presence of ferric oxide containing some sulphur.

In an oxidation process developed by Mann and Chappell[80] heated petroleum oil, together with air, is passed over the suboxides of nickel, iron, or copper to produce aromatic compounds such as benzene, toluene and xylene. Mann and Chappell used temperatures which vary from 600° to 750° C. These are considerably higher than the temperatures employed in other processes mentioned in this section. They maintain the pressure at slightly less than 1 atmosphere. The proportions of air required vary from 500 to 800 cubic feet for each 15 to 20 gallons of oil. The main reaction involved is considered to be a dehydrogenation. Conversion of 20 to 45 per cent of the oils to permanent hydrocarbon gases, and 40 to 75 per cent to aromatic hydrocarbons is said to be secured.

The judicious use of oxidation or blowing is generally found to be the most desirable method of finishing petroleum asphalts, particularly those produced in pipe stills. There appears to be considerable need, however, for an investigation of the reactions which take place when various asphalt stocks are subjected to blowing. Some theoretical reactions have been hazarded but few detailed investigations have been conducted. It has never been definitely proven under what condition, if at all, oxygen is added to the hydrocarbons in the finished asphalt, or whether the process is one of dehydrogenation. The products obtained by blowing a poorly stripped asphalt differ in physical characteristics from those of an asphalt which has been carefully stripped of heavy oils. When such reactions are more thoroughly understood it may be possible to correlate them directly with the adaptability of asphalts for various purposes.[81]

MISCELLANEOUS PROCESSES

Egloff and Morrell[82] produced a liquid of lower boiling range together with oxidation products (aldehydes, alcohols, ketones and acids) by heating a petroleum oil in the presence of metallic oxides such as copper oxide or barium peroxide in a still under pressure to a temperature sufficient to cause vaporization. The vapor which is evolved is separated into lighter and heavier fractions. The latter, after condensation, are treated with an oxidizing gas (air, oxygen, ozone, or the oxides of nitrogen) and then returned to the still. Hydrogen, carbon monoxide and nitrogen are the products of oxidation of methane or natural gas with the oxides of chromium, titanium, tungsten and molybdenum at 800° to 1000° C.[83] Each of these metals are capable of forming several higher oxides which are stable to hydrogen under the working conditions. The reduced oxide is reconverted to the higher oxide by treating with air, steam or carbon dioxide.

Herrmann and Baum[84] oxidized petroleum oil by burning a flame of oxygen and hydrogen (or other combustible gas) beneath the surface of the liquid. When the temperature of the liquid near the flame becomes high enough to allow it to burn with oxygen alone, the flow of hydrogen is discontinued. Ethylene and acetylene are formed together with liquid and gaseous products due to the cracking of the petroleum oil by heat liberated by the flame. Reaction may be accelerated by dissolving or suspending catalytic material in the liquid or using such materials in the construction of the burner. This procedure is said to be applicable to the decomposition of other organic liquids, e.g., alcohols.

For the oxidation of liquid hydrocarbons Esmarch[85] proposed treating oils with air between the closely adjacent surfaces of water-cooled electrodes which produce high-frequency corona arc discharges.

Since alcohols are frequently obtained in the oxidation of petroleum hydrocarbons some mention of the oxidation of these substances would not be out of place. Sabatier and Mailhe[86] studied the oxidation of primary alcohols in the presence of oxides, particularly those of silicon, molybdenum, and tungsten, at temperatures between 250° and 350° C. At 300° C. some carbon dioxide was obtained in addition to aldehydes and acids. At about 350° C. those oxides which were not easily reduced by the alcohol vapors caused the oxidation to proceed in one of three ways: to form (1) aldehydes and hydrogen; (2) water and unsaturated hydrocarbons; or (3) to cause both of these reactions (1 and 2) to take place simultaneously. At this same temperature oxides of the type represented by cadmium or stannous oxide, which are only slowly reduced by the alcohol vapors, reacted very much like the non-reducible oxides. In the presence of easily reducible oxides, however, the alcohol vapors were oxidized with the formation of carbon dioxide.

The indirect oxidation of olefins to ketones, through the intermediate formation of alcohols, has been proposed by Ellis and Wells.[87] Light hydrocarbon gases obtained in the cracking of heavy petroleum distillates are absorbed in sulphuric acid which has a specific gravity of about 1.8. The acid extract is diluted with twice its volume of water and distilled. The alcohols collected are treated with a mild oxidizing agent such as sodium dichromate, and the ketones are removed by distillation. The rectified ketones can be used as solvents. The olefin gases can be absorbed in the acid and the acid extract oxidized directly, thus omitting one distillation step (that in which the alcohols are separated). In place of dichromates, other oxidizing agents such as nitric or hypochlorous acid can be used in the presence of catalysts.

[87] U. S. Patent 1,450,493, Apr. 3, 1923.

Faber[87a] described a method of "reforming" natural gases, which consists of a partial combustion of the gases with air at a temperature between 540° and 925° C. Other examples of similar processes have already been mentioned in Chapters 8 and 10.

OXIDATION WITH OZONE

Ozone is sometimes used in the oxidation of hydrocarbons, and as frequent examples of this type of oxidation are given in the following chapters, it need only be briefly mentioned at this point. Ozone is generally mixed with oxygen for the oxidation of unsaturated compounds, such substances reacting with ozone to form ozonides which can be decomposed, by heat or hydrolysis, to yield aldehydes, ketones and acids (see Chapter 38). The reaction of unsaturated hydrocarbons with ozone has been used to determine the number of double bonds in the molecule.[88]

Harries[89] has shown that oxozone (O_4) is present in ordinary ozone (O_3), hence this may often lead to conflicting results. Oxozone may be eliminated by washing the ozone mixture with sulphuric acid and with sodium hydroxide. 2-Butene, for example, when treated with "washed" ozone yields the normal ozonide,  $CH_3CH\cdot O_3\cdot CHCH_3$, (which can be distilled *in vacuo*), together with a sirupy dimeric product, $(C_4H_8O_3)_2$ (which is not distillable). When the same olefin is treated with "unwashed" ozone the normal ozonide is again obtained together with the oxozonide, $C_4H_8O_4$, and the viscous dimeric product, $(C_4H_8O_4)_2$.

Products, part of which are said to be substitutes for turpentine and linseed oil or resins, and another part of which can be used as motor fuel, are reported by Ramage[90] to be obtained by ozonizing at a temperature of 30° to 40° C. below its boiling point an olefin fraction boiling at 125° to 250° C. The vapors evolved during ozonization are condensed for use as a motor fuel. Ozonization is stopped when the material reaches a specific gravity of 1.16. This material is intended as a substitute for linseed oil. If during ozonization the vapors are returned to the still by means of a reflux condenser then only a turpentine substitute is obtained. Further ozonization of this product yields resinous bodies.

Kita, Abe and Tada[91] studied the effect of ozonized oxygen (containing about 5 per cent ozone) at 0° C. on a fraction of Kurokawa petroleum, boiling between 150° and 300° C., and consisting principally of saturated hydrocarbons. After treatment, the oil was mixed with water and heated. It was observed that the iodine value, acid value, specific gravity, refractive index and viscosity were higher but the rotary power was lower than that of the original. The extent to which these changes took place was found to depend upon the length of the period of treatment. With a higher fraction (liquid parmaceutical paraffin) similar results were obtained except that the refractive index and iodine value did not change.

On prolonged treatment of lubricating oils with ozone, Dover and Cromwell[92] noted that the coefficient of static friction was reduced with paraffin base oils though a less regular and pronounced change took place with asphaltic base oils. They failed to obtain any definite relationship between the physical and chemical properties of the oil and its value as a lubricant. Unsaturated oils appeared to be more efficient lubricants than more highly saturated oils.

Chapter 37

Oxidation of Methane and Its Homologues

In this chapter the oxidation of saturated hydrocarbons is considered particularly from the standpoint of the production of substances other than aldehydes. Such substances include oxides of carbon, water, hydrogen, and unsaturated hydrocarbons. Several theories of the mechanism of the oxidation of hydrocarbons are also discussed. The methods employed in the preparation of these oxidized substances belong to the slow combustion or non-explosive type. The explosive oxidation of hydrocarbons is considered in Chapter 44. Furthermore, this discussion is limited to the oxidation of the gaseous or relatively low-boiling hydrocarbons. The oxidation of high-boiling liquid and solid hydrocarbons is reviewed in two later chapters (42 and 43) relating to the production of acids and the oxidation of paraffin wax.

OXIDATION OF METHANE

A study of the oxidation mechanism of methane made by Bone and Wheeler[1] showed that, in the presence of an excess of methane, the reaction between methane and oxygen took place at temperatures below the ignition point. In no case was there a preferential oxidation of either element of the hydrocarbon molecule, inasmuch as neither free hydrogen nor free carbon was observed at any stage of the oxidation. In slow-oxidation experiments they isolated formaldehyde as an intermediate oxidation product. This evidence served as a basis for the hydroxylation theory of oxidation. Briefly, this theory states that oxidation proceeds through the successive conversion of the hydrogen atoms (attached to a carbon atom) to hydroxyl groups.[2] Oxidation in the presence of a catalyst was held to take place in exactly the same way, however, with this difference: hydroxylation progressed with such velocity that intermediate oxidation products could not be detected. Only end-products such as the oxides of carbon and water were obtained. Later work by Bone and Drugman[3] with explosive mixtures of hydrocarbon gases indicated that this same explanation, with some slight modification, was also applicable.

Although other theories have been proposed (and these will be discussed later) it is certain that one of the intermediate oxidation products of methane is formaldehyde and from that stage onward the oxidation mechanism is clear. Depending upon the conditions under which oxidation is taking place, the formaldehyde may either yield hydrogen and carbon monoxide by decomposition, or the aldehyde may be oxidized to formic acid. The formic acid, in turn, can be oxidized to carbonic acid, which then yields carbon dioxide and water by decomposition.

Newitt and Haffner[4] isolated another intermediate oxidation product, methyl

alcohol, by the reaction of methane and oxygen at 360° C. under 100 atmospheres pressure. With a 9: 1 mixture of methane and oxygen the reaction was complete in a few minutes. Seventeen per cent of the methane oxidized was recovered as methyl alcohol, 0.6 per cent as formaldehyde, and the remainder as carbon monoxide and dioxide and water. No hydrogen was formed and no evidence of the formation of peroxides was found.

The rate of oxidation of methane in a quartz tube was found to increase exponentially with time and to result finally in ignition of the methane-oxygen mixture. Kovalskii, Sadovnikov and Chirkov,[5] believed the oxidation to be predominantly a surface reaction.

The oxidation of approximately 4 per cent of methane in air in the presence of metals, metallic oxides, and mixtures of oxides has been investigated by Yant and Hawk.[6] The temperatures at which oxidation occurred in their experiments varied from 150° to 350° C. Of the catalysts used, cobaltic oxide was found to be the most efficient, with manganese dioxide and nickel (ic) oxide next in order. Mixtures of oxides gave results corresponding to the proportion of each active material. Metallic nickel and platinum black were the least effective. The addition of 10 per cent of platinum black to metallic nickel appeared to act as a promoter, as the efficiency of the mixture was greater than that of either of the metals alone. Analysis of the gases after oxidation indicated that the products of the reaction were carbon dioxide and water.

With metallized silica gels at temperatures varying from 200° to 400° C. Reyerson and Swearingen[7] observed the complete oxidation of methane by oxygen. Only carbon dioxide resulted, no intermediate oxidation products being obtained. The metals used were silver, copper, palladium and platinum. Silver did not exert any catalytic effect upon the methane oxidation. With copper, oxidation started at 200° C.; with platinum, at 240° C.; and with palladium, at 330° C. Copper had to be oxidized before it was catalytically active. The platinized gel probably adsorbed oxygen better than the palladium gel which might, therefore, account for its greater activity. It was observed that there was a limited range of oxygen content in which maximum oxidation occurred and above and below which the effect of the catalyst decreased. With platinized silica gel and with about 28 per cent oxygen in the gas mixture, nearly 2 per cent of the methane was oxidized to carbon dioxide and water.

Campbell[8] investigated the oxidation of methane with the following catalysts: silver and copper supported on pumice, vanadium oxides on pumice, platinized asbestos, platinum black and palladium black on asbestos. A wide range of temperatures was used, varying from 172° C. to as high as 700° C. No intermediate oxidation products, or only traces, were noted when silver, platinized asbestos and platinum black catalysts were employed. With copper, however, some formaldehyde was produced between the temperatures of 397° and 517° C. This aldehyde was formed also with palladium black below 400° C. and with vanadium oxides on pumice between the temperatures of 520° to 640° C. With two of the catalysts, silver and vanadium oxides, free hydrogen was found in the gases after oxidation.

Although, in the presence of catalysts, the various stages of oxidation or decomposition succeed each other so rapidly that difficulty was experienced by Campbell in attempting to isolate intermediate products in any quantity, nevertheless, the results were considered to be in accord with Bone's hydroxylation theory.

The course of oxidation, however, varied with the catalysts and the temperature. Thus, after the aldehyde stage has been reached, vanadium oxides apparently favor the decomposition of the aldehyde to hydrogen and carbon monoxide, with the subsequent oxidation of these latter products to water and carbon dioxide. Palladium black, on the other hand, seems to favor the oxidation of the aldehyde to formic acid, followed by thermal decomposition to water and carbon monoxide, and subsequent oxidation of the carbon monoxide to dioxide.

The conditions under which methane in contact with copper oxide undergoes complete combustion to water and carbon dioxide have received considerable attention. Though this is of particular interest in analysis of this compound, some of the conclusions are pertinent to oxidation in general.

Campbell and Gray[9] studied the combustion of methane, methane-hydrogen, and methane-ethylene mixtures by copper oxide, lead chromate and cobalt oxide. They showed that below 280° C. the proportion of carbon dioxide formed with copper oxide is practically negligible at moderate periods of contact. Up to 400° C. oxidation is slow but at 700° C. the rate is very rapid and complete combustion is effected within 7 minutes. The addition of cuprous chloride, cobalt oxide, manganese dioxide, nickel oxide and vanadium pentoxide to copper oxide promotes the oxidation. If hydrogen or ethylene is added to methane the temperature required for complete oxidation is reduced. Fused lead chromate is inferior to and cobalt oxide is no better than copper oxide for this oxidation. Wheeler[10] investigated the kinetics of the combustion of methane by copper oxide and tentatively suggested that the reaction took place at the copper-copper oxide interface. The study was extended to ethane, propane, butane, hydrogen, and carbon monoxide by King and Edgecombe.[11] It was found that at 280° C. with a 10-minute contact period, copper oxide effected the oxidation of no methane, 0.8 volume per cent ethane, 1.0 volume per cent propane and 1.4 volume per cent butane. These rates increased with a rise in temperature.

A further investigation of the oxidation of methane by metallic oxides brought out the following facts:[12] Copper oxide and methane begin to react at 350° C., and at 725° C. water and carbon dioxide are formed quantitatively. Ferric oxide (Fe_2O_3) is completely reduced to Fe_3O_4 at 680° C., carbon dioxide and water being formed. Zinc oxide begins to react at 800° C., but even at 1000° C. only 50 per cent oxidation occurs. The products in this case are carbon monoxide and hydrogen with traces of carbon. Stannic oxide is unreactive below 800° C. but at 972° C. it effects 73 per cent oxidation to carbon dioxide and water.

Yoshikawa[13] oxidized methane with air under ordinary pressure at 600° C., the products being carbon monoxide and dioxide, formaldehyde, methyl alcohol and formic acid. The same substances were formed by oxidation at 300° to 400° C. at pressures from 12 to 100 atmospheres.[14] Increase of pressure brought about greater yields of methyl alcohol. Hydrogen appears at higher temperatures (700 ° C. under 1 atmosphere pressure). The results indicated a chain reaction mechanism, for on enlarging the reaction vessel oxidation was suppressed and the proportions of methyl alcohol and formaldehyde were greater. Addition of nitric acid promoted the reaction but lead tetraethyl had a retarding influence.

The oxidation of methane to carbon monoxide and hydrogen was also studied.[15] The most efficient catalyst for this reaction is nickel, together with silica or thoria as promoters. At 850° to 900° C. methane and oxygen react almost quantitatively to yield carbon monoxide and hydrogen. The production of hydrogen from methane by oxidation with air or oxygen has been the subject of considerable research.[16] In one such process [17] the catalysts are metallic oxides capable of being reduced to lower oxides, for example, titanium dioxide or a mixture of chromium and magnesium oxides. The production of hydrogen by oxidation of hydrocarbons with steam has already been reviewed in Chapter 10.

The oxidation of methane by zinc oxide has been suggested by Doerner [18] as a method for the refining of zinc. At about 927° C., zinc oxide and methane react to yield zinc (vapor), carbon monoxide and hydrogen, according to the following:

$$ZnO + CH_4 \longrightarrow Zn\,(gas) + CO + 2H_2$$

The temperatures in this process are kept below 1000° C. Although the reaction rate increases with higher temperatures, the formation of carbon dioxide and subsequent reoxidation of the zinc also increase. Crude natural gas gives practically the same results as methane, the greater reducing power of the homologues of methane being compensated for by their greater tendency towards thermal decomposition. This method was suggested by de Simó [18a] for the production of carbon monoxide and hydrogen.

Oxidation takes place on passing a stream of methane, or gases rich in methane, into heated concentrated sulphuric acid which contains a very small quantity of mercury.[18b] At 180° C. the evolution of sulphur dioxide begins and the methane content of the exit gases decreases while the carbon dioxide content increases. The main reaction appears to be the oxidation of methane to carbon dioxide, the sulphuric acid being reduced to sulphur dioxide and water.

$$CH_4 + 4H_2SO_4 \longrightarrow CO_2 + 6H_2O + 4SO_2$$

Brewer and Kueck [19] observed that methane is quantitatively converted into ethylene and hydrogen in the glow discharge at the temperature of liquid air, one molecule of ethylene being formed per CH_4^+ ion. When oxygen is mixed with the methane the products are carbon dioxide and water. The reaction seems to be initiated primarily by the CH_4^+ ions, and is accelerated by excess methane and retarded by excess oxygen. The maximum rate occurs with a mixture of equal volumes of methane and oxygen. The oxidation is most pronounced in the negative glow, is negligible in the dark spaces, and is approximately constant throughout the positive column. The efficiency of the positive column (in terms of electron volts per molecule) rapidly increases with pressures above 5.5 mm., indicating the presence of ionic chain reactions.

The effect of inert gases on the oxidation of methane has been studied by Melville,[20] who found that the velocity of oxidation is governed by a factor which is inversely proportional to the diffusion coefficient of the reaction chains through the gas mixture.

OXIDATION OF ETHANE

From work on the slow-combustion of ethane at temperatures of 300° to 500° C., Bone[21] concluded that the reaction proceeded in a manner similar to that for methane. Ethane, however, under analogous conditions burned more rapidly than methane. In the presence of insufficient oxygen for complete combustion there was no preferential oxidation of either carbon or hydrogen. On the other hand, oxidation appeared to proceed in stages, with the formation of aldehydes, water, carbon monoxide and dioxide. All the steps were in accord with the Bone hydroxylation theory. The appearance of hydrogen or methane, or both, among the products of the reaction and the absence of any liberated carbon was attributed to the thermal decomposition of the aldehydes formed: formaldehyde yielding a mixture of hydrogen and carbon monoxide, and acetaldehyde yielding methane and carbon monoxide. Ethylene was also found, probably as the result of thermal decomposition of ethane. The oxidation of ethane, therefore, appears to be a much more complicated reaction than that of methane. Later, Bone and his collaborators[22] showed that the oxidation reactions which took place in the explosive combustion of hydrocarbons were similar to those in the non-explosive or slow-combustion of such substances.

In a further study[23] of the slow-combustion of ethane efforts were made to determine if peroxides were formed at any stage. The investigation was conducted over a temperature range of 290° to 323° C. and at initial pressures of 440 to 778 mm. The results indicated that oxidation proceeds homogeneously throughout the medium, though it may be greatly retarded by increasing the surface exposed to the gases. It was preceded, however, by a well-defined induction period, which could be shortened or obliterated by the addition of small quantities of ethyl alcohol, formaldehyde, iodine or nitrogen peroxide, without altering the non-explosive character of the reaction. The addition of 1 per cent of acetaldehyde vapor results in the instantaneous inflammation of the mixture. A rise in temperature as well as an increase in pressure also shortens the induction period. These same factors affect the reaction period in a similar manner. Both the induction and reaction periods are much shorter for a gaseous mixture consisting of two molecules of ethane and one of oxygen than for a mixture of the gases in equimolecular proportion. An increase of the oxygen content beyond this latter proportion still further increases both of these periods. This experimental demonstration is in agreement with the hydroxylation theory and is not what might be expected according to the peroxide theory of combustion. Although small quantities of peroxides may be formed at the aldehyde stage no evidence was obtained of an earlier peroxide formation. Indirect indications showed that either ethyl alcohol or some lower "oxyethane" was the initial product in the combustion of ethane.

Taylor and Riblett[24] investigated the progress of oxidation of ethane by observing the rate of change of pressures for mixtures of ethane and oxygen at different temperatures. In all experiments a short induction period of about 2 minutes was noted, followed by a slow reaction which was accelerated in the same manner as autocatalytic reactions. The oxidation exhibited all the characteristics of a chain reaction,[25] namely: (1) great sensitiveness to foreign substances, (2) negative surface effect (effect of increased surface in the reaction chamber), (3) specific effect of diluent gases, and (4) an induction period.

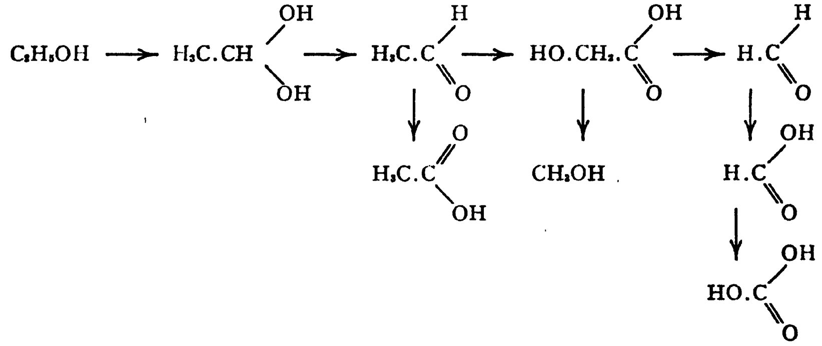
It was also observed that with the oxygen in excess the rate of reaction was directly proportional to the oxygen pressure. Increasing the proportion of ethane while keeping the oxygen constant accelerated the reaction so greatly that it was difficult to avoid explosions.

Considering the oxidation of ethane as a chain reaction,[26] Taylor and Riblett calculated the energy of activation for a 1:3.5 mixture of ethane and oxygen as 43,000 calories at 200 mm. pressure, 38,000 calories at 215 mm., and 32,000 calories at 300 mm. These values indicated that the reaction chains were not very long.

Newitt and Bloch[27] used pressures of 15 to 100 atmospheres and temperatures of 260°-316° C. in their study of the slow combustion of ethane-oxygen mixtures containing from 85 to 90 per cent ethane. The products consisted of water, methyl alcohol, formaldehyde, formic acid, and acetaldehyde with a predominant proportion of ethyl alcohol and acetic acid. Increased pressure favored the survival of substances which result without rupture of the ethane molecule. Representatives of each step postulated in the hydroxylation theory were isolated:



No peroxides were found, hence the hydroxylation theory of oxidation was favored.

In ethane-oxygen mixtures held at a given temperature, the pressure first increases exponentially with time, passes through a maximum and then decreases. If the initial pressure is below a definite limiting value an explosion results when the pressure maximum is reached. Kovalskii, Sadovnikov, and Chirkov [27a] observed this in their study of the oxidation rate. The surface of the reaction vessel was probably activated in the course of a run, for washing it with sodium chloride solution greatly reduced the initial pressure rise, but treatment with hydrogen fluoride, on the other hand, accelerated it.

---

[25] The critical explosion pressures agree with those of thermal explosion predicted by Semenoff's theory of reaction velocity (*Z. physik. Chem.*, Abt. B, 1929, 2, 161; *Chem. Abs.*, 1929, **23**, 2870), but Taylor and Riblett consider the reaction best explained as chain explosions preceded by thermal accelerations.

[26] Other explanations of oxidation by a series of chain reactions have been proposed. See, for example, Kistiakowsky and Lenher, *J.A.C.S.*, 1930, **52**, 3785, and Spence and Kistiakowsky, *J.A.C.S.*, 1930, **52**, 4837, for oxidation of acetylene; Bodenstein, *Sitzungsber. Preuss. Akad. Wiss., Berlin*, 1931, III; *Z. physik. Chem.*, 1931, **B12**, 151; *Brit. Chem. OXIDATION OF HIGHER PARAFFIN HYDROCARBONS

The non-explosive oxidation of propane and of n- and iso-butanes has been investigated by Pease.[28] Mixtures of propane and oxygen were passed through glass tubes heated at 300° to 625° C. No attempt was made to analyze the liquid products of the reaction and all conclusions, therefore, were based on gas analyses. The reactions taking place were classified into three types which, using propane as an example, are as follows:

(1) Dissociation: $C_3H_8 \longrightarrow C_3H_6 + H_2$

(2) Unsaturation by Oxidation: $C_3H_8 + \frac{1}{2}O_2 \longrightarrow C_3H_6 + H_2O$

(3) Aldehyde Formation: $C_3H_8 + 2O_2 \longrightarrow CO + 2H_2O + CH_3CHO$

The dissociation (Reaction 1) and the unsaturation by oxidation (Reaction 2) of propane are homogeneous gas reactions of the first order and appear at 500°-600° C. They are subject, however, to induction by the aldehyde formation reaction (3) at lower temperatures. Aldehyde formation appears to be a chain reaction of the luminous type and begins at 300°-350° C. It is particularly sensitive to suppression by minor changes such as an increase in the area of the surfaces of contact, reduction of the pressure, or dilution of the gas mixture with gases such as oxygen, methane, or nitrogen. Suppression by dilution with gases is greater at higher temperatures, so that the reaction may have a negative temperature coefficient, even though it eventually becomes explosive.[29] Low temperatures favor the production of aldehydes containing one carbon atom less than the original hydrocarbon. High temperatures and maximum suppression favor the formation of olefins.

Both n- and iso-butane react similarly to propane, but they are more readily oxidized. Of the two butanes, n-butane is the more reactive.

The partial oxidation of pentane by air in the presence of a platinum catalyst supported on asbestos [30] resulted in the formation of water, formaldehyde, and amylene as condensible products and carbon dioxide, ethylene, propylene, butylene, amylene and butadiene as gaseous products. When hexane was substituted for pentane a considerable proportion of hexylene was obtained. In oxidation reactions of this type, polymerized materials are always found with the unsaturated hydrocarbons.

Mixtures of equal volumes of pentane and oxygen showed an induction period followed by an increase in rate of pressure rise when heated in glass at 245° C. and 760 mm. According to Pidgeon and Egerton,[31] rapid heating, change of concentration, or lowering of pressure raises the temperature required for reaction, and dilution with nitrogen or use of silica vessels lowers it. Naphthalene was formed by incomplete combustion of normal pentane, but not of normal hexane, heptane, or octane, as shown by Mondain-Monval and Quanquin.[32]

[31] *J.C.S.*, 1932, 661.

From their work with hexane Brunner and Rideal[33] concluded that the oxidation of hydrocarbons was very similar to the autoxidation of benzaldehyde. There is a period of induction during which peroxide molecules are formed and react with hexane molecules. This induction period is greatly shortened by increased oxygen pressure. Aniline exerts an inhibiting effect on the oxidation, and surface catalysts such as pumice cause slow combustion accompanied by slight decreases of pressure. The temperature of initial combustion, furthermore, is not a characteristic of the hydrocarbon, for rapid combustion will set in after a period of induction at lower temperatures.

When a mixture of hexane and oxygen (42 per cent hexane, 57 per cent oxygen and 1 per cent nitrogen) is heated in a closed vessel there is always a period of induction during which the pressure increases very slowly, followed by a rapid increase of pressure.[34] This period of increased pressure is associated with an oxidation by the peroxide molecules formed during the induction period, and includes reactions which result in the formation of water, unsaturated compounds, fatty acids, carbon monoxide and dioxide and other gases. The unsaturated intermediate products thus formed take up oxygen and form new (secondary) peroxides. The decomposition and reaction of both primary and secondary peroxides results in a series of further changes which lead to the production of aldehydes, peracids and other products. Soon after the peroxide formation has attained a maximum value all of the free oxygen disappears. A further production of peroxides, moloxides, water and fatty acids, therefore, cannot occur even though the decomposition of the peroxides present into carbon monoxide and dioxide and other gases continues. It is this decomposition which causes a marked increase in the pressure toward the end of the reaction.

It has also been shown that the absorption of oxygen during the induction period is very rapid. The reactions may be represented as follows:[35]

$$
\begin{aligned}
&C_6H_{14} + O_2 \longrightarrow C_6H_{14}\dot{O}_2 \text{ (active moloxide)}\\
&C_6H_{14}O_2 + C_6H_{14} \longrightarrow H_2O + 2C_6H_{12}\\
&C_6H_{12} + O_2 \longrightarrow C_6H_{12}O_2 \longrightarrow \text{decomposition}
\end{aligned}
$$

Time-pressure curves were constructed from the oxidation of various saturated cyclic hydrocarbons having side chains.[36] Temperatures between 200° and 700° C. and an initial pressure of 1110 millimeters were chosen. In every case, the pressure remained constant for a considerable time, then fell and passed through a minimum, followed by a steady rise. Ultimately it tended to become constant. 1,1-Dimethylcyclohexane varied from the others in that no minimum was observed. The apparent induction period became shorter as the length of the side chain increased, indicating that impurities were not the sole influence on the rate of oxidation. The conclusions reached as to the meaning of the minimum point is that oxidation takes place according to the peroxide theory, peroxides being formed at this minimum and initiating the reaction chains.

This theory of the formation of an active moloxide,[37] which is subsequently converted into a more stable peroxide which then reacts in either the gas phase or on surfaces when its concentration reaches a critical value, differs greatly from the hydroxylation theory proposed by Bone.

Hexane, cyclohexane, and cyclohexene absorb oxygen readily when heated. When mixtures in the proportions of 1 molecule of oxygen to 4 molecules of these hydrocarbons were passed through a furnace, Estradère[38] observed that the formation of peroxides reached a maximum at 330°, 340°, and 410° C., respectively, carbon monoxide appearing simultaneously. Peroxides disappear at high temperatures. Accordingly, cyclicization of saturated hydrocarbons increases their resistance to oxidation only slightly but unsaturation gives marked effects.

The production of peroxides during the direct oxidation of hydrocarbons with air was also observed by Mondain-Monval and Quanquin.[39] On oxidizing pentane, hexane, octane, or gasoline in the vapor state at 300° C., or at slightly lower temperatures, with air there was obtained, in addition to the gaseous products, an oily liquid which possessed marked oxidizing properties. This liquid, on treatment with sodium hydroxide, yielded hydrogen, methyl alcohol, and sodium formate. When heated to 200° C. it underwent an exothermic change with the production of a blue luminescence and white fumes. Simultaneously, large quantities of aldehydes, particularly formaldehyde, were formed. This oily liquid was considered to be a mixture of peroxides, including methyl and ethyl peroxides. The inflammation of mixtures of hydrocarbons and air at relatively low temperatures is attributed[40] to the explosive decomposition of the peroxides. The production of a luminescence during the oxidation of hydrocarbons was noted by Brunner and Rideal,[41] Prettre, Dumanois and Laffitte,[42] and also by Pope, Dykstra and Edgar.[43] The latter workers investigated the non-catalytic oxidation of n-octane and five other isomeric octanes.

In the vapor phase oxidation of n-octane it was found that the gaseous products were carbon monoxide, carbon dioxide, and a small quantity of an unidentified gas which was absorbed by fuming sulphuric acid. Neither hydrogen nor methane could be detected among these gases. The condensible products consisted of unoxidized octane, aldehydes, peroxides and water. Below 200° C. practically no oxidation takes place. Between 200° C. and 270° C. there is an appreciable oxygen consumption though the amount of gaseous products is very small. Practically no carbon monoxide is detected until the temperature is about 270° C. The quantity of carbon dioxide formed, however, increases regularly from zero at 200° C. to 0.4 mole per mole of octane fed to the reaction chamber at 270° C. Above 270° C. the quantity of carbon monoxide produced increases very rapidly, reaching a maximum at 650° C.; at this temperature the ratio of carbon monoxide to carbon dioxide is nearly 3.5:1. The quantity of carbon dioxide formed during this same period (270° to 650° C.) increases very slowly, reaching a maximum value at 400° C., and remaining constant above this temperature. Above 650° C. the carbon monoxide content of the gaseous products decreases very rapidly with increasing temperature and becomes practically zero at 670° C. The carbon dioxide content, on the other hand, increases very rapidly until it becomes practically the only gaseous product. The oxidation of octane is luminescent above 270° C. and the intensity of the luminescence increases with rising temperatures.

---

[37] This concept of the formation of moloxides, or peroxides, goes back further. For earlier explanations of oxidation phenomena based on this theory see Engler and Wild, *Ber.*, 1897, **30**, 1669; Bach, *Compt. rend.*, 1897, **124**, 951; Grün, Ulbrich and Wirth, *Ber.*, 1920, **53**, 987.

The data seem to indicate that the first step in the oxidation of n-octane is the formation of the aldehyde:

$$CH_3(CH_2)_6CH_3 + O_2 \longrightarrow CH_3(CH_2)_6CHO + H_2O$$

Octaldehyde is then oxidized to heptaldehyde accompanied by the liberation of carbon monoxide or dioxide, as follows:

Main Reaction, $CH_3(CH_2)_6CHO + O_2 \longrightarrow CH_3(CH_2)_5CHO + HO_2 + CO$
Side Reaction, $CH_3(CH_2)_6CHO + 1\frac{1}{2}O_2 \longrightarrow CH_3(CH_2)_5CHO + HO_2 + CO_2$

Oxidation then continues in similar steps, the product each time being an aldehyde containing one carbon atom less than the substance being oxidized.

At temperatures above 650° C. oxidation of n-octane to carbon dioxide and water was found to take place so rapidly that it was practically explosive. The luminescence associated with carbon monoxide formation at the lower temperatures was still seen. This indicated that the oxidation of aldehydes to lower aldehydes, carbon monoxide and water also takes place at the higher temperatures. The luminescence observed during both low and high temperature oxidation, also probably indicates the occurrence of chain reactions.

Other octanes studied by Pope, Dykstra and Edgar were: 3-methylheptane, 2-ethylhexane, 2,5-dimethylhexane, 2-methyl-3-ethylpentane, and 2,2,4-trimethylpentane. From the data obtained it appeared that the oxidation of the first four isomeric octanes proceeded in a manner similar to that of n-octane, that is, the primary product was an aldehyde which could be further oxidized to yield either a lower aldehyde, carbon monoxide and water, or a lower aldehyde, carbon dioxide and water. These reactions progress until products are formed which resist further oxidation, or until temperatures are reached which are high enough to bring about complete oxidation with the formation of carbon dioxide and water. In general, the methyl group at the end of the longest open-end straight chain is attacked by the oxygen, yielding an aldehyde and water. This aldehyde is then oxidized forming another aldehyde of one less carbon atom, water, and either carbon monoxide or dioxide. The reaction proceeds in this manner until a fork in the hydrocarbon chain is reached when the oxidation product will be a ketone instead of an aldehyde. At this point oxidation becomes slower, as ketones are much more resistant to oxidation than aldehydes.

The temperatures at which oxidation begins vary with the different octanes. With 3-methylheptane and 2,5-dimethylhexane these investigators found that it began at a temperature slightly above 200° C.; with 3-ethylhexane at 250° C.; and 2-methyl-3-ethylpentane, at nearly 300° C. Apparently the more condensed the structure of the hydrocarbon the higher the temperature required. The highly condensed structure of 2,2,4-trimethylpentane rendered the hydrocarbon so resistant that no reaction occurred until such high temperatures were reached that complete oxidation took place very rapidly.

Chavanne and Tock[44] found that the induction period decreased with increasing molecular weight. This was shown by the slow oxidation of octane, nonane and decane. A mixture of the hydrocarbon and oxygen was heated to 120° C. The gaseous products were the same in each case, viz.: from 30 to 40 per cent carbon dioxide, 1 to 3 per cent carbon monoxide, 5 to 7 per cent hydrogen, and 1 to 2 per cent paraffins. The liquid fractions consisted of formic, acetic, and succinic acids, and formaldehyde. In addition, the liquid portions from decane contained methyl octyl ketone, that from nonane, methyl heptyl ketone, and from octane, octanol and methyl hexyl ketone. In all cases acids were formed containing 1 carbon atom less than the original hydrocarbon. These acids were incompletely identified. The presence of preponderant proportions of methyl ketones with an equal number of carbon atoms as the original material led to the conclusion that slow-oxidation is not to be regarded as an attack of the terminal carbon atom of the chain.

---

[44] *Bull. soc. chim. Belg.*, 1932, **41**, 630; *Chem. Abs.*, 1933, **27**, 2131.

The catalytic vapor-phase oxidation of two tetraalkylmethanes, 3,3-dimethylpentane and 3,3-diethylpentane, studied by Faith, Swann, and Keyes,[45] yielded only water, carbon oxides, unsaturated hydrocarbons and traces of lower aldehydes. In this respect they resemble normal saturated hydrocarbons. The catalysts used were copper, vanadium oxide, and cerium oxide.

The action of oxygen on alkylbenzenes at 100° C. has been investigated by Stephens.[46] The oxidation of methylbenzene was found to proceed in two stages: (1) the formation of the aldehyde, and (2) the oxidation of the aldehyde to an acid. When the side-chain contained more than one carbon atom a ketone was produced, for example, ethylbenzene yielded acetophenone. With compounds having a secondary group as the side-chain, a ketone and an acid were formed. Thus, cumene (isopropylbenzene) was oxidized to acetophenone and formic acid. No oxidation took place with ter.-butylbenzene. Stephens concluded, therefore, that the oxidation of substituted benzenes took place at the α-carbon atom if at least one hydrogen atom was directly attached to it.

The presence of water inhibited the oxidation of the alkylbenzenes when two or three hydrogen atoms were attached to the α-carbon atom, but favored the reaction when only one hydrogen atom was attached. This suggested that in the oxidation of the first two types of compounds there was a reversible stage in which water was eliminated.

Ethylbenzene in liquid phase oxidation is oxidized to acetophenone more rapidly in the presence of manganese acetate than in that of acetic anhydride,[47] according to King, Swann and Keyes.[48] Metallic oxides and acetates of other metals have negligible catalytic action.

Slow-oxidation of liquid 1,3-dimethylcyclopentane[49] at 80° C. yields acetic acid, the methyl isoamyl ketone, $H_3CCOCH_2CH(CH_3)C_2H_5$ and the acid $H_3CCOCH_2CH(CH_3)CH_2COOH$ in the largest proportions. Other products are carbon dioxide, carbon monoxide, hydrogen, traces of methane and ethane, formic acid, small quantities of isopropylacetic and methylethylacetic acids, traces of a hexanoic acid, 1,3-dimethyl-1-cyclopentanol, methyl isobutyl ketone, 1,3-dimethyl-1,3-cyclopentanediol and two ketols, $C_7H_{14}O_2$. Similarly[50] 1,3-dimethylcyclohexane in oxygen at 100° C. under the influence of sunlight gave, as the predominant products, 1,3-dimethylcyclohexanol and a keto-acid which may be either $CH_3COCH_2CH(CH_3)CH_2CH_2COOH$ or $CH_3COCH_2CH_2CH_2CH(CH_3)COOH$ and acetic acid, together with smaller proportions of carbon dioxide and monoxide, hydrogen, methane, possibly propane, formic and acetic acids, two hexanoic acids not fully identified, 6-methyl-2-heptanone, 1,3-dimethyl-1,3-cyclohexanediol. Chavanne and his co-workers thus show the oxidation to be chiefly a hydroxylation of the tertiary carbon atoms, supporting the combustion theory of Bone.

The formation of alcohols and aldehydes during the oxidation of paraffin wax was considered by Landa[51] as a clear indication of the correctness of Bone's hydroxylation theory of oxidation, particularly for the slow-combustion of hydrocarbons. A paraffin wax, melting at 51° C., was heated to 280°-300° C. and oxidized by blowing a stream of air through it. The products of the reaction were carried over by the gas and collected in receivers containing water. A portion of these products was soluble in water, but the remainder separated as an oily insoluble layer. Some gases were also obtained, as well as a small quantity of residual asphaltic material. The water-soluble products, after two rectifications, were divided into three fractions with the following boiling ranges: (1) 45°-60° C., (2) 60°-70° C., and (3) 70°-80° C. The aldehydes in each fraction were then converted to acids with silver oxide. These acids were identified by their salts, particularly those of lead and silver. Substances which did not react with silver oxide were also determined. The results thus obtained indicated that the first fraction contained propionic aldehyde and acetone; the second fraction, methyl alcohol and acetone; and the third fraction, ethyl alcohol, methyl ethyl ketone, and butyric aldehyde. In the supernatant oil layer the following aldehydes were identified: oenanthylic, caprylic, nonanylic, capric and undecanylic. The oily layer also contained other substances which were not identified but appeared to be alcohols and higher aldehydes.

Landa and Pokorny[52] identified formaldehyde, acetaldehyde, propionaldehyde, methyl alcohol and acetone in the products of the slow-combustion of 2-methyltricosane, $H_3C(CH_2)_{20}CH(CH_3)CH_3$. The acetone originated from the rupture of the side chain, but since only about 3 per cent of the theoretical yield was obtained, it did not appear to them to be a normal product of combustion. Accordingly, they believe the acetone formed in the slow-combustion of natural paraffins indicates the presence of more highly branched-chain hydrocarbons.[53]

THEORIES OF THE OXIDATION MECHANISM OF SATURATED HYDROCARBONS

Some of the theories which have been advanced to explain the mechanism of the oxidation of saturated hydrocarbons will be summarized briefly.[54] One of the earliest regarded the hydrogen of the hydrocarbon as being preferentially oxidized. This, however, was vigorously opposed by Kersten,[55] who, taking the opposite view, stated that the carbon was burned preferentially either by direct oxidation of the hydrocarbon to form carbon monoxide and hydrogen or by oxidation of the carbon after thermal dissociation of the molecule. This latter view was also held by Misteli.[56]

From the experimental results obtained by Bone and his collaborators[57] on the oxidation of methane, ethane, ethylene, acetylene and other gaseous hydrocarbons, was formulated the hydroxylation theory.[58] This theory postulates the successive oxidation of hydrogen atoms in the hydrocarbon molecule to hydroxyl groups. The resulting compounds then either lose a molecule of water, or break down in one or more ways. For example, methane would be oxidized first to methyl alcohol, and then to methylene glycol, which in turn would decompose to formaldehyde and water. The formaldehyde would then react in one of two ways depending upon the conditions, principally on the temperature under which oxidation was taking place: (1) decompose to yield hydrogen and carbon monoxide, which in turn would be oxidized to water and carbon dioxide, respectively; or (2) be oxidized to formic acid and then to carbonic acid, the latter yielding carbon dioxide and water. This may be represented in the following way:

$$CH_4 \xrightarrow{\text{Oxidation}} CH_3OH \longrightarrow H_2C(OH)_2 \longrightarrow HCHO + H_2O$$

For hydrocarbons containing more than one carbon atom in the molecule oxidation proceeds in similar, though somewhat more complicated, steps.

This theory has been criticized because the intermediate products between the hydrocarbon and the aldehyde, particularly the primary alcohol, are extremely difficult to isolate. Bone,[59] however, found that the alcohol was more easily oxidized than the corresponding hydrocarbon under similar conditions, hence attached no significance to its absence. Nevertheless, in a few instances, the primary alcohol has been detected, for example, in the oxidation of methane with the oxides of nitrogen,[60] in the oxidation of ethane with ozone,[61] and in the slow-combustion of ethane at high pressures.[61a]

Another point in Bone's theory which has been criticized is the postulation of compounds in which two hydroxyl groups are attached to one carbon atom. This grouping has been actually demonstrated in but few compounds. In addition, the work of Wieland[62] appeared to indicate, in some instances at least, that the formation of the aldehyde from the primary alcohol takes place by dehydrogenation rather than by hydroxylation.

Callendar[63] was unable to establish the presence of any hydroxyl compounds in the oxidation of aliphatic hydrocarbons and has, therefore, objected to the hydroxylation theory on the ground that the formation of such compounds could only take place after the disruption of the oxygen molecule. This rupture of the oxygen molecule would hardly take place at the low temperatures used. Furthermore, such a breaking up of the oxygen molecules would be accompanied by ionization and no evidence of this was observed. He interpreted the results in the light of the peroxide theory.

In the peroxide theory, which is held by many of the later workers, the formation of the aldehyde is preceded by the formation of an intermediate peroxide resulting from the direct addition of a molecule of oxygen to a molecule of the hydrocarbon. The oxygen thus combined in the peroxide is held to be much more active. This mechanism is analogous to the oxidation of benzaldehyde, the peroxide of which has been isolated. Bach[64] was among the first to report the formation of such peroxides during the oxidation of petroleum distillates. Grün, Ulbrich and Wirth[65] termed such a substance a moloxide, and considered it to be an unstable peroxide. The active oxygen in a partially reacted mixture of hexane and oxygen was determined by Brunner and Rideal.[66] They established the presence of peroxides (which liberated iodine from an acid solution of potassium iodide) equivalent to 3.2 per cent of the hexane. Berl, Heise and Winnacker,[67] however, suggested that dehydrogenation preceded peroxide formation. This loss of two hydrogen atoms from the molecule results in the formation of a free radical which then combines with a molecule of oxygen to form a peroxide.

According to Mardles,[68] methane is exceptionally resistant to oxidation in air. Its temperature coefficient is low. He concluded that the oxidation of methane proceeds according to the peroxide theory, methyl hydrogen peroxide being the initial substance formed. This undergoes decomposition to methyl alcohol, formaldehyde and other products.

Further evidence for the peroxide theory was indicated by the oxidation of white oil at 120° C. for various periods of time.[69] On analysis, it was found that the peroxide value passed through a maximum and then decreased before the acetyl value (apparently signifying the formation of alcohols) reached a maximum. The saponification value also increased as the oxidation proceeded. These results were explained on the basis that peroxides are first formed, which then decompose to give alcohols and acids.

Lewis,[70] on the other hand, has criticized the peroxide theory because of the lack of conclusive proof of the formation of peroxides from saturated compounds. As an alternative, he suggested that the hydrocarbon reacts directly with oxygen to form an unsaturated compound and water. This unsaturated compound then later reacts with oxygen to yield aldehydes or peroxides.

It has been pointed out that although the peroxides of the saturated hydrocarbons have not been isolated, their formation has often been indicated.[71] Peroxide formation from unsaturated hydrocarbons, on the other hand, has been well established, and the isolation of some of these peroxides has been accomplished.[72]

From his study of the oxidation of alkylbenzenes referred to previously, Stephens [73] concluded that the formation of alcohol was not an intermediate step. He suggested that the oxidation of paraffin hydrocarbons takes place in the same way as the oxidation of the aliphatic side-chains of aromatic hydrocarbons. He therefore proposed an oxidation mechanism which involves the union of the hydrocarbon molecule with an oxygen molecule to form a complex. This complex then decomposes to yield water and an unsaturated oxygenated residue which rearranges to form an aldehyde or a ketone.

[73] This question of peroxide formation from unsaturated hydrocarbons is discussed more fully in Chapter 40.

Chapter 38

Formaldehyde and Other Aldehydes

Formaldehyde was discovered by Hofmann[1] in 1867 as one of the oxidation products of methyl alcohol. Since its industrial production from the same raw material, which started somewhat later,[2] this substance has assumed a position of increasing importance.[3] The industrial applications which have been made of it are manifold, in keeping with its enormous reactivity.

The antiseptic properties of formaldehyde are well known. This characteristic serves to explain its wide use in sterilization, disinfection, embalming, and as a preservative for tissue. Some applications have also been made of the therapeutic properties of its compound with ammonia (hexamethylenetetramine, which is also known as urotropin, hexa, formin, cystamin), or with other substances in preparations such as tannoform and "Formamint". By far the most important use of hexamethylenetetramine, however, is in the manufacture of plastics.[4] Formaldehyde has also found applications in the tanning of leather, for the hardening of gelatin and other nitrogenous material such as casein (for example, in the manufacture of the plastic called "Galalith"), in the paper and textile industries and for fixing glues and sizes. Because of its reducing action it has been employed in the recovery of silver and gold and in the silvering of mirrors. Diphenylmethane dyes of the auramine and acridine types are made by condensation of formaldehyde with aromatic amines.[5] Condensation of formaldehyde with phenol, urea, or thiourea in the presence of acids or bases yields resinous products such as "Bakelite" or "Unyte" with a wide variety of applications.[6]

Commercial formalin, a 40 per cent (by volume, 37 per cent by weight) aqueous solution of formaldehyde, is generally made by the oxidation of methyl alcohol. Methyl alcohol vapors and air, in carefully regulated quantities, are led over a contact catalyst, generally copper, and the products are then condensed. It is necessary to heat the copper at the beginning, but after the reaction is once started the heat of reaction is sufficient to keep the catalyst at an appropriate temperature (dull red heat). The condensate must be subsequently freed from excess methyl alcohol by distillation.

One of the largest sources of supply for methyl alcohol has been the wood distilleries. With the decrease in demand for wood charcoal, together with the synthetic production of methyl alcohol, particularly in Germany, this source has been curtailed. However, the greatly increased production of gaseous hydrocarbons such as coal gas, natural gas, and cracking gas has led to investigation of their suitability as raw materials for the production of formaldehyde[7] by partial oxidation. In this chapter only the partial oxidation of the gases of the saturated aliphatic series, such as methane and ethane, will be discussed, leaving the oxidation of unsaturated hydrocarbon gases for the next chapter(39).

[6] Further detailed descriptions of these resinous materials and their uses can be found in Ellis, "Synthetic Resins and Their Plastics," Chemical Catalog Co., Inc., New York.

Formaldehyde is a gas which can be condensed to a liquid boiling at —21° C. It is very soluble in water.[8] The liquid aldehyde slowly polymerizes at its boiling point.[9] The evaporation of a solution of formaldehyde yields the solid polymer known as paraformaldehyde, which melts at 150° to 160° C. Reaction of the aldehyde with ammonia to form hexamethylenetetramine, $(CH_2)_6N_4$, is characteristic. From this compound the aldehyde can be regenerated by warming with acid. With sodium bisulphite and sulphurous acid it forms addition compounds.[10] With oxidizing reagents in acid solution, it is converted to formic acid, carbon dioxide and water, but in alkaline solution formates are the principal products.

NON-CATALYTIC OXIDATION OF METHANE

Although the oxidation of methane to formaldehyde, particularly in the presence of catalysts, has been the subject of many investigations, the available information on the slow or partial oxidation of methane, on the other hand, is somewhat limited. Bone and Wheeler[11] showed that oxygen and methane in contact with a refractory surface reacted between 400° to 500° C. to give formaldehyde (yields sometimes as high as 22 per cent of the methane burned), as well as carbon monoxide and carbon dioxide. In some of their experiments they were also able to detect small quantities of formic acid. Methyl alcohol was not detected by them among the products of the slow-oxidation of methane.

Subsequent to Bone and Wheeler's studies, Blair and Wheeler[12] carried out an investigation of the slow-oxidation of methane and from their work the following conclusions were reached:

(1) The rate of thermal decomposition of methane is much slower than its rate of oxidation. Below 850° C. no complications from this source were encountered during heating periods of about 1 second.

(2) The rate of oxidation of methane is much slower than that of ethylene, so that methane requires a temperature of at least 600° C. to react at all during a short period of heating.

(3) The explosive limits of methane and oxygen are between 57 and 60 per cent of methane and the ignition temperature of methane is between 550° and 700° C.

(4) To obtain formaldehyde the heating period must be very short, decomposition beginning at 310° C.

Below 700° C. the reaction is very slow. Increasing the temperature increases the rate of reaction. For the production of formaldehyde a temperature of 720° C. appeared to be the optimum. The presence of steam increased the yield of formaldehyde. The presence of ammonia gas seemed to stabilize the formic acid, but had no great effect upon the formaldehyde. Ledbury and Blair[13] also discussed the production of formaldehyde by the controlled oxidation of methane and ethylene, arriving at similar conclusions.

---

[7] Formaldehyde has also been produced by the reduction of carbon monoxide or dioxide with hydrogen; see Brodie, *Proc. Roy. Soc.*, 1872, **21**, 245; Thénard, *Compt. rend.*, 1873, **76**, 1508; Losanitch and Jovitchitsch, *Ber.*, 1897, **30**, 135; Collie, *J.C.S.*, 1901, **79**, 1063 (used $C_2H_4 + CO$); Heptinere, *Bull. acad. roy. Belg.*, 1897, **34**, 269; also Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., New York, 1930, 707, 675, 677.

[13] *Dept. Sci. Ind. Research* (*Brit.*) *Report* 1, 1927; *Chem. Abs.*, 1928, **22**, 574.

In their work on the slow oxidation of methane, Tropsch and Roelen[14] passed mixtures of methane and air through heated quartz tubes which contained no catalyst. The gas rate was such that the mixture was in the heated zone for a period of about 0.001 second. By varying the experimental conditions it was found that the optimum concentration of methane in the mixture was 16 per cent, and the yield of formaldehyde at 1000° C. was equivalent to 5.96 per cent of the methane used. At 700° C., however, 70 per cent of the methane actually reacting with the oxygen was converted to formaldehyde. This latter result apparently indicates that formaldehyde is the principal product of the reaction of methane and oxygen under these conditions.

The action of ozone on methane to produce formaldehyde has been studied by Wheeler and Blair.[15] Mixtures containing 97 per cent oxygen and 3 per cent methane were first passed through an ozonizer (giving approximately 4 per cent ozone) and then through a heated hard glass tube. The heating temperature varied from 15° to 400° C. and the time of contact of the gases in the hot tube was about 2½ minutes. The optimum temperature was found to be 300° C., and at this temperature 20 per cent of the methane was converted to formaldehyde. When oxygen alone was passed through the ozonizer and then mixed with methane, similar results were obtained. With a mixture of ozone, methane and ammonia, it was again found that the ammonia stabilized the formic acid that was formed, but had no effect on the formaldehyde.[16] No methyl alcohol was found in any of the experiments.

The oxidation of methane by ozone was investigated also by Wartenburg, Muchlinski and Riedler.[17] Their yields of formaldehyde, even under the most varied conditions, were small. Elworthy,[18] on the other hand, considered this type of oxidation commercially promising.

Catalytic Oxidation of Methane

One of the first processes for producing formaldehyde, together with methyl alcohol, from methane, was that of Glock.[19] In this process methane and oxygen are passed over a heated mixture of metallic copper and pumice or asbestos, and the products condensed. A mixture of coke-oven or illuminating gas and air could likewise be used.

Blackmore[20] suggested the preparation of methyl alcohol or formaldehyde by the oxidation of methane with ferro-ferric oxide (Fe_3O_4). The substance obtained depends principally upon the temperature at which the oxidation takes place. At 125° C. (260° F.) the main product of the reaction is methyl alcohol, but at 330° C. (625° F.) formaldehyde is obtained in large quantities.

A number of metals have been mentioned as catalysts.[21] In one process[22] a mixture of methane and air or oxygen (3 volumes of methane and 100 volumes of moist air) is passed over copper or silver[23] at 150° to 200° C. A portion of the methane is converted to formaldehyde, which is removed by treating the gaseous mixture with water. The residual gas is mixed with a further quantity of air, or oxygen, and again passed over the heated metal.

A larger yield of formaldehyde may be obtained if oxidation is carried out in the presence of ammonia.[24] For example, when 6 volumes of methane, 12 volumes of oxygen (or the corresponding quantity of air) and 4 volumes of ammonia are passed through a reaction tube provided with a heated constriction the product consists principally of hexamethylenetetramine, in about 70 per cent yield. The temperature at the constriction in the tube is kept at 300° to 500° C., or at 700° C. if the reaction is conducted under reduced pressure. The tube itself or a steel tube packed at the constriction with thin silver, or nickel, or copper wire may serve as the catalyst. Formaldehyde can be easily regenerated from the hexamethylenetetramine obtained. The use of ammonia to effect the formation of hexamethylenetetramine was also described by Plauson.[25]

Carbon dioxide has also been suggested as the oxidizing agent. For example, when methane and carbon dioxide are passed through a constricted tube heated to 500° to 700° C., a 56 per cent yield of formaldehyde is procured.[26] The tube can be made of copper, silver, nickel, or alloys of these metals with one another or with tin, zinc, or aluminum. The reactions appear to be:

$$2CO_2 \longrightarrow 2CO + O_2$$

$$O_2 + CH_4 \longrightarrow HCHO + H_2O$$

Another method of oxidizing methane to formaldehyde, in which a mixture of methane and air or oxygen is passed through molten lead at 327° C., was described by Morgan.[27]

In a study of the effect of different catalysts on the oxidation of methane to formaldehyde, Schönfelder[28] observed that if methane is conducted with steam and air over copper or silver heated to 500° C., about 55 to 58 per cent is oxidized to formaldehyde, 25 to 40 per cent remains unattacked, and 10 to 20 per cent burns to carbon monoxide, carbon dioxide and water.

Medvedev[29] used gold, platinum, manganous oxide, nickelous oxide, aluminum oxide, cupric oxide, silver oxide, lead oxide (PbO) and ceric oxide catalysts dispersed on an asbestos base. At low gas-flow rates and low temperatures (250° to 350° C.) only carbon dioxide formed. By working at temperatures above 500° C. with a copper catalyst and increasing the gas-flow rate twenty-fold, he was able to obtain, in addition to carbon dioxide, a small quantity of carbon monoxide and a trace only of formaldehyde. At 600° C., however, the use of glass gave a large yield of formaldehyde. This was attributed to the lesser chemical activity of the glass surface. The use of lead catalysts (borate or phosphate or their mixtures) gave high yields of formaldehyde at 500° to 700° C. when the methane carried 3 to 7 per cent hydrogen. The activity of these catalysts, however, was probably due to the presence of volatile impurities, such as lead chloride or hydrogen chloride, as other experiments showed increased yields of formaldehyde when a small quantity (0.13 per cent) of hydrogen chloride was present during oxidation. Medvedev[30] also employed tin borate and phosphate, which were heat-resistant at the reaction temperature.

[29] *Trans. Karpov. Inst. Chem.*, 1924, **3**, 54; *Chem. Abs.*, 1927, **21**, 2457.

A stripped natural gas (containing 1 to 5 per cent air, 0,1 per cent carbon dioxide, 52 to 56 per cent methane, 10 to 12 per cent ethane, 17 to 20 per cent propane and 10 to 12 per cent higher hydrocarbons) was oxidized by air in the presence of various catalysts by Korovatzki.[31] Nitrogen dioxide had scarcely any catalytic activity and copper caused considerable decomposition. Up to 32 per cent of liquid oxidation products, consisting of alcohols, aldehydes, and acids, were formed by oxidation with oxygen, the yield depending upon the concentration of the latter and the rate of flow. The formaldehyde in the condensate corresponded to 10 per cent of the total or 2 to 3 per cent of the charge. Temperatures of 600° to 700° C. caused oxidation to water, carbon dioxide and unsaturated compounds.

The oxides of molybdenum, vanadium, manganese, tungsten, uranium, chromium, titanium and zirconium, or mixtures of these oxides with silver oxide, have been used as catalysts by James.[32] Methane with 1 to 3.5 volumes of air is passed over such catalysts at 550° C., the period of contact being about 1 second. Both formaldehyde and formic acid are produced, the yield of the former being about 6.75 per cent based on the methane used. It is advantageous to use several reaction chambers in series, and to remove the reaction products between successive chambers. This process is applicable not only to methane, but also to coal gas and to petroleum still gases. The products from the latter, however, consist of a mixture of aldehydes and acids. It is also possible to substitute ozonized air in place of air.

For the oxidation of natural gas, or other gases, containing a high percentage of methane, Boomer[33] proposed mixtures of zinc and lead chromates. A mixture of natural gas and oxygen, under pressures of 60 to 300 atmospheres, is passed over these catalysts at 250° to 500° C.

In the United States the production of formaldehyde and other aldehydes as well as alcohol was undertaken for a considerable period by the Empire Gas and Fuel Company. Natural gas, or gases from the distillation of coal, petroleum or shale, were mixed with air, oxygen or carbon dioxide and allowed to react in the presence of a catalyst at 425° to 485° C. (800° to 900° F.). Aldehydes and alcohols were obtained together with a gas of more uniform calorific power.[34] Platinum, palladium, gold, silver, copper, chromium, manganese, iron or nickel or their oxides could be used as catalysts. The reacting substances were maintained under a pressure of 100 to 300 pounds. By varying the conditions and catalysts it was possible to carry out the oxidation in stages. For example, methane in one stage could be oxidized to methanol, and in another to formaldehyde; or ethane could be oxidized in one stage, and methane in another.

OXIDATION OF METHANE WITH GASEOUS CATALYSTS

The oxidation of methane in the presence of gaseous catalysts in place of metallic or metallic oxide catalysts has also received some attention. The most important of these gaseous catalysts are the oxides of nitrogen, particularly nitrogen dioxide, though chlorine, sulphur dioxide, sulphur trioxide, and hydrogen chloride have been used also.

One of the first methods in which nitrogen dioxide was used was described by Bailey.[35] In this process one volume of methane, or its equivalent in the form of natural gas, or any other gas having a high methane content, is mixed with two volumes of nitric oxide and sufficient oxygen, or air, to convert the nitric oxide to nitrogen dioxide. The mixture of gases is then passed through a tube heated to 450° C. The tube may be made of porcelain or any other material which is not affected by the gases. The reaction products are quickly brought into contact with an aqueous sludge of calcium carbonate which unites with the oxides of nitrogen, except nitric oxide, and thus prevents the further oxidation of formaldehyde to carbon dioxide and water. The solid portions of the sludge are removed by filtration and the formaldehyde in solution is recovered by distillation.

In the process developed by Bibb[36] the quantity of nitric oxide used is much smaller (1 to 2 per cent), and it acts more as a carrier or a catalyst. The mixture of methane or natural gas and oxygen is further mixed with air which has been passed through nitric acid and which, therefore, contains some of the oxides of nitrogen. This mixture of methane, air, and nitrogen oxides is preheated to 200° C., passed through a reaction chamber kept at a temperature of 250° to 560° C., and then through a scrubber. The aldehyde is recovered in the usual manner and the residual gases are used again. The presence of only small proportions of nitric oxide is an aid in controlling the extent of oxidation.

Somewhat later, Bibb and Lucas[37] modified the operation by first passing the methane through concentrated nitric acid after which it was mixed with 3.5 to 7 volumes of air. The resulting mixture was heated at 700° to 750° C. It was observed that the highest concentration of formaldehyde in the condensate was obtained with a furnace temperature of 750° C., a time of contact of 0.13 second, and a low air-hydrocarbon ratio. In a later investigation, Bibb[38] obtained yields as high as 7.42 pounds of 40 per cent formaldehyde solution from 1 pound of nitrogen dioxide and about 390 cubic feet of natural gas.

Both gaseous and solid catalysts have been used simultaneously. Harter[39] made oxides of nitrogen by passing a mixture of nitrogen and oxygen into a quartz tube through which a high tension arc is conducted. Hydrocarbon gases, particularly methane, are then added to the mixture of oxygen and nitrogen oxides and the resulting gas is passed through a heated reaction chamber which contains catalysts of copper, silver, cobalt or manganese dispersed on silica gel. Activated carbon can also be used. The reaction products are quickly cooled and recovered.

From a study of the oxidation of methane with nitrogen dioxide Frolich, Harrington and Waitt[40] found that the minimum temperature for reaction in an open pyrex tube is about 430° C. The yield of formaldehyde was less than 25 per cent of the methane reacting and methyl alcohol could not be detected. The conditions which favor formaldehyde production are: low concentration of nitrogen dioxide, slow rate of flow of the reactants, and the absence of reacting surfaces. Attention was also called to the possible formation of acetic acid by the reaction of liquid nitrogen dioxide with higher hydrocarbons of the methane series. Smith and Milner[41] concluded, from their work on the oxidation of methane with nitrogen dioxide in quartz tubes at 500° to 700° C., that the production of formaldehyde under such conditions was too small to be commercially feasible.[42]

Carman[43] proposed the addition of chlorine to the gaseous mixture of methane and oxygen, and also the use of such catalysts as barium, calcium, or strontium chloride at temperatures of 400° to 500° C. A large yield of formaldehyde was obtained, probably because the chlorinated products, which are first formed, are more easily oxidized than methane itself. The reactions which appear to take place have been represented as follows:

$$2CH_4 + 2Cl_2 \longrightarrow 2CH_3Cl + 2HCl$$
$$2CH_3Cl + O_2 \longrightarrow 2CH_2O + 2HCl$$
$$4HCl + O_2 \longrightarrow 2H_2O + 2Cl_2$$

The hydrogen chloride and formaldehyde are absorbed in water, from which the formaldehyde may be obtained as its solid polymer by cooling to a point where polymerization and precipitation is rapid.

The possibility of partially oxidizing methane with sulphur dioxide or sulphur trioxide in the presence of silica as a catalyst and at temperatures of 250° to 800° C. was investigated by Berl and Fischer.[44] No formaldehyde was obtained with sulphur dioxide, most of the methane being oxidized to carbon dioxide. With sulphur trioxide and a large excess of methane, about 0.5 per cent of the methane was converted to formaldehyde, no other oxidation products being observed. When using air alone it was reported that 1.8 per cent of the methane was converted to formaldehyde, 32.4 per cent to carbon monoxide, 3.45 per cent to carbon dioxide, and 63.35 per cent remained unchanged.

CATALYTIC OXIDATION OF METHANE BY SILENT ELECTRIC DISCHARGE

An investigation of the catalytic oxidation of methane with a silent electric discharge employing a number of metallic oxide catalysts was made by Elworthy.[45] Oxidation of mixtures of methane and oxygen by this means yielded a viscous liquid which contained polymerized aldehydes, resins, methyl alcohol, formaldehyde, and formic acid. This process was considered to possess possible commercial interest.

Kloppenburg[46] proposed to make methyl alcohol and formaldehyde by treating a mixture of methane and oxygen in the presence of activated coconut carbon with the dark electric discharge. During the operation of this process the apparatus is cooled to keep the temperature below 35° C.

Formaldehyde has been prepared by passing a mixture of air or oxygen and methane through the field of a high frequency and high voltage current.[47] Catalysts such as copper or silver may be used.[48] The gases issuing from the apparatus are washed to remove the formaldehyde. Yields of from 350 to 480 grams of formaldehyde are realized from 1 cubic meter of methane. Other catalysts such as calcium or magnesium carbonates,[49] quartz,[50] metals or their oxides and nitrogen oxides[51] can also be employed. The methane may be mixed with steam. Hexamethylenetetramine is formed due to the action of the nitrogen of the air and can be removed by washing.

When carbon dioxide and methane are treated with high frequency currents both formaldehyde and acetaldehyde result.[52] The same catalysts which can be used in the oxidation of methane likewise promote this reaction, i.e., calcium or magnesium carbonate, or quartz glass.

OXIDATION OF HIGHER HYDROCARBONS TO ALDEHYDES

Bone and Stockings[53] observed that during slow-combustion, ethane was oxidized much more rapidly than methane. Mixtures of ethane and oxygen in borosilicate glass tubes were heated to 250° to 400° C. under pressures of 1.75 to 2.33 atmospheres, or to 400° to 500° C. under reduced pressures in a "circulation apparatus." The products were carbon monoxide and dioxide, water, traces of formic acid and acetaldehyde, and a relatively large quantity of formaldehyde. The absence of ethyl alcohol and any large quantity of acetaldehyde is explained by the hydroxylation theory.[54]

In the partial oxidation of ethane and propane, formaldehyde is the oxygenated product obtained in the greatest quantity. Curme[55] carried out the oxidation at temperatures above 600° C. (generally 700° to 710° C.), using a silica heating surface as the catalyst. The gases leaving the reaction chamber are scrubbed with cold water to remove the formaldehyde, and the residual gases are recirculated. In addition to formaldehyde, higher aldehydes are obtained in small amounts. Thus, with ethane, some acetaldehyde is also produced. Another procedure consists in heating the hydrocarbons (ethane and propane) to 700° C. in the absence of air (which is termed the "degradation" treatment) and then introducing air.[56] The yield of formaldehyde is about 85 per cent.

Working with the liquid hydrocarbons, Stepski[57] passed a stream of air, saturated with the vapors of the hydrocarbon, over glowing platinum. The products were then cooled to -15° C., and the uncondensed gases led into bromine. His qualitative results showed that isopentane yields formaldehyde and ethylene in large quantities, together with propylene, the three isomeric butylenes, two isoamylenes, carbon dioxide, and water, whereas n-hexane gives formaldehyde and ethylene, together with propylene, 1- and 2-butene, two amylenes, three hexylenes, carbon dioxide, and water.

Wheeler and Blair[58] carried out the slow-oxidation of hexane vapors at 480° to 590° C. in glass tubes in the absence of catalysts. The products which were isolated included higher aldehydes, formaldehyde, unsaturated hydrocarbons, acids (in small quantities), carbon monoxide and dioxide, water, and hydrogen (at the higher temperatures). Excess oxygen was found to increase the proportion of higher aldehydes as well as of carbon dioxide. Increase in temperature decreased the percentage of higher aldehydes formed, but increased the proportion of formaldehyde and unsaturated hydrocarbons, ethylene forming a large proportion of the latter. The quantities of carbon monoxide and dioxide also increased with increasing temperatures. No saturated hydrocarbons, it was stated, are formed, which indicates that no thermal decomposition of hexane (which would give considerable methane) takes place throughout the temperature range of these experiments.

In oxidizing boiling hexane with ozone, Blair, Wheeler and Ledbury[59] reported that formaldehyde and acetaldehyde were produced in relatively large proportions, together with much smaller proportions of higher aldehydes; some acids, principally hexanoic; traces of water and carbon monoxide and dioxide. Some esters were also present, probably mostly hexyl hexanoate. The higher aldehydes were not found in quantity due, no doubt, to the ease with which oxidation to acetaldehyde takes place.

Higher aldehydes are also made by oxidizing petroleum oils. Oxidation processes of this kind, however, result in the formation of a mixture of different aldehydes, alcohols, and acids, which are discussed more fully in succeeding chapters. As an example, the work of Schulz[60] is of interest. By passing a rapid stream of air through Boryslaw oils heated to 300° C. in a retort which was connected to a series of wash bottles, formaldehyde, acrolein, and other aldehydes, together with other products were obtained.

CATALYTIC OXIDATION OF ALCOHOLS

As previously mentioned, the first methods for the production of formaldehyde were dependent upon the oxidation of methyl alcohol.[61] Blackmore[62] led the vapors of methyl alcohol and air through a series of electrically heated copper screens. Other alcohols than methyl could be used. Fokin[63] obtained better yields of formaldehyde by placing silver in front of the copper catalyst and using a volume of air which contained the stoichiometrical quantity of oxygen. Jaeger[64] employed a metal oxide which is not easily reduced by hydrogen, such as the oxides of the alkalies or alkaline earths, together with compounds of molybdenum or vanadium. A combustion retarder, such as potassium oxide and manganese oxide, has been added to the vanadium oxide catalyst by Craver.[65]

Kuss[66] conducted a mixture of air and the vapors of anhydrous methyl alcohol over a silver catalyst at 500° C. The quantity of air used contains the theoretical quantity of oxygen required for oxidation. A 60 per cent solution of formaldehyde is thus obtained. In solutions of such concentrations the formaldehyde slowly polymerizes to the solid, paraformaldehyde. This polymerization can be hastened by slightly warming the solution. By evaporating under reduced pressure, paraformaldehyde can be separated. The hot gases from the reaction can be used for this evaporation.

Acetaldehyde was made in much the same manner by Woolcock,[67] from ethyl alcohol and air, except that some steam is mixed with the alcohol vapors and the quantity of air used contains somewhat less (about 75 per cent) oxygen than that theoretically required for the production of the aldehyde.

The activity of the copper catalyst used in the oxidation of alcohols can be increased in two ways: (1) by dispersing it on pumice, and (2) by mixing it with small quantities of rare earth oxides, such as samarium oxide.[68] The first method appears to give better yields of aldehydes from both methyl and ethyl alcohol. In the second method, however, the samarium oxide promoted the activity of the catalyst to such an extent that oxidation beyond the aldehyde stage occurred and very much lower yields of aldehydes were obtained. The second method would, as is stated, therefore be of no advantage with methyl and ethyl alcohols, but might be with substances which were somewhat more difficult to oxidize. It is believed that the presence of the rare earth oxides minimizes poisoning of the catalyst and thus greatly increases its life. The addition of silver, cobalt, zinc oxide or manganese oxide to a copper catalyst for the oxidation of ethyl alcohol to acetaldehyde has also been proposed.[69]

For the catalytic oxidation of both aromatic and aliphatic alcohols Maxted and Coke[70] found that metallic vanadates, heated to 300° C., could be used as catalysts. The best of these appeared to be tin vanadate. They are particularly applicable to the production of acetaldehyde from ethyl alcohol. Silver catalysts[71] have also been used for the oxidation of ethyl alcohol to acetaldehyde. That form of catalyst which has the greatest coefficient of heat transfer gives the highest yield of aldehyde from alcohol, according to Faith and Keyes.[72] They obtained higher yields of acetaldehyde with both copper and silver than had been reported previously.

When the vapors of butyl alcohol are passed over copper oxide heated to 260° to 320° C. there is obtained a mixture of butyl alcohol, butyl butyrate and butyraldehyde.[73] The aldehyde and ester can be separated by fractionation. The aldehyde may be further oxidized to butyric acid[74] by passing the liquid, containing about 0.5 per cent manganese butyrate, through a tower countercurrent to a stream of air.

Simington and Adkins[75] investigated the oxidation of ethyl, isopropyl and butyl alcohols by air in the presence of silver, nickel, copper, and platinum gauzes; copper wire; silver pellets; pellets of alloys of copper with zinc, nickel, bismuth, palladium, platinum, gold and manganese; mixtures of the oxides of uranium and copper, tungsten and copper, molybdenum and copper, and vanadium, iron and copper. Silver and silver-copper alloys produced yields of aldehydes and ketones in excess of 70 per cent of the theoretical. With all catalysts, butyl alcohol formed a small proportion of ester and with the mixed oxide catalysts, some formaldehyde. Ethyl alcohol gave 3 times as much carbon dioxide as butyl alcohol and twice as much as propyl alcohol.

OXIDATION OF ALDEHYDES

The oxidation of acetaldehyde to acetic acid has been applied industrially. At the Shawinigan Falls plant[76] of Shawinigan Chemicals, Ltd., acetylene is hydrated to acetaldehyde in the presence of mercury.[77] The acetaldehyde is then oxidized to acetic acid with air in the presence of manganese acetate at a temperature of 60° C. and a pressure of about 4.5 atmospheres.

The oxidation of acetaldehyde has been studied by Hatcher, Steacie and Howland.[78] They observed that the main reaction was of the chain type and that acetaldehyde, on coming into contact with air, forms a compound which in water behaves as an organic peroxide.[79] A number of catalysts have been proposed for the oxidation of acetaldehyde, including manganese, iron, cobalt, chromium, and copper,[80] or active carbon charged with zinc oxide and phosphoric acid.[81]

Formaldehyde may be formed by the partial oxidation of acetaldehyde.[82] The extent to which such action takes place is determined by the time of contact which, in turn, is regulated by conducting oxygen and acetaldehyde vapors through capillary tubes heated for a small portion of their length.

Chapter 39

Oxidation of Unsaturated Hydrocarbons

Olefins are generally considered to react more rapidly with oxidizing agents than do the corresponding saturated hydrocarbons.[1] This oxidation, however, need not necessarily involve a scission of the molecule as olefins yield intermediate products such as peroxides, alcohols and ozonides. The formation of gum in light petroleum distillates, made by the cracking of the heavier fractions, has been attributed to the presence of olefins which readily unite with oxygen of the air to form peroxides. These latter substances yield gum on evaporation of the gasoline. The rates of oxidation of olefins vary widely. The monolefins are less rapidly oxidized than diolefins, the latter appearing to be chiefly responsible for the gum in gasoline (see Chapter 40).

Oxidation of unsaturated hydrocarbons with dilute permanganate solution (either neutral or alkaline) often results in the addition of two hydroxyl groups at the double bond to give the corresponding glycol. Further oxidation with permanganate causes a rupture of the molecule at the double bond with the formation of acids. Identification of the acids is frequently helpful in determining the constitution of the original hydrocarbon. Occasionally, however, as in the case of some cyclic unsaturated compounds, the break in the molecule does not occur at the double bond.

Oxidation with ozone also frequently indicates the position of the double bond in the hydrocarbon molecule. Unsaturated compounds unite with ozone to form ozonides which can be hydrolyzed to give aldehydes or ketones and hydrogen peroxide, rupture of the molecule simultaneously taking place at the double bond. From the identification of the aldehydes or ketones it is possible to determine the structure of the original hydrocarbon.[2]

The largest source of unsaturated hydrocarbons is, of course, the cracking of heavy petroleum distillates. Unsaturated hydrocarbons are prepared also by the oxidation (or what probably better corresponds to dehydrogenation) of saturated or paraffin hydrocarbons. Before considering the oxidation reactions of olefins and acetylene it is of interest to discuss briefly the production of such compounds by the oxidation of petroleum hydrocarbons. Methods for preparing unsaturated hydrocarbons from paraffins by thermal decomposition or by oxidation with steam are given in Chapters 4 and 10, respectively.

Production of Unsaturated Hydrocarbons by Oxidation

This type of oxidation requires much more closely regulated conditions than the slow combustion of saturated hydrocarbons to aldehydes and acids. For example, acetylene is obtained by heating mixtures of methane and air or oxygen for very short periods of time (about 0.005 second) at 1000° to 1600° C.,[3] the short period of heating preventing action of the steam formed on the unsaturated hydrocarbon.[4] The yield of acetylene appears to depend primarily upon the temperature and the time of contact. At 1400° C. and with about 0.006 second contact, 30 per cent of the methane is converted to acetylene, and at 1600° C. and 0.001 second contact, the conversion is 50 to 60 per cent. Decreasing the pressure does not appear to increase the yield of acetylene but does favor the production of the oxides of carbon and water. Subjecting gaseous hydrocarbons to incomplete combustion at 700° to 1100° C., under pressures of 0.5 to 5 atmospheres, and in the presence of a catalyst containing free silicon also yields acetylene.[5] Or mixtures of saturated hydrocarbons and oxygen may be diluted with steam and heated to 1300° C. or higher.[6]

---

[1] Estrade (*Ann. combustible liquides*, 1933, **8**, 484; *J. Inst. Pet. Tech.*, 1933, **19**, 413A) stated that, during the oxidation of saturated hydrocarbons, cyclicization does not greatly increase the resistance of the hydrocarbon to oxidation but the introduction of a double bond into the molecule does.

[2] Verley (*Bull. soc. chim.*, 1928, **43**, 854; *Chem. Abs.*, 1929, **23**, 595) pointed out that rearrangement of certain types of ozonides is possible and decomposition on hydrolysis may not therefore take place at the position originally occupied by the double bond.

In another process, methane or other gaseous hydrocarbons together with oxygen are heated to temperatures of about 1000° C., using porous or refractory ceramic materials as catalysts.[7] In some instances a gas containing 50 per cent oxygen gives better results than oxygen alone. This procedure is also applicable to tars, petroleum residues and other similar products. For instance, coal tar is heated to 250° C. and the vapors mixed with oxygen are passed through a tube containing refractory material heated to 800° C. The reaction products consist of ethylene, propylene and butylene.

The vapors of gasoline, kerosene or lubricating oils are converted to acetylene by flames of oxygen or air burning in them.[8] The yield is increased if the flame jets are of small diameter arranged in a group, rather than separate jets of a large diameter.

Ethylene is made by the careful oxidation of ethane with air or oxygen, mixed with coke-oven or water gas. This is effected by heating the gaseous mixture to temperatures of 600° to 900° C. in contact with pumice or silica.[9] Spindler[10] obtained ethylene from methane and oxygen by a process which requires two steps. The methane and oxygen is first passed over heated copper to yield formaldehyde. This substance is then made to react with more methane at 500° C. under 1000 atmospheres pressure to give water and ethylene. The catalysts employed in the second step consist of various compounds of iron, nickel, cobalt, platinum and copper. In the presence of zinc chloride, at this same temperature and pressure, ethylene undergoes polymerization and yields pentane and hexane together with unsaturated aliphatic and cyclic hydrocarbons.

Ethylene and other olefinic hydrocarbons are formed when natural gas or coal gas is mixed with air and the heated mixture passed over metallic catalysts. The catalysts can be platinum black, or the oxides of iron, copper, nickel, chromium and other metals. These unsaturated gaseous hydrocarbons may be further converted to liquid hydrocarbons by conducting the heated gases over a nickel catalyst.[11]

The production of olefins from liquid or solid hydrocarbons is accomplished by heating a mixture of the vapors of such hydrocarbons with a gas containing at least 50 per cent oxygen, and in proportions which are insufficient for complete oxidation, to temperatures of 650° to 900° C. Water, either in the form of liquid or vapor, may be added to the gaseous mixture. This process is applicable to such substances as tars, petroleum residues and bitumen.[12] The gases so obtained are rich in olefins which can be used in the preparation of glycols and higher alcohols (see Chapter 22). Conversion of these gases to benzene can be effected with contact agents such as pumice, heavy metals, carbonates and other salts of the alkaline earth metals (see Chapter 5).

In dehydrogenating gaseous hydrocarbons, Hopkins [13] causes the gases to pass through a heated tube into which air or oxygen is fed at regular intervals. The temperature maintained during the process varied from 250° C. for gases of high molecular weight to 470° C. for those of lower molecular weight. For the dehydrogenation of natural gas or the vapors of petroleum distillates a series of reaction zones kept at progressively higher temperatures is recommended. Ramage,[14] on the other hand, suggests the use of reducible metallic oxides, such as ferric oxide, at temperatures of about 550° C.

OXIDATION OF ETHYLENE HYDROCARBONS

The oxidation of ethylene to formaldehyde was reported by Schützenberger,[15] who obtained the solid polymer (trioxymethylene) by conducting a mixture of ethylene and oxygen through a glass tube heated to 400° C. Bone and Wheeler [16] from a study of the slow oxidation of ethylene, at 250° to 400° C. under pressures of 1¾ to 2⅓ atmospheres or at 300° to 500° C. under reduced pressure, also observed the formation of formaldehyde. Later, however, Willstätter and Bommer [17] showed that by working at higher temperatures (545° to 600° C.) larger yields of formaldehyde could be obtained, though it was necessary to dilute the reacting gases with nitrogen. They also found that catalysts accelerated the oxidation of ethylene but were unable to detect any formaldehyde under these conditions. With an osmium catalyst oxidation of ethylene (with oxygen) began at 130° C., but with copper a somewhat higher temperature (250° C.) was required.

The slow oxidation of ethylene was studied by Blair and Wheeler [18] and their conclusions were in general agreement with those reached by Willstätter and Bommer. In these experiments, Blair and Wheeler passed gaseous mixtures of ethylene and oxygen diluted with nitrogen (usually about 60 to 65 per cent of the mixture) through a circulation apparatus for periods of time varying from 12 to 50 hours. The temperatures ranged from 560° to 575° C., and the time of contact for the gases in the reaction zone varied from 1 to 4 seconds. The best result, 75 per cent of the reacting ethylene converted to formaldehyde, was obtained under the following conditions: temperature, 575° C.; circulation

period, 40 hours; and time of contact, 1 second. In addition to formaldehyde they obtained appreciable quantities of both acetaldehyde and formic acid. A short heating period is necessary for the production of both these substances, since acetaldehyde is an early intermediate product and formic acid is unstable. A slight excess of oxygen in the gaseous mixture favors a larger yield of formic acid, whereas a slight deficiency or a large excess assists in the formation of acetaldehyde. The presence of steam tends to stabilize the formaldehyde (another intermediate product) and prevent its immediate oxidation. Ammonia, however, exhibits a much stronger stabilizing effect.

Blair and Wheeler further observed, using an apparatus similar to that of Willstätter and Bommer, that formaldehyde was not produced when the diluted mixture of ethylene and oxygen was passed once at 405° to 540° C. through a heated tube containing a platinum or ferric oxide catalyst, unless the time of contact was extremely short (less than 0.0001 second). Even then the quantity of formaldehyde was very small. They therefore concluded that the catalyst lowers the temperature at which the various oxidation reactions take place and makes them follow one another at very short intervals.

In the light of Bone's hydroxylation theory, the oxidation of ethylene can be represented as follows:

$$\begin{aligned} C_2H_4 \longrightarrow CH_2{:}CHOH \longrightarrow CH_3CHO &\longrightarrow CH_2(OH)CHO \\ &\longrightarrow HCHO \longrightarrow HCOOH \longrightarrow CO_2 + H_2O \end{aligned}$$

Continuing their work Wheeler and Blair [19] investigated the oxidation of mixtures of methane and ethylene in the presence of some of the oxidation products. The gas used was coal gas, which contained both methane and ethylene together with two of their oxidation products, namely hydrogen and carbon monoxide. The temperatures employed varied from 400° to 720° C. and the times of contact in the reaction chamber, from 0.8 to 2.4 seconds. As in their previous experiments, the mixtures of coal gas and oxygen were diluted with nitrogen.

The rate of oxidation of the hydrocarbons was not greatly affected by the presence of the intermediate oxidation products. The yield of formaldehyde was slightly less than that obtained from methane alone. With increasing temperatures first one constituent and then another begins to react, and the rates of reaction increase rapidly until they attain a constant ratio to one another. A comparison of these rates shows that carbon monoxide and water are the chief products of the slow-oxidation of methane under conditions which decompose formaldehyde. At these temperatures and times of contact hydrogen is oxidized first, then methane, and finally carbon monoxide. The rapid increase in the rate of oxidation of carbon monoxide with rising temperature explains the presence of carbon dioxide among the oxidation products at high temperatures.

The influence of contact agents was also investigated. It was observed that at low temperatures the oxidation and decomposition of the intermediate products were accelerated in the presence of pumic to a greater degree than that of the hydrocarbons. At higher temperatures, however, the oxidation of the hydrocarbon increased and there was an accumulation of hydrogen and carbon monoxide. Ferric oxide has a similar effect, but, in addition, accelerated the decomposition of formaldehyde. The catalytic effect of mercury was found to be small; the rate of oxidation of ethylene, carbon monoxide and hydrogen was accelerated somewhat, but the rate of oxidation of methane was hardly affected. With mercury the yield of formaldehyde was greater than that obtained when either pumice or ferric oxide was employed as the catalyst.

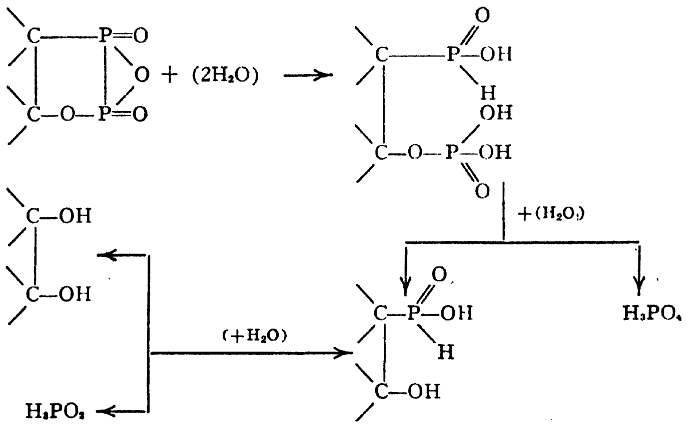
---

[19] *J.S.C.I.*, 1923, 42, 260T.

When coal gas, without the addition of oxygen, was passed over ferric oxide at 410° C. the carbon monoxide and hydrogen were oxidized while the hydrocarbons were unattacked. It was suggested, therefore, that this be made the basis of a partial combustion method of gas analysis in which the carbon monoxide and hydrogen are first burned by ferric oxide, and the methane is then determined in the usual manner.

Inasmuch as one of the effects of a catalyst is to lower the temperature at which reaction between ethylene and oxygen takes place, Reyerson and Swearingen[20] investigated the use of metallized silica gels. They expected such catalysts to so lower the temperature of reaction that the partial oxidation of ethylene could be effected and a mechanism for its oxidation ascertained. The gels were metallized with gold, silver, platinum, palladium and copper, and the working temperatures ranged from 100° to 300° C. Mixtures of ethylene, oxygen and nitrogen were used and in no instance did the sum of the ethylene and oxygen volumes exceed 50 per cent of the total gas volume. The rates of flow of the gaseous mixtures were varied over wide ranges. Only water and carbon dioxide were produced and aldehydes could not be detected. The catalysts, however were effective with ethylene at lower temperatures than were reported with methane (see Chapter 37). The copper, platinum and palladium began to be effective at 100° C. Silver was the least effective catalyst.

Willstätter and Sonnenfeld[21] tried sulphur as a catalyst and found it inactive at room temperature, while phosphorus was active, but reacted with the olefins yielding compounds of a new type, olefinphosphorous oxides. For instance, if the reaction between one molecule of cyclohexene and two atoms of phosphorus is interrupted after three atoms of oxygen have been absorbed, the product is a yellow, hygroscopic powder, having the formula $C_6H_{10}P_2O_3$. It is known as a phosphorite and is more unstable than the final product obtained by allowing the reaction to be completed. The end result is a phosphorate of the formula $C_6H_{10}P_2O_4$. The phosphorates are very hygroscopic, snow-white to faintly yellowish crystals, and have a violent reaction with water, hydrolyzing to an acid ester. On further hydrolysis, phosphenylous acid and phosphoric acid are formed along with phosphinic acid and an alcohol. The reaction may be indicated in the following manner:



---

[20] *J.A.C.S.*, 1928, 50, 2872.
[21] *Ber.*, 1914, 47, 2801.

In a process of Mittasch, Willfroth and Balz,[22] a mixture of ethylene and oxygen is passed over a catalyst consisting of burnt clay or diatomaceous earth impregnated with boric or phosphoric acid. The reaction temperature is 375° C. Bibb,[23] on the other hand, used oxides of nitrogen as catalysts for the oxidation of ethylene to formaldehyde with air.

The slow or incomplete oxidation of ethylene can also result in the formation of unsaturated hydrocarbons of high molecular weight. Thus, Weinmann[24] observed when ethylene is suddenly heated with insufficient oxygen for complete combustion (particularly moist oxygen) to a temperature corresponding to red heat and then rapidly cooled, the condensate contains unsaturated hydrocarbons other than ethylene. On distillation the condensate yielded one fraction, boiling about —7° C., which contained a mixture of butadiene and ethylethylene. Another fraction, boiling about 80° C., proved to be a mixture of hexene and hexane. The former can be used for welding and as an aviation fuel.

Glycol is also obtained from ethylene by the action of air and water under pressure, using arsenic, antimony, gold, copper, iron, or compounds or mixtures of these metals as catalysts.[25] A temperature of 150° to 300° C. is employed.

Cyclic glycols are prepared by treating unsaturated cyclic compounds with hydrogen peroxide in the presence of acids or of easily hydrolyzed salts.[26]

Ethylene oxide has been made by heating equimolecular quantities of ethylene and oxygen in the vapor phase under pressure.[27] Formation of acetaldehyde is suppressed by controlling the temperature of reaction. Acetaldehyde may be produced by the use of hydration catalysts such as zinc chloride or phosphoric acid. Likewise acetic acid can be formed by using an excess of oxygen at high temperatures and silver, copper, or metallic oxides as catalysts.

Schultze[28] studied the effect of oxygen on unsaturated hydrocarbons in the presence of bromine. If ethylene, propylene or butylene were absorbed by bromine water in the presence of pure oxygen, more of the gaseous mixture was absorbed than corresponded to the quantity of hydrocarbon present. Obviously some oxygen was also absorbed. This was not accounted for by the solubility of oxygen in bromine water, for similar results were obtained when the latter was presaturated. Therefore a bromine-sensitized oxidation of the hydrocarbons to carbon dioxide and water was suspected. On analysis of the solution carbon dioxide was found to be present. This proved that some oxygen had been used to oxidize the hydrocarbons.

Riley and Friend[29] investigated oxidation with selenium dioxide. When gaseous ethylene was passed over selenium dioxide at temperatures between 50° and 300° C. glyoxal was formed. It was isolated either as glyoxal ($CHO{\cdot}CHO$) or as a solid polymer ($(CHO{\cdot}CHO)_n$). The reaction may be indicated as

$$2CH_2{=}CH_2 + 3SeO_2 \longrightarrow 2(CHO)_2 + 3Se + H_2O$$

At 110° to 120° C. the reaction is only about 33 per cent complete due to the coating of selenium on the selenium dioxide; at 220° to 240° C. the unreduced selenium dioxide sublimed through the molten selenium, and reacted with ethylene giving an 82.4 per cent yield of glyoxal. The carbon dioxide formed probably accounts for the remainder of the ethylene.

At temperatures of about 150° C. and under pressure, ethylene is oxidized by solutions of oxidizing agents (e.g., 40 per cent sulphuric acid containing chromic acid) to acetic acid or its esters.[30]

The oxidation of isoprene with perbenzoic acid yields β-methyl-butadiene αβ-oxide, an oxide containing a double bond.[31] It is violently isomerized by mineral acids to tiglaldehyde.

MECHANISM OF THE OXIDATION OF OLEFINS

As already mentioned, Blair and Wheeler[32] concluded that the oxidation of unsaturated hydrocarbons took place in steps which were in accord with the hydroxylation theory.

Thompson and Hinshelwood,[33] from their work on the rate of reaction of oxygen with ethylene at temperatures between 400° and 500° C., believed that the reaction progressed by a chain mechanism. It was suggested that the first stage was the formation of an unstable peroxide, $C_2H_4:O_2$. When one molecule of this peroxide collides with an ethylene molecule, two hydroxylated molecules, e.g., $CH_2:CHOH$, are produced and these continue the chain. If, however, the peroxide collides with an oxygen molecule, then it is either decomposed or oxidized to stable products. The reaction is greatly retarded by an increase in the surface of the vessel exposed to the gases. Furthermore, a consideration of the temperature coefficient and the influence of foreign gases on the velocity of reaction indicates that the reaction chains are not of great length. Spence and Taylor[34] studied the reaction of ethylene with oxygen and with ozonized oxygen at temperature between 260° and 440° C. They found that the extent of total reaction is greatly increased by the presence of small quantities of ozone and concluded, therefore, that ozone is an initiator of reaction chains of short lengths.

The slow combustion of ethylene has also been investigated by Lenher, using both long times of contact in a single-pass system[35] and short times of contact in a circulatory system.[36] When the first method was employed the products were carbon monoxide and dioxide and hydrogen, and the condensible products contained ethylene oxide, ethylene glycol, glyoxal, formaldehyde, formic acid and water. Raising the temperature increased the yields of the various substances. Above 400° C., however, the proportion of condensate began to decrease on account of secondary reactions. Increasing the time of contact also increased the yields. The rate of reaction was proportional to the third power of the ethylene concentration.[37] On the other hand, increasing the surface in contact with the gases reduced the reaction velocity. In fact, the reaction was entirely inhibited in a packed vessel below a temperature of 450° C. These last two phenomena are characteristic of chain reactions. The lining of the reaction vessel also influenced the course of the reaction. Oxides of nitrogen were found to react directly with ethylene and, therefore, could not be considered as catalysts.[38]

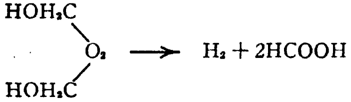
[36] *J.A.C.S.*, 1931, **53**, 3752.

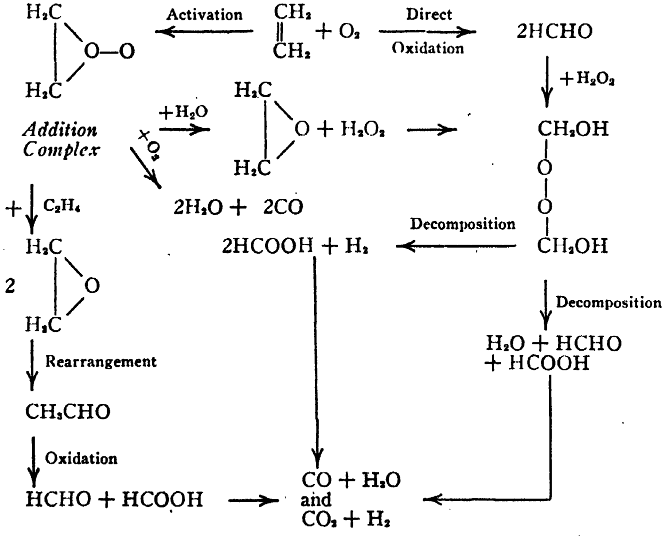
[37] Thompson and Hinshelwood (*loc. cit.*) also observed that the rate of reaction was proportional to the third power of the ethylene concentration.

Similar results were obtained in a much larger reaction vessel except that dioxymethyl peroxide, $(HOCH_2)_2O_2$, was the principal product in the condensate. Other products obtained at the same time were formaldehyde, formic acid, ethylene oxide, the oxides of carbon, and hydrogen. In silica vessels the formation of dioxymethyl peroxide was greatly reduced, and entirely suppressed in iron or aluminum vessels coated with potassium chloride or silicate. Decreasing the formation of this substance resulted in an increased yield of formaldehyde. The formic acid obtained in these experiments apparently came from the dioxymethyl peroxide, as this compound decomposes to yield hydrogen and formic acid.



The experiments in the circulatory system were conducted between temperatures of 410° and 600° C. with short times of contact, usually about 3 seconds. The principal products of the reaction were ethylene oxide and formaldehyde. Other products, such as dioxymethyl peroxide, acetaldehyde, formic acid, oxides of carbon and water, were formed in varying quantities. At temperatures above 450° C. the polymerization of ethylene to higher monolefins becomes an important reaction, the principal polymerization products being propylene and a small quantity of butylene.

Lenher represented the possible mechanism of the oxidation of ethylene as follows:



According to Lenher, the reaction of ethylene with oxygen appears to take place in two ways: either by the direct oxidation of ethylene to formaldehyde, or by the formation of an addition complex or peroxide which in turn yields ethylene oxide. The early appearance of both formaldehyde and ethylene oxide as intermediate oxidation products is evidence that the formation of these two substances is the primary step in the oxidation of ethylene. Hydrogen peroxide is also formed during the reaction and probably reacts with formaldehyde to form dioxymethyl peroxide.

---

[38] *Cf.* Bibb, *loc. cit.*

The effect of oxygen on propylene at high propylene and low oxygen concentrations was investigated by Lenher.[39] The time of contact varied from 3 to 18 seconds and the temperature from 500° to 600° C. In addition to oxidation, pyrolysis takes place due to the activation of the propylene by oxygen. The oxidation products were acetaldehyde, formaldehyde, formic acid, carbon oxides and water.

The primary reaction products of pyrolysis were higher monolefins; butylenes, amylenes, and hexylenes. Secondary products were olefins, paraffins and hydrogen. Comparison of results, both in the presence and absence of oxygen, showed that the temperature at which pyrolysis is appreciable, is lowered greatly by the presence of small amounts of oxygen, and the rate is quite markedly increased.

Riley and Friend reported that oxidation of propylene with selenium dioxide gave a 19 per cent yield of methyl glyoxal.[40]

The formation of peroxides as one of the intermediate oxidation products was also demonstrated by Lewis[41] in a study of the low-temperature oxidation of amylene. The variations of pressure with temperature of mixtures of amylene and oxygen were observed. The pressure-temperature curves showed three distinct sections which were accounted for as follows: (1) a region up to 220° to 230° C., which deviates but slightly from the vapor pressure curve and indicates very little reaction; followed by (2) a region of vigorous reaction (up to 237° to 241° C.), which is characterized by a decrease in pressure to a minimum; (3) and a region of rapid increase in pressure, attributed to the oxidation of the products formed in the second stage. Analysis of the gases during the first stage gave evidence of the formation of oxides of carbon and aldehydes. Lewis, therefore, suggested that peroxides are formed and decompose to yield aldehydes during the first stage. Increasing the temperature increases the rates of formation, decomposition and polymerization of the aldehydes, hence the drop in pressure during the second stage. After the minimum pressure is reached sufficient unstable material is present to set up chain reactions giving rapid oxidation. Catalysts, such as pumice or charcoal, accelerate oxidation. Inhibitors, such as lead tetraethyl, almost eliminate the contraction part of the curve. These observations also suggest that the second step in the combustion of a paraffin hydrocarbon is the oxidation of a primarily formed unsaturated compound to a readily decomposed peroxide. The energy of decomposition of the peroxide assists the further oxidation of the aldehyde formed during its decomposition.

The mechanism proposed by Reyerson and Swearingen[42] accounts for the oxidation of ethylene in the presence of metallized silica gels as the result of collisions of the ethylene molecules with oxygen molecules which have been adsorbed and activated by the effective catalyst centers. On the other hand, the collision of oxygen molecules with adsorbed ethylene molecules was ineffective.

RELATIVE RATES OF OXIDATION OF OLEFINS

In determining the relative rates of oxidation of olefins Davis[43] exploded various ethylene-propylene and ethylene-isobutylene mixtures with oxygen and analyzed the gases before and after reaction. In every instance combustion was incomplete, that is, both olefins and oxygen were found in the reaction products. The analyses, however, indicated that both propylene and isobutylene burned faster than ethylene.

Mixtures of ethylene and isobutylene were also dissolved in water and oxidized by slowly adding a saturated solution of permanganate. The quantity of reagent added was not sufficient for complete oxidation and the proportion of each olefin unoxidized was determined by boiling out the gases and analyzing them. The relative rates of reaction of the olefins in these two series of oxidations were calculated using the formula developed by Francis, Hill and Johnston:[44]

$$\frac{K_A}{K_B} = \frac{\log(1 - r_A)}{\log(1 - r_B)}$$

where r_A and r_B = fractions of olefins A and B which react; and
K_A and K_B = velocity constants of oxidation reactions of the two olefins.

From the data obtained in the combustion with oxygen the following ratios were derived:

$$\frac{K \text{ propylene}}{K \text{ ethylene}} = 1.71 \quad \text{and} \quad \frac{K \text{ isobutylene}}{K \text{ ethylene}} = 2.8$$

from which it is apparent that the relative rates of combustion with oxygen are

Ethylene	1
Propylene	1.7
Isobutylene	2.8

Similarly, it was found that for oxidation with aqueous permanganate $\frac{K \text{ isobutylene}}{K \text{ ethylene}} = 1.64$; or the relative rates of oxidation with permanganate for ethylene and isobutylene may be represented by 1 and 1.6, respectively.

This greater reactivity of the higher molecular weight olefins with oxygen is somewhat analogous to their reaction with sulphuric acid. As pointed out in Chapter 16, the maximum reactivity with sulphuric acid is shown with olefins containing 6 or 7 carbon atoms.

Howes and Nash[45] studied the oxidation with potassium permanganate of pentene-2, trimethylethylene, cyclohexene, methyldiethylethylene, diisobutylene (2,4,4-trimethylpentene-2) and diamylene (2,3,4,4-tetramethylhexene-2) dissolved in n-hexane. Five per cent solutions of the hydrocarbons were prepared and agitated with 2 per cent alkaline permanganate solution for 6 hours at 0° C. Samples were withdrawn from time to time and the bromine values determined. The results indicated that the pentene, cyclohexene and trimethylethylene were easily oxidized, reaction being complete in 5 hours. Diisobutylene and diamylene, on the other hand, were surprisingly stable. It was further observed that reaction was more rapid when alkaline permanganate was employed than with neutral permanganate.

Unsaturated hydrocarbons could not be removed quantitatively from cracked gasoline with permanganate. Howes and Nash reported that at 0° C. only a small proportion of these hydrocarbons reacted with permanganate (as indicated by the change in bromine number), and at higher temperatures (room temperature) some aromatics were oxidized. The difficulty of removal not only increases with the molecular weight of the olefin but also with its molecular configuration.

AUTOXIDATION OF OLEFINS

One of the characteristic reactions of olefins is that of autoxidation. As has been mentioned, this reaction is especially important in the case of cracked gasolines since it, no doubt, ultimately results in the formation of gum (see Chapter 40).

Hyman and Wagner[46] have shown that hydrogen chloride, stearic acid, and cobalt stearate catalyze the reaction. Acetic acid was almost inert, and triethylamine exerted a negative effect. Their work has shown that for a homologous series the structure of the olefin greatly affects its rate of autoxidation. Generally, olefins with a terminal double bond react less readily than those with an internal double bond. This can be easily seen from the following results obtained with the amylenes. The hydrocarbons were saturated with oxygen, and a catalyst (0.0424 gram of cobalt stearate per 100 cc. of olefin) was added. The samples were kept in ice water and the rate of autoxidation measured after various periods. One cc. of the olefin was added to an alcoholic solution of potassium iodide, and the liberated iodine was titrated with thiosulphate solution.

	Cc. of 0.01*N* $Na_2S_2O_3$ Used After					
	13 Hrs.	19 Hrs.	36 Hrs.	84 Hrs.	156 Hrs.	252 Hrs.
n-Propylethylene	0.00	0.00	0.00	0.00	0.00	—
Isopropylethylene	0.00	0.00	2.90	11.60	23.15	—
unsym.-Methylethylethylene	0.00	0.00	0.00	0.00	0.00	0.00
sym.-Methylethylethylene	1.65	2.85	3.75	7.70	18.00	15.10
Trimethylethylene	1.65	3.00	4.80	8.80	19.75	16.90

Both n-propylethylene and unsym-methylethylethylene which contain terminal double bonds did not undergo autoxidation. On the other hand, sym-methylethylethylene and trimethylethylene, both of which possess an internal double bond, suffered rapid autoxidation. The unusually long induction period for isopropylethylene may possibly have been caused by extensive purification received just prior to use.

These same workers also observed that cobaltic soaps were much more active catalysts than cobaltous soaps. They therefore concluded that, when a cobalt soap acts as a catalyst, the active agent is the oxidized soap.

Bodendorf[47] stated that substances containing two conjugated ethylenic linkages are oxidized by oxygen (in the absence of a catalyst) much more rapidly than compounds containing only one such linkage. The reaction is autocatalytic and results in the formation of multimolecular peroxides which do not show the full normal reactivity of peroxides.

REACTION OF OZONE WITH OLEFINS

It has long been known that olefins react with ozone, though the true character of these reactions was first made clear by Harries.[48] He showed that, in the absence of water, the olefins react with ozone to form thick viscous substances often of an explosive nature. In spite of this characteristic Harries demonstrated that the reaction products contained one ozone molecule for each double bond in the original hydrocarbon.

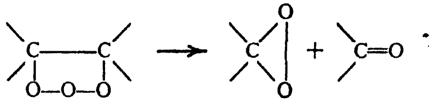
[46] *J.A.C.S.*, 1930, **52**, 4345; *ibid.*, 1931, **53**, 3019.

[47] *Arch. Pharm.*, 1933, **271**, 1; *Brit. Chem. Abs.* **A**, 1933, 279.

[48] For a summary of Harries' work, see *Ann.*, 1905, **343**, 311; 1910, **374**, 288; 1912, **390**, 236; 1915, **410**, 1. See also Brooks, "The Non-Benzenoid Hydrocarbons," Chemical Catalog Co., Inc., New York, 1922, 137.

Ozonides, or their solutions in absolute alcohol or glacial acetic acid or other solvents, can be decomposed by warming, to yield ketones or aldehydes and peroxides, as follows:



The ozonides also react with water to form hydrogen peroxide and aldehydes or ketones, thus effecting a rupture of the original hydrocarbon at the double bond.

$$\underset{\text{O—O—O}}{>\text{C——C}<} + \text{H}_2\text{O} \longrightarrow >\text{C=O} + \text{O=C}< + \text{H}_2\text{O}_2$$

This hydrolysis of the ozonide, therefore, supplies a method for the preparation of aldehydes and ketones from unsaturated compounds. Since hydrolysis results in a rupture of the original hydrocarbon at the double bond, the identification of the products of hydrolysis often affords a clue to the structure of the unsaturated hydrocarbon.

Blair and Wheeler[49] investigated the production of formaldehyde by the action of ozone on ethylene. They effected the reaction (1) by passing a mixture of air and ethylene (about 3 per cent of the latter) through an ozonizer and (2) by the direct action of ozonized oxygen or air on ethylene. Both of these reactions were carried out in the presence and in the absence of both water and ammonia.

In dilute mixtures the ozone and ethylene combined at ordinary temperatures to form the ethylene ozonide, $C_2H_4O_3$. In the absence of moisture the ozonide decomposes to give formic acid, formaldehyde, and other products. On the other hand, in the presence of moisture, hydrolysis takes place with the formation of formaldehyde and hydrogen peroxide. Most of the latter decomposes, though some of it may react with either ozone or formaldehyde. With small concentrations of ozone very little oxidation of formaldehyde was observed. For example, with about 1 cc. of ozone per liter of mixed gases, 90 per cent (of the ozone) reacted to give formaldehyde. The rate of decomposition of the ozonide appeared to be more or less proportional to its concentration. The addition of ammonia to the gases was said to increase somewhat the yield of formaldehyde by reacting with the aldehyde to form hexamethylenetetramine, and thus preventing oxidation of the aldehyde.

By allowing ozonized air or oxygen to react with ethylene in the presence of steam, Carter and Coxe[50] obtained formaldehyde and formic acid in yields of 70 and 15 per cent, respectively. Formaldehyde was recovered as such or was converted to hexamethylenetetramine by the addition of ammonia. This amine can be separated from the reaction products with carbon tetrachloride. Steam is employed to prevent the accumulation of the explosive ethylene ozonide during oxidation.

[49] *J.S.C.I.*, 1923, 42, 343, 347.

[50] U. S. Patent 1,423,753, July 25, 1922; assigned to S. Karpen and Bros.; *Chem. Abs.*, 1922, 16, 3095.

In another process both glycol and formaldehyde [51] are produced when ethylene is allowed to react with ozonized air or oxygen, and steam or atomized water at a temperature slightly above 100° C. The reacting gases are mixed in towers which are packed with porous material impregnated with either water or a solution of a catalyst. When the catalyst is a concentrated alkaline solution, or a 0.1 to 1.0 per cent solution of potassium permanganate or potassium chlorate, a yield of 50 to 60 per cent of glycol and 15 to 30 per cent of formaldehyde is obtained. In the absence of such catalysts, however, the yield of glycol is only 15 to 20 per cent and that of formaldehyde rises to 70 to 80 per cent. The reaction may be carried out under pressure and in the presence of tungstic and osmic oxides as catalysts.

Ethylene and ozone react, according to Briner and Schnorf,[52] to form a liquid ozonide which is stable at 0° C., becomes a vitreous mass at —80° C., and can be isolated by vacuum distillation as a highly explosive liquid boiling at 20° C. (at 16 to 17 mm. pressure). It is soluble in water in all proportions. Such aqueous solutions decompose slowly at ordinary temperatures, but rapidly at 65° C. In the hydrolysis of the ozonide more formic acid is obtained than formaldehyde, and hydrogen is also evolved. The evolution of hydrogen is caused by the presence of formaldehyde peroxide (dioxymethyl peroxide) which results from the interaction of water, ozone and ethylene.

$$CH_2{=}CH_2 + O_3 + H_2O \longrightarrow (OH{-}CH_2{-}O)_2$$

The water is present either because of incomplete drying or from the oxidation of some ethylene. On decomposition of the peroxide both hydrogen and formic acid are obtained, as previously mentioned. This is the explanation advanced for the preponderance of formic acid among the reaction products of ozone and ethylene.

Ozonation of ethylene can also be accomplished in the presence of water and the products obtained are the same as those mentioned above. When the ozonide is decomposed with sodium acid sulphite, the chief product is formaldehyde, which is isolated as its addition compound with the acid sulphite. Addition of an ammoniacal solution of this ozonide to a solution of ammonium chloride yields hexamethylenetetramine together with a small quantity of ammonium formate and oxygen.

The ozonation of propylene takes place in a very similar manner, and the decomposition products are formaldehyde, acetaldehyde, formic and acetic acids. Peroxides, however, are not formed to as large an extent as from ethylene. This was indicated by a smaller hydrogen evolution during the decomposition of the ozonide of propylene.

All of the three butylenes form ozonides.[53] On hydrolysis, these ozonides can be distinguished from one another by the proportions of acids, aldehydes and acetone formed, as well as by the gas evolved. For example, 2-butylene, when dissolved in methyl chloride and treated with ozone at —80° C., yields a liquid ozonide. Decomposition of this ozonide with water at 70° to 75° C. yields, in addition to acetaldehyde, the principal product, some acetic acid, methane, formic acid, and a small quantity of the oxides of carbon. The principal reaction, therefore, seems to be

[51] Plauson's Forschungsinstitut G.m.b.H., German Patent 344,615, 1920; *J.S.C.I.*, 1922, **41**, 392A.

$$\underset{\text{O—O—O}}{CH_3CH{-}{-}CHCH_3} + H_2O \longrightarrow H_2O_2 + 2CH_3CHO$$

which is accompanied by the side reaction:

$$\underset{\text{O—O—O}}{CH_3CH{-}{-}CHCH_3} + H_2O \longrightarrow CH_3COOH + HCOOH + CH_4$$

This formation of methane appears to be characteristic of the acet-grouping, as methane was also found as one of the decomposition products of propylene ozonide.

The ozonide from isobutylene decomposes rapidly in the absence of water to yield acetone peroxide and formaldehyde. When hydrolyzed with water at 70° C. the same products are obtained together with acetone, formic acid, hydrogen and the oxides of carbon.

The ozonide from 1-butylene which contained 20 per cent of 2-butylene, when hydrolyzed yielded products similar to those obtained from 2-butylene except that hydrogen was obtained instead of methane. These results with isobutylene and 1-butylene indicate that the formation of hydrogen during decomposition of the ozonide is characteristic of the formic grouping.

Although the ozonides just mentioned were made in the presence of inert liquids, it was also observed that the butylenes react with ozone in the gas phase to form non-explosive water-soluble products. These represent intermediate steps in the transformation of the ozonides into their stable end products, aldehydes, acetone and acids. Of the aldehydes and ketones formed, formaldehyde appears to be the most resistant to the action of ozone. The yields of products from the butylenes were somewhat lower than those obtained from ethylene. The maximum yield, based on the ozone, was 72 per cent from isobutylene.

The reactions of the higher molecular weight olefins with ozone are very similar to those already mentioned. They have been used in determining the structures of various compounds. For example, McCubbin and Adkins[54] treated diisobutylene in acetic acid with ozonized oxygen, and then hydrolyzed the ozonides with water and zinc dust. The principal products obtained were acetone, trimethylacetaldehyde and methyl neopentyl ketone. Since the first two products were obtained in practically equivalent quantities, and the quantity of the last named substance was about four times that of either of the other two, it was concluded that diisobutylene is a mixture of 2,4,4-trimethylpentene-1 and 2,4,4-trimethylpentene-2, the former being present in the greater quantity. In a similar manner, McCubbin[55] found that triisobutylene is a mixture of three isomeric dodecylenes.

Likewise Whitmore and Church[56] used ozonolysis in the determination of the constitution of diisobutylene. They first fractionated this substance, obtaining two portions (one boiling at 101.2° and another at 104.5° C.) in the ratio of 4 to 1, the lower boiling constituent being present in the greater amount. Ozonolysis of each portion was carried out, the low-boiling constituent giving formaldehyde and methyl neopentyl ketone, as well as a small amount of tertiary butylacetic acid, thus proving it to be 2,4,4-trimethylpentene-1. The high-boiling portion gave acetone, trimethylacetaldehyde and trimethylacetic acid, indicating it to be 2,4,4-trimethylpentene-2. These results agreed with those of McCubbin and Adkins.

Harries and Haeffner[57] obtained amylene ozonide by passing ozone into a dilute solution of the olefin in hexane. Evaporation of the solvent by heating at 60° C. in a vacuum yielded the crude ozonide as a limpid colorless liquid. This crude product was treated with an aqueous solution of sodium bicarbonate. The purified ozonide was analyzed giving values of composition between $C_5H_{10}O_3$ and $C_5H_{10}O_4$.

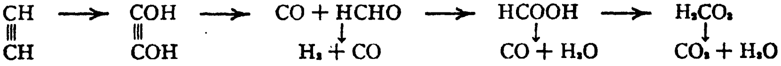
Hexylene ozonide was prepared in the same manner. The crude material was a very viscid liquid, but on distillation gave the normal ozonide as a free-flowing liquid. Distillation was carried out at 60° C. under a pressure of 12 mm. These ozonides were relatively stable, not being readily decomposed by water.

Ozonides of cracked petroleum distillates, derived principally from an olefin mixture of boiling point 125° to 150° C., were suggested by Ramage[58] as substitutes for turpentine and linseed oil.

OXIDATION OF ACETYLENE

Bone and Andrew[59] observed that when oxygen and acetylene are heated in sealed tubes reaction begins at 250° C. and becomes very rapid at 300° C. With a mixture containing equal volumes of oxygen and acetylene or two volumes of acetylene to one of oxygen, explosive combustion[60] occurs at 350° C. With a mixture of two volumes of acetylene to three of oxygen, explosive combustion takes place at 375° C. A relatively large excess of oxygen was found to retard the reaction.

Investigation of the slow combustion of acetylene in a circulatory system indicated that oxidation occurs in a manner similar to that of ethane and ethylene. The main products are formaldehyde, formic acid, water and the oxides of carbon. These products could be accounted for by the hydroxylation theory according to the following transformations:



$$\begin{tikzcd}[column sep=small] \begin{array}{c}CH\\ \vert\vert\vert\\ CH\end{array} \arrow[r] & \begin{array}{c}COH\\ \vert\vert\vert\\ COH\end{array} \arrow[r] & CO + HCHO \arrow[r] \arrow[d] & HCOOH \arrow[r] \arrow[d] & H_2CO_3 \arrow[d] \\ & & H_2 + CO & CO + H_2O & CO_2 + H_2O \end{tikzcd}$$

The reactions, however, are complicated by the fact that, in the presence of a hot catalyzing surface, acetaldehyde is formed from water and acetylene even in the presence of oxygen. This aldehyde then decomposes to methane and carbon monoxide ($CH_3CHO \rightarrow CH_4 + CO$) and competes with the acetylene for the oxygen present, thereby yielding formaldehyde and carbon monoxide:

$$CH_3CHO \longrightarrow CH_2OHCHO \longrightarrow CO + H_2O + HCHO$$

The oxidation of acetylene mixed with oxygen at 250° C. to 315° C. with times of contact of 50 to 200 seconds, has been investigated by Kistiakowsky and Lenher.[61] The condensible reaction products are glyoxal, formaldehyde, formic acid and water. Carbon monoxide and dioxide are the gaseous products. These investigators disagreed with Bone and Andrew, and considered the aldehyde glyoxal (OHC—CHO) the first intermediate oxidation product of acetylene and not the unsaturated alcohol $HOC\equiv COH$. Furthermore they also concluded that glyoxal decomposes to yield carbon monoxide and formaldehyde, ($CHOCHO \rightarrow CO + HCHO$), the formaldehyde being oxidized to formic acid, and this acid in turn being oxidized to carbon dioxide and water. The reaction rates indicate a chain reaction which is homogeneous. In packed reaction vessels, however, the homogeneous oxidation is almost suppressed and a heterogeneous oxidation to carbon monoxide and water takes place on the glass surfaces. The rate of this reaction is roughly proportional to the acetylene and oxygen concentrations. In unpacked reaction vessels the rate is proportional to the square of the acetylene concentration and is slightly retarded by the oxygen concentration. Reaction between acetylene and oxygen was always preceded by an induction period.

[59] *J.C.S.*, 1905, 87, 1232.

[60] Mondain-Monval and Wellard (*Compt. rend.*, 1933, 196, 1226; *Brit. Chem. Abs.* A, 1933, 694) compare explosive combustion when heating at different rates and constant volume. Various mixtures of acetylene and oxygen (17 to 85 per cent acetylene) will explode at a mean temperature of 310° C., on heating at the rate of 40° C. per minute. At 25° C. per minute the explosive mixture varies from 35 to 70 per cent acetylene content.

[61] *J.A.C.S.*, 1930, 52, 3785.

Oxidation of acetylene in a circulatory system at slightly higher temperature (320° C.) was studied by Spence and Kistiakowsky.[62] The oxidation products were found to be the same as those reported by Kistiakowsky and Lenher. At this temperature the rate of reaction is slightly accelerated or retarded according to whether acetylene or oxygen is in excess. At optimum concentrations the rate of reaction is proportional to the square of the acetylene concentration. With less oxygen present the rate is proportional to a lower power of the acetylene concentration. The presence of nitrogen has very little retarding influence on the reaction rate. An induction period was also observed at this temperature (320° C.) and was considered to be caused by the accumulation of an intermediate product taking part in the chain reaction. It was observed that formaldehyde is oxidized very much faster when mixed with reacting acetylene.

The size of the reaction vessel has an effect on the reaction rate.[63] In vessels smaller than 4 mm. in diameter the reaction took place very slowly, but in vessels greater than 6 mm. in diameter, it proceeded at its normal rapid rate. By coating the surface of a vessel greater than 6 mm. diameter with potassium chloride it was noted that the reaction proceeded at a much slower rate than in a plain glass vessel, indicating that potassium chloride inhibited the reaction.

The catalytic oxidation of acetylene to formaldehyde has been described by Mittasch, Willfroth and Balz.[64] In this process, similar to that used by them for the production of formaldehyde from ethylene, the acetylene and air react at 375° C. in the presence of a catalyst prepared by heating burnt clay or diatomaceous earth impregnated with boric or phosphoric acid.

When acetylene is oxidized in the presence of steam, acetaldehyde and acetic acid are produced. Thus in the process developed by Wohl[65] a gaseous mixture of acetylene, air and steam is passed over a catalyst at 300° to 400° C. and the resulting acetaldehyde and acetic acid are fractionally condensed, or the mixture is completely oxidized to acetic acid. The catalysts used are basic metallic salts (zinc vanadate, molybdate, or chromate dispersed on pumice).

Stuer and Grob[66] described a process in which acetaldehyde is produced from a mixture of acetylene and steam in the presence of metallic oxides at 300° to 500° C. Either atmospheric or increased pressures can be used. Thus, at 400° to 420° C. acetaldehyde is the main product from 1 part of acetylene and 4 parts of steam using bog iron ore as the catalyst. A 50 per cent yield of acetonitrile, together with nitrogenous bases, is obtained by passing equal proportions of acetylene and ammonia over bauxite at 350° to 380° C. Two parts of acetylene and 1 part of hydrogen sulphide passed over specially treated bauxite at 320° C. give almost pure thiophene. Horst and Wietzel[67] use a catalyst such as silicotungstic acid which is free of iron or its compounds.

The production of either acetaldehyde or ethyl alcohol from acetylene should be briefly mentioned again[68] for comparison, although neither is strictly an oxidation of acetylene. The acetylene is first passed into a solution of dilute sulphuric acid which contains a mercury compound as a catalyst. The acetylene combines with water to form acetaldehyde,[69] which can be either oxidized to acetic acid or reduced to ethyl alcohol.[70]

Eberhardt[71] passed a mixture of acetylene, steam and oxygen charged with mercury vapor over compounds of mercury or other heavy metal salts or mixtures of these. For instance, the gases are led over a mixture of active carbon and mercury phosphate. A 60 per cent yield of acetic acid and a 14 per cent yield of acetaldehyde are obtained. A change in the catalyst, such as the use of carbon and aluminum oxide, will alter the proportions of the products formed.

REACTION OF OZONE WITH ACETYLENE

Acetylene and ozone react to form an ozonide which, however, because of its explosive properties, has not been isolated and investigated.[72] An attempt was made to prepare this ozonide by the reaction of acetylene and ozone in the presence of an inert solvent. When the solvent was slowly evaporated the product was a yellow viscous transparent liquid which consisted of about 81 per cent glyoxal and 5.6 per cent formic acid. As carbon dioxide was evolved during this operation there is no doubt but that some acetylene was lost through decomposition of the ozonide. Although the evidence seems to indicate that the ozonide exists temporarily it is an extremely unstable substance. One interesting point, however, is brought out in comparing the reactions of ozone with acetylene and with olefins. In acetylene, the triple bond appears to maintain the linkage of carbon atoms, but with olefins ozonization breaks the double linkage.

OXIDATION OF UNSATURATED HYDROCARBONS IN THE PRESENCE OF NITROGEN OXIDES

Lenher[73] has shown that the reaction between acetylene and oxygen between the temperatures of 170° and 250° C. is catalyzed by the presence of nitrogen peroxide. The acetylene is oxidized, and nitrogen peroxide forms nitric oxide which is oxidized by the oxygen again to nitrogen peroxide. The main reaction product found by Lenher was trimeric glyoxal, yields of 50 per cent or more being obtained. The occurrence of large quantities of carbon monoxide and of only traces of formaldehyde, formic acid and hydrogen seem to indicate that the thermal decomposition of glyoxal to carbon monoxide and formaldehyde is the principal source of this oxide of carbon. The formaldehyde is then either oxidized to formic acid, which in turn decomposes to carbon monoxide and water, or it is oxidized by the nitrogen peroxide to carbon monoxide and water. The course of the oxidation reactions can be indicated as follows:

Chapter 40

Autoxidation of Petroleum Distillates. Gum Formation

By autoxidation or spontaneous oxidation is meant, according to Moureu, Dufraisse and Chaux,[1] the combination of the whole molecule of oxygen with an oxidizable substance to form a primary peroxide which may then change in a number of ways to yield stable oxidation products. The theory proposed by these investigators assumes that autoxidation starts with the union of an oxygen molecule, O_2, with a molecule of an autoxidizable substance, A, to yield the peroxide, $[AO_2]$. Such peroxides are formed with the absorption of energy and may then decompose to yield various products or react with other molecules of the autoxidizable substance. It is suggested also that antioxygens or antioxidants catalyze the reverse action, the destruction of these peroxides. Antidetonants or knock suppressors likewise inhibit the formation of peroxides whose explosive properties allow them to act as detonating agents (see also Chapter 44).

Substances which undergo autoxidation include phosphorus and sulphur compounds, sodium sulphite, benzaldehyde, paraffin, petroleum distillates, rubber, turpentine, spermaceti, silk, living tissues, and many other substances.

The oxidation of turpentine or pinene by air is similar to the behavior of olefins and of petroleum distillates containing unsaturated compounds. A brief survey, therefore, of the oxidation of this substance, together with that of some of the cycloparaffins, is of interest. The slow oxidation of pinene results in the formation of peroxides, carbon dioxide, water, organic acids, alcohols, aldehydes, ketones and resinous bodies.[2]

Oxygen is readily absorbed by turpentine oil (which contains pinenes) to yield molecular oxygen compounds (peroxides). On mixing this oxidized oil with indigo the latter rapidly becomes decolorized as a result of oxidation. In fact it seems that one of the characteristic properties of such peroxides is the ease with which half of their oxygen is taken up by substances which are otherwise oxidized with difficulty. Other compounds which exhibit this same behavior towards oxygen are amylene, hexylene, trimethylethylene, some of the fulvenes, ketenes, and unsaturated naphthenes.[3]

In studying the autoxidation of pinene by oxygen Dupont and Crouzet[4] employed two methods: (1) measuring the decrease in the oxygen pressure in the reaction flask by the rise of mercury in a narrow manometer connected to the apparatus (the constant volume method); and (2) measuring the decrease in oxygen volume as indicated by the rise of the meniscus in a eudiometer (the constant pressure method). In diffused light the rate of absorption of oxygen is proportional to the time. The rate of absorption, however, is greatly affected by the intensity of the light and the temperature. For example, when the reaction flask was covered with black paper no oxidation took place for 1200 hours. At the end of that time the rate of oxidation increased very rapidly until it reached the corresponding rate of oxidation in the presence of diffused light. At 80° C. the rate was 2500 times as great, and at 60° C. it was 130 times as great as it was at 15° C. Carbon dioxide was formed at the higher temperatures.

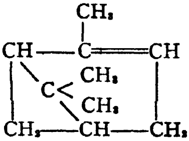
The rate of oxidation also increases in the presence of certain metallic catalysts, such as the resinates of cobalt, iron, lead, chromium and nickel. The first of these was found to be the most active, but after a time its effectiveness diminishes as a result of decomposition.[5] The rate of oxidation is reduced by the presence of hydroquinone, gallic and pyrogallic acids, stannous chloride, reduced copper, copper resinate, sulphur, and other substances.[6]

Some substances act first as antioxidants and then as pro-oxidants. Manganese resinate, for example, when added in the proportion of 1 part to 1000 parts of pinene was found to reduce the rate of oxidation for 100 hours, after which the rate is accelerated several hundred times. When added in the proportion of 1 part to 100 parts of pinene, oxidation did not start for 700 hours.

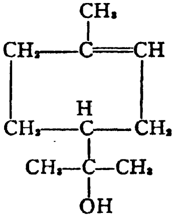
The autoxidation of pinene can be shown also by the spontaneous ignition of cotton on exposure to air after being treated with turpentine to which has been added a heavy metal resinate.[7] When asbestos fiber is substituted for cotton the temperature of the oil rose to 300° C. The spontaneous ignition of cotton can be retarded by phenol, β-naphthol or quinol, and prevented by α-naphthol, aniline, diphenylamine, quinhydrone, and other similar substances, and also by sulphur.

When dissolved in acetic acid and oxidized with aqueous hydrogen peroxide at 50° to 60° C., α-pinene yields principally α-terpineol (partly in the free state and partly as the acetate), small proportions of borneol (as the acetate) and dipentene, a trace of aldehyde of the formula $C_{10}H_{16}O$, a small quantity of trioxyterpan, $C_{10}H_{17}(OH)_3$, and some resinous material.[8] β-Pinene, on the other hand, when oxidized with hydrogen peroxide under the same conditions yields an oily product in which were identified principally borneol and fenchyl alcohol (as acetates).[9]

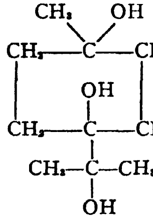
The relation of these substances can be shown by the following formulas:



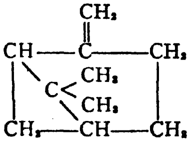
α-pinene



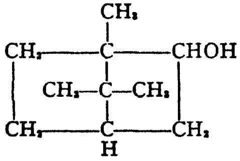
α-terpineol



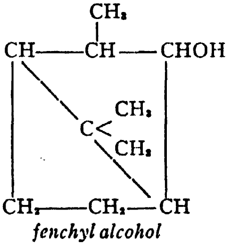
trioxyterpan



β-pinene



borneol



fenchyl alcohol

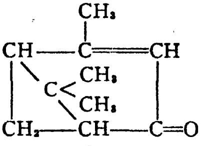
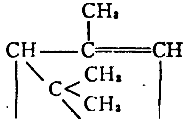
When oxidized in acetic anhydride with chromium trioxide, the CH_2 group adjacent to the double bond is converted to a ketone or an alcohol grouping. Thus α-pinene yields verbenol and verbenone.[10] Acetic anhydride is used as a solvent in order to absorb any water formed during the oxidation, and also to acetylate alcohols as formed and thus prevent their further oxidation.



verbenone



verbenol.

On passing a mixture of turpentine vapor and air through a copper net heated to 400° C., the hydrocarbon is oxidized and the heat of the reaction is sufficient to keep the copper glowing. The products of the reaction are carbon monoxide, carbon dioxide, some ethylene hydrocarbons, about 21 per cent of water-soluble substances, and 60 to 70 per cent of oil. About 75 per cent of the oil distills between 160° and 173° C. and this particular fraction contains a large percentage of cymene.[11] It therefore has a pleasant odor and is suitable for use in perfumery. The presence of steam in the gaseous mixture during oxidation reduces the yield of oil.

Peroxides are formed in some instances when ozone is used. Ramage[12] suggested the production of the terpene peroxide, $C_{10}H_{18}O_2$, by blowing ozonized air through eucalyptus oil at 80° C. After removing the peroxide by a current of air it could be further oxidized to the diperoxide, $C_{10}H_{18}O_4$, with an excess of ozonized air. This diperoxide is a colorless oil which, when placed in contact with water, slowly liberates active oxygen for a long period of time.

Another class of compounds which are easily oxidized and polymerized are cyclopentadiene and its derivatives, the fulvenes. Cyclopentadiene, , can be isolated from the first fractions in the distillation of crude benzene. It polymerizes on standing to the dimer, $C_{10}H_{12}$, which is partially reconverted to the original hydrocarbon on distillation. The dimer takes up oxygen from the air forming the diperoxide.[13]

The fulvenes, which were first prepared by Thiele,[14] are made by condensing ketones (acetone, acetophenone, or benzophenone) with cyclopentadiene. Dimethylfulvene, for example, has the formula  and when dissolved in benzene quickly absorbs oxygen from the air to form a voluminous white precipitate which gradually becomes granular.[15] Light and heat shorten the time required for this reaction. The precipitate is a diperoxide of dimethylfulvene ($C_8H_{10}O_4$), which decomposes with violence when heated to 130° C. It is insoluble in the usual organic solvents, but dissolves, with some decomposition, in hot nitrobenzene and in acetic acid. On standing, it gradually becomes yellow and loses its explosive properties. This peroxide however is a very mild oxidizing agent. Methylphenylfulvene takes up oxygen much more slowly, forming the diperoxide of the formula $C_{18}H_{12}O_4$. Contrasted with these, cyclopentadiene absorbs only a small quantity of oxygen and forms a resinous product.

In diffused sunlight 1,3-dimethylcyclopentane absorbs oxygen even at pressures as low as 60 mm. The product formed is a peroxide which, after reacting with potassium iodide, yields a mixture of 5-methyl-2-hexanone and 4-methyl-2-hexanone. These ketones must have been formed from the peroxide, the initial product of oxidation, by a rupture of the cyclic nucleus.[16]

Cyclopentane is found in certain fractions of some crude oils, and from such oils cyclopentanone (adipic ketone) can be obtained by oxidation. This ketone, according to Mentzel,[17] is very easily condensed with aromatic aldehydes in the presence of alkalies.

Cyclohexene, when kept in contact with oxygen for a long period, yields a small quantity of cyclohexene peroxide.[18] This substance, which is a mobile liquid boiling at 54° to 56° C. at 0.5 mm., possesses a pungent odor and is an energetic oxidizing agent. Molecular weight determinations indicate that the peroxide is monomolecular, but the sirupy residue from the distillation of the peroxide, which has the same composition as the peroxide, is bimolecular. These facts appear to indicate that two molecules of the peroxide combine to form a new substance with peroxide properties. Determination of the active oxygen content of the dimeric form indicates that it contains only one peroxide group.

Zelinsky and Borisov[19] observed that 20 grams of cyclohexene can absorb 3200 cc. of oxygen in 151 days. The rate of absorption is rapid at first, then decreases, and finally ceases altogether. The oxygen absorbed corresponds to about 1 atom of oxygen per molecule of cyclohexene. The unchanged cyclohexene was removed by allowing the mixture to stand for three months in a vacuum desiccator over sulphuric acid. After evaporation, a tough, resinous, reddish yellow mass was obtained which gave the characteristic peroxide tests. Analysis indicated the substance to be cyclohexene peroxide of the formula $C_6H_{10}O_2$.

Cyclohexene, however, is oxidized much more rapidly in the presence of certain metallic catalysts. Willstätter and Sonnenfeld[20] prepared a catalyst for such a reaction by heating osmium ammonium chloride in the presence of hydrogen. When 0.5 gram of the osmium so prepared was added to a solution of 10 grams of cyclohexene dissolved in 10 grams of acetone the mixture absorbed 0.86 moles of oxygen in 22 hours. The products consisted chiefly of 2-cyclohexene-1-ol and 1-cyclopentene-1-aldehyde (1-methylal-1-cyclopentene) and adipic acid together with small proportions of unchanged cyclohexene and 2-hydroxycyclohexanone. No oxidation occurred when the cyclohexene was dissolved in acetic acid. Platinum, palladium, and ruthenium could not be substituted for osmium, and tellurium showed very little catalytic activity. No indication of the intermediate oxidation products (peroxides) was found, which showed that osmium accelerated their decomposition. Oxidation generally proceeds in more than one direction with the formation of secondary and transformation products. Substances which possess acidic properties appear to retard oxidation.

Later, Medvedev and Alekseeva[21] oxidized cyclohexene in the presence of a less active catalyst, osmium dioxide deposited on asbestos. The activity of this catalyst was greatly reduced when metallic oxides such as aluminum oxide, ferric oxide, manganese sesquioxide, or cupric oxide were substituted for the asbestos. These investigators also observed that the oxidation products formed depend upon the nature of the solvent and that, contrary to Willstätter and Sonnenfeld, oxidation with this mild catalyst proceeds energetically in benzene. The products obtained from the oxidation of cyclohexene were 2-cyclohexene-1-ol, adipic acid, an unidentified aldehyde, and some peroxides.

The oxidation of cyclohexene may also be accomplished with lead tetrasalts[22] (lead tetra-acetate, tetrabenzoate, and others). For example, cyclohexene is oxidized with lead tetra-acetate at 80° C. to yield 2-cyclohexene-1-ol acetate. Cyclopentadiene, however, oxidized at 40° to 45° C., yields two products: 3-cyclohexene-1,2-diol diacetate and the monoacetate monoacetylglycolate of this diol. These results, together with those obtained with many other unsaturated compounds, indicate that the lead salts react in two ways: (1) by the addition of two acid groups to the double bond, and (2) by the replacement of hydrogen by a hydroxyl group while the double bond remains unattacked. In no instance did substitution alone take place.

Staudinger and Lautenschläger[22a] measured the velocity of autoxidation of trimethylethylene, styrene, isoprene, dimethylbutadiene, cyclopentadiene, tetrahydrobenzene, myrcene, limonene, terpinene, pinene, and menthene in sealed vessels at 80° C. and determined the oxygen absorbed. The rate of polymerization was approximated by heating 10 grams of the substance in a distillation flask in the presence of carbon dioxide or oxygen for various periods and removing all the matter volatile below 80° C. under reduced pressure. In all cases polymerization occurred more rapidly in oxygen than in carbon dioxide but the differences were small for the terpenes. From this it is concluded that autoxidation accelerates polymerization. The behavior of 1,5-hexadiene, 2,4-hexadiene, 2-methyl-2,4-pentadiene and 2,3-dimethyl-1,3-butadiene on autoxidation was studied by Kogerman.[22b] Practically no oxygen was absorbed during 3 months at 19° to 27° C. Two moles of oxygen per pair of double bonds were absorbed by 2,4-hexadiene and 2-methyl-2,4-pentadiene, but 2,3-dimethyl-1,3-butadiene absorbed only 1 atom of oxygen per molecule. The resulting compounds were similar to gums in cracked gasoline. Kogerman believed that a 1,4 addition of oxygen occurs in hydrocarbons with conjugated double bonds.[22c]

GUM IN GASOLINE

Among the early investigators who observed the autoxidation of light petroleum distillates was Fudakowski.[23] After shaking "commercial benzine" with a large volume of air in sunlight he found that the liquid became "activated," and that water extracted a neutral substance, apparently hydrogen peroxide. Longer exposure to air and light, followed by extraction with water, indicated that formic acid had been produced by the action of air on the distillate. The air above the distillate gave tests for what Fudakowski designated as "ozone." Similar results were obtained by Schaer[24] with American oils.

Robinson [24a] noticed that water shaken up with light distillate of petroleum gave various aldehyde reactions, indicating the presence of acetaldehyde (estimated at 0.001 per cent). The formation of acetaldehyde was accounted for by the decomposition of some oxygen-containing compounds in the crude oil. However, Kramer [24b] searched for acetaldehyde and ketones in oils but did not detect their presence.

Schönbein [25] observed that a small proportion of resins was also formed under these conditions in addition to formic acid and its homologues. A part of the dissolved oxygen is in a very active state. He also noted the formation of "ozone" in the air above the distillates.

From our present knowledge of the autoxidation of unsaturated hydrocarbons it is very probable that the "ozone" thus reported was the vapor of the peroxides formed by oxidation. The formation of resins or gums by the oxidation of distillates on exposure to air, as well as its prevention, has become of paramount interest, particularly since the introduction of cracked gasoline as an antiknock fuel. Hunn, Fischer and Blackwood [26] discussed methods for the determination of gum in gasoline and the behavior of gasolines of different gum contents during engine tests.

Cracked gasoline as it comes from the stills usually contains very little, if any, gum but it does contain certain hydrocarbons (unsaturated compounds) which form gum on storage. Gum formation is essentially an oxidation process, and the gum itself contains a high percentage of oxygen. Gasolines stored in the absence of air show no increase in gum content.

The gum formed by oxidation during storage is of particular interest as it remains dissolved in the gasoline except in extreme instances when part of it precipitates. This gum is sprayed from the carburetor with the gasoline and is deposited on the heated portions of the intake manifold and on the intake valves, causing imperfect operation of the engine through the delayed seating of these valves. Only a portion of the dissolved gum, however, is deposited, the remainder being carried into the combustion chamber to be burned with the charge.

The determination of dissolved gum,[27] and of the stability of the gasoline is of importance. The product marketed must be sufficiently stable toward oxidation to keep the dissolved gum content below the permissible maximum until the time of consumption.

The usual copper-dish method for the determination of the gum content, which consists in evaporating 100 cc. of the gasoline in a copper dish on a steam bath, has been found to yield erratic and unreliable results. As pointed out by Voorhees and Eisinger,[28] the results obtained by this test vary, being dependent upon the rate of evaporation and accompanying oxidation and upon the catalytic action of the copper during evaporation. Voorhees and Eisinger agree with Hunn, Fischer and Blackwood that a gasoline which shows a high gum content by this test may perform satisfactorily in an engine.

Hunn, Fischer and Blackwood suggested that the dissolved gum content be determined by directing a jet of air towards the center of a 100 cc. sample of gasoline which is being evaporated in a glazed porcelain dish on a steam bath. As much air as possible should be used in order to cause complete evaporation in 12 to 15 minutes. The residue is then dried at 100° to 105° C. until constant weight is obtained.[29] Nitrogen or carbon dioxide may be substituted for air. The results with either of these gases agree with those obtained with air, indicating that no appreciable oxidation takes place during the short time required for evaporation. Mulligan, Lovell and Boyd [29a] modified this method of determination of gum content by substituting a heated jet of air for the unheated air.

FIG. 32.—Typical Oxidation Stability Curves of Gasolines.

(These show the definite instability of the Vapor-Phase Gasoline, the slightly greater stability of Cracked Gasoline No. 1, and the marked stability of Cracked Gasoline No. 2, which can be stored for prolonged periods.) (Hunn, Fischer and Blackwood.)

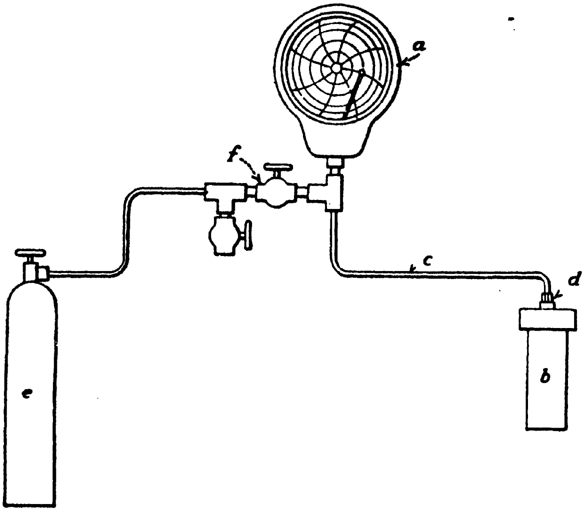
The following method of determining the stability of a gasoline was suggested by Hunn, Fischer and Blackwood: A 100 cc. sample of the motor fuel in an 8-ounce bottle is placed in a bomb and oxygen is admitted until a gage pressure of 100 pounds per square inch is obtained (Fig. 33). The bomb is placed in a steam bath, and the pressure rises quickly to a maximum and remains constant, as shown by a recording gage, until oxidation starts. From then on the drop in pressure is very rapid (Fig. 32). A gasoline which will stand up for 1½ to 2 hours before "breakdown" occurs may be considered sufficiently stable for usual storage conditions.[30] Winning and Thomas [30a] suggested using the copper dish method in conjunction with the bomb test to predict the stability of gasolines.

---

[29] The U. S. Bureau of Mines Steam Oven Test (Cooke, *U. S. Bur. Mines Rep.* 2686, 1925) gives essentially the same results.

[29a] *Ind. Eng. Chem.*, 1932, 4, 351; *cf.* methods of Norris and Thole (*J. Inst. Pet. Tech.*, 1929, 15, 681) and Mardles and Moss (*J. Inst. Pet. Tech.*, 1929, 15, 657).

Results obtained by actual engine tests [30b] indicate that a dissolved gum content of 15 mg. per 100 cc. is permissible. The usual copper-dish gum determinations give no indication of the quantity of gum deposit that might be formed in the engine. On the basis of engine tests, Voorhees and Eisinger [31] suggested 10 mg. of gum per 100 cc. of gasoline, as determined by the steam oven test, as a permissible quantity. They also indicated that the potential gum found in the oxygen test should not exceed 10 mg. per 25 cc. of gasoline.



Courtesy of S.A.E. Journal.

FIG. 33.—Apparatus for Measuring Stability of Cracked Gasoline toward Oxygen. (In making the accelerated oxidation test for gum formation, an open 8-oz. bottle containing the sample is placed in the Bomb *b*, the cover of which is screwed on tightly, and oxygen is admitted under pressure from the Cylinder *e*, until the pressure on the Recording Gage *a* registers 100 lbs., when the bomb is heated to 212° F. by a steam bath. The pressure then rises to a maximum that remains practically constant until oxidation starts and the gasoline breaks down. This point being indicated by a sharp break in the pressure curve drawn by the gage.) (Hunn, Fischer and Blackwood.)

Rogers, Bussies and Ward [31a] correlated results obtained by the Voorhees and Eisinger method with gum storage tests in glass bottles at 35° C.

The formation of gum during storage can be prevented, at least for long periods of time, by the addition of a small proportion of certain oxidation inhibitors to the gasoline.[32] The antioxidant efficiency of a number of these compounds (examined by the Voorhees method) shows that the induction period is directly proportional to the concentration of antioxidant.[33] The readily oxidizable monosubstituted p-aminophenols are particularly effective for this purpose. Egloff, Morrell, Lowry and Dryer[34] found that substances which contained phenolic or aromatic amine groupings had pronounced inhibiting power. Most of the effective compounds contained one of the following groupings: more than one hydroxyl or amine group, an aromatic hydroxyl and amine group, a single aromatic hydroxyl or amine group with one or more alkyl or other modifying groups, or an aromatic secondary amine grouping. Modifying groups in amines and phenols were most effective in the ortho or para position, but they exerted some beneficial influence when placed meta to the inhibiting group. The introduction of a nitro group into the phenols studied was generally disadvantageous. Hydrocarbons showed no positive inhibiting action nor did aromatic compounds which contained a halogen or other substituent group. Ethers exhibited no inhibiting properties but the presence of an amino group and an ether group in the same molecule had a slight beneficial influence. Ketones and quinones had variable effects as did acids and acid derivatives. Of the sulphur compounds, thiodiphenylamine showed marked inhibiting power.

---

[30] The test suggested by Voorhees and Eisinger (*loc. cit.*) is to shake gasoline in long-necked Pyrex flasks filled with oxygen and placed in boiling water, and to note the decrease in pressure by a manometer. Oxidation appeared to be auto-catalytic as, in all cases, an induction period was noted. The duration of this induction period indicates the resistance of the gasoline to oxidation. The oxygen bomb test has also been described by Zublin, *Oil and Gas J.*, 1931, **30** (9), 26; *Chem. Abs.*, 1931, **25**, 5976.

[30a] *Ind. Eng. Chem.*, 1933, **25**, 511.

[30b] Marley and Gruse (*Ind. Eng. Chem.*, 1932, **24**, 1298) also studied gum deposition in engines.

[31] *Loc. cit.*

[31a] *Ind. Eng. Chem.*, 1933, **25**, 397.

Various substances have been suggested for the stabilization of gasoline by many investigators. Fischer and Gustafson[35] proposed α-naphthol, α-naphthylamine, and hydrocarbons such as naphthalene or anthracene with a hydroxyl or amino group in the α position. sec.-Amyl-p-aminophenol, hexyl-p-phenylenediamine, methylaniline, toluidine, aminophenol, resorcinol, tricresol, anthraquinone, and a dye (blue indophenol formed by the condensation of α- or β-naphthol with p-nitroso-dimethylaniline or the red indophenol obtained by condensing diphenylamine with p-nitrosophenol) have been suggested by Winning, Sargent and Dudley.[36] Oxazine, indamine, eurhodine, safranine, aposafranine and aminoazobases containing no sulphonic acid or thiobenzyl groups were recommended by Gutzeit.[37] Lewis and Mead[37a] proposed phloroglucinol, phenol, resorcinol, hydroquinone, thymol or pyrogallol. The Pure Oil Company[37b] suggested catechol, aniline, camphor, pyridine, tannic acid, nitrobenzene, amyl acetate and β-naphthol. Calcott and his co-workers proposed acyl derivatives of arylamines (acetanilide),[37c] methylaniline, ethylaniline, diphenylamine, 4-anilinobiphenyl, 2-methyldiphenylamine, ditolylamines and dixylylamines.[37d] Hyman and Ayers[37e] employed ammonia or its organic substitution products and catechol. The Gulf

Refining Company[87f] suggested stabilizing gasoline with a substance which increases the period of induction of gum, such compounds being α-naphthol, pyrogallol, triphenyl phosphate, benzidine, ortho-, meta- and para-toluidine, together with a substance which reduces the rapidity of formation after the period of reduction, for example, α- and β-naphthylamines, diphenylamine, dimethylaniline, amyl alcohol, triphenylcarbinol and xylidine.

Rather, Beard and Reiff recommended an alkaloid[87g] such as brucine in a butyl alcohol solution and nicotine or thiocarbanilide.[87h] Jaeger employed various imidines[87i] and phthalide compounds and aniline.[87j] Phosphatides of animal or vegetable origin were recommended by the Hanseatische Mühlenwerke A.-G.[87k] A semicarbazide or a derivative of semicarbazide such as 4,4-diphenylsemicarbazide, or a hydrazine containing an aromatic radical, for example, unsym.-diphenylhydrazine, was suggested by Burk,[87l] and a small amount of crude petroleum spirit distilling above 140° C., by Vellinger and Radulesco.[37m] Selenomercaptans such as phenyl selenomercaptan also stabilize gasoline, according to Rosenstein and Hund.[87n] Ward, Jordan and Fulweiler[87o] found that mercaptans catalyze and phenols retard gum formation and that stannic chloride and antimony chloride remove gum-forming constituents. Lowry and Dryer,[87p] to stabilize gasoline, add a small quantity of the tar fraction obtained from the destructive distillation of wood.

Egloff, Morrell, Lowry and Dryer[87q] established a correlation between the effectiveness of gasoline inhibitors and their critical oxidation potentials. The results indicated that the best inhibitors had potentials between 0.6 and 0.8 volts but fair inhibitors occur in the range of 0.8 to 1.043 volts. Compounds having potentials above 1.043 volts were observed to have no inhibiting action under the conditions of the test.

Schuemann[87r] proposed a "gum-inhibiting index" defined as:

$$\text{Gum-inhibiting index} = \frac{(\text{Average percentage of potential gum reduction})}{(\text{Average concentration of inhibitor in mg. per 100 cc.})}$$

to show the efficiency of an inhibitor.

Ramsay[88] extended the study of the accelerated gum test by varying the time, oxygen pressure, and temperature of heating. Comparison of the weight of gum formed with the induction period indicated that the steam-oven test gives a reliable index of the stability of the gasoline in storage. Ramsay also observed that the induction period with 100 pounds per square inch oxygen pressure could be multiplied by 1.41 to give the induction period for air at 1 atmosphere pressure. When the induction periods were plotted against the absolute temperatures, on semi-logarithmic coordinate paper, a linear relation was established and the curve could be extrapolated to give the induction period at ordinary temperatures. The general equation for such curves is:

$$\log I = a - bT$$

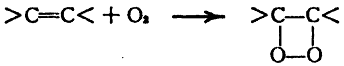
in which I is the induction period, T is the Centigrade temperature, and a and b are specific constants for each gasoline. The ratio of a to b, however, did not give the exact slope of the straight line, and the induction periods at two different temperatures, at least, should be determined in order to obtain, by extrapolation, the induction period at ordinary storage temperatures.

Although the actual mechanism of gum formation has not yet been determined, nevertheless all investigators agree that gum is an oxidation product and that peroxides are formed as intermediates.[38a]

Several methods have been devised for the estimation of the peroxides formed by the oxidation of unsaturated hydrocarbons but none of them appears to be entirely satisfactory. All are based upon the oxidizing property of the peroxides.

Stephens[39] attempted to determine the peroxide oxygen in cyclohexene peroxide with stannous chloride. The method, however, gave low results. The total oxygen by difference, after determining the carbon and hydrogen contents by combustion methods, nevertheless, checked with the theoretical values. Marks and Morrell,[40] who worked with linseed oil and similar products, suggested that the sample be dissolved in glacial acetic acid, and a concentrated solution of potassium iodide be added, after which the liberated iodine can be titrated with thiosulphate. A possible source of error in the general use of this method is that in some instances the iodine may react with a portion of the unsaturated hydrocarbons present. Yule and Wilson[41] allowed the peroxides to react with ferrous sulphate, in a water-acetone solution, and determined the ferric sulphate formed by titration with titanous chloride. From the quantity of ferric sulphate formed the "peroxide number" was calculated. This peroxide number is defined as the number of gram equivalents of active oxygen per 1000 liters of gasoline. The last method, though rapid and sufficiently accurate for studying gum formation in gasoline, is open to two objections. (1) It cannot be used when the peroxide number exceeds 10. If this is the case, the sample must be diluted with a peroxide-free gasoline before test. (2) A correction factor has to be applied. The corrections are calculated by making the arbitrary assumption that the method gives a correct result for samples with a peroxide number of 3. The observed values are always lower than the corrected ones. The corrections with peroxide numbers of about 3 to 5 are small but become quite appreciable with numbers of 8 to 10. Variations in the concentration of the reagents are said to alter the results.

Peroxides are, as stated previously, the first products of the oxidation of unsaturated compounds by air, oxygen of the air uniting with the molecule at the double bond:



$$>C{=}C< + O_2 \longrightarrow \begin{array}{c}>C-C<\\ |\quad\;|\\ O-O\end{array}$$

The rate of formation of these peroxides is greatly affected by the presence of small quantities of positive or negative catalysts, and by the temperature at which oxidation takes place. The temperature coefficient, however, is rather difficult to determine because of the lack of accurate data for the solubility of oxygen in gasoline at various temperatures.

[38a] Naphtali (*Chem.-Ztg.*, 1930, 54, 371; *Chem. Abs.*, 1930, 24, 3892) summarized the work of various investigators in this field and showed that it substantiates the theory that gum-formation is associated with oxidation.

[39] *Loc. cit.*

[40] *Analyst*, 1929, 54, 503; *Chem. Abs.*, 1929, 23, 5439.

[41] *Ind. Eng. Chem.*, 1931, 23, 1254. This article gives an excellent review of the properties and the methods of determination of peroxides.

The induction period observed in the oxidation of gasoline may be due to either of two causes: (1) the slow initial formation of peroxides which, after a certain concentration is reached, actually catalyze the oxidation and (2) the naturally occurring inhibitors which delay the reaction until they have been oxidized.

Peroxides react with reducing agents (hydrogen, hydrogen sulphide, or mercaptans) to form either glycols or substituted ethylene oxides. With lead mercaptides they yield substituted ethylene oxides, lead oxide, and disulphides. Sulphur dioxide reacts in a similar manner with the peroxides, being converted to sulphur trioxide. Solutions of sodium hydroxide convert peroxides into alcohols and sodium salts of acids. Concentrated sulphuric acid readily decomposes peroxides and assumes a deep red color.

Although the peroxides are stable at room temperature and can be kept for long periods, nevertheless decomposition or reaction with unsaturated hydrocarbons present occurs. These decomposition or reaction products are probably the source of gum for, in many instances, the quantity of gum obtained on evaporation of the sample, is proportional to the peroxide number.

The presence of peroxides is, no doubt, the explanation of the decomposition observed by Ellis and Wells[42] during the distillation of a cracked gasoline which had stood for some time and also for the explosion which occurred when the residue from distillation *in vacuo* was heated with a little sulphur.

Yule and Wilson[43] suggested that the gum in gasoline, particularly during storage, is present entirely in the peroxide form. Actual gum is not obtained until the gasoline is evaporated and the residue heated. All peroxides do not form gum since some of them are volatile. The actual mechanism of gum formation has not yet been definitely established.

Cassar[44] showed that simple olefins, when added to olefin-free gasolines (to the extent of 20 per cent or less), do not produce gum on evaporation. When such mixtures are subjected to an accelerated gum test for 4 hours little gum is obtained (under these conditions, most cracked gasolines yield large quantities of gum). When treated for 24 hours, however, gum was found. On the other hand, when diolefins such as dimethylbutadiene are added to olefin-free gasolines, large quantities of gum result on evaporation.

Brooks and Humphrey[44a] stated that tars sometimes observed in refining gasolines and kerosenes are due to the presence of diolefins. Cracked gasoline fractions which were found by Martin, Gruse and Lowy[44b] to give the greatest gum formation had boiling points corresponding to conjugated diolefins and cycloolefins. After the fractions were treated with maleic anhydride, or partially hydrogenated, or the gasoline was refined with sulphuric acid before fractionation, the fractions were more stable to oxidation at 38° but formed gum at 50° C., the maleic acid-treated one being the least, and the hydrogenated fraction the most, resistant. The stability at 38° C. was attributed to the removal of conjugated diolefins and the instability at 50° C. to the presence of cycloolefins.

Sulphuric acid converts olefins into gummy substances which are not volatile with steam and can be eliminated by distillation (see Chapter 26). The action

[42] *J. Ind. Eng. Chem.*, 1915, 7, 1029.

[44b] *Ind. Eng. Chem.*, 1933, 25, 381.

of sulphur dioxide on olefins is negligible. This substance, however, promotes gum formation if the olefins contain peroxides, and such gum cannot be completely removed by washing with sodium hydroxide solutions. Washing with alkaline solutions reduces the gum content of stored gasolines which give a positive peroxide test with potassium iodide. The gum content of gasolines which do not give a positive test is increased in some instances and reduced in others. Peroxides were found to be strong knock-inducers and should therefore be removed before knock-rating is determined for the purpose of standardization. Removal of peroxides can be accomplished by washing with caustic alkali solutions [45] or by the addition of formaldehyde.

Flood, Hladky and Edgar [46] showed that aliphatic monolefins could be added to olefin-free gasoline in proportions up to 10 per cent by volume without producing gum on evaporation or a drop in pressure for 4 hours during the accelerated test. As the olefin content was increased, however, a shortening of the induction period was observed. Straight-chain olefins with double bonds near the end are more stable than those with double bonds in other positions. For olefins of similar structures those of low molecular weight are the least stable. Branched-chain compounds are less stable than straight-chain isomers. Naphthenic monolefins with a double bond in the ring are only slightly less stable than aliphatic monolefins. Naphthenes with a side-chain containing a double bond resemble the simple olefins. Aromatic compounds having a double bond adjacent to the benzene ring are particularly unstable. The diolefins as a class are unstable, but stability increases as the double bonds are more widely separated. For equivalent concentrations phenylbutadiene yields more gum than any other hydrocarbon investigated.

Analyses of various types of gum were made by Story, Provine and Bennett.[47] They found that gum can be divided into saponifiable and unsaponifiable portions, and that some of the acids obtained from the saponifiable portion are soluble and others insoluble in water. A typical analysis of gum obtained by the evaporation of a cracked gasoline in a copper dish is given in Table 142.

TABLE 142.—*Composition and Characteristics of Gum (from Copper Dish).*

	Original Gum 100 Per Cent	Unsaponifiable Matter 13.00 Per Cent	Insoluble Acids 55.00 Per Cent	Soluble Acids 30.50 Per Cent
Carbon	70.73	64.20	73.22	66.70
Hydrogen	6.95	6.32	6.81	7.20
Oxygen	19.51	13.81	18.58	24.23
Nitrogen	0.13	Trace	Nil	Nil
Sulphur	0.68	0.29	0.41	1.07
Ash	2.00	15.38	0.98	0.80

The ash was considered to be largely dust particles accumulated during evaporation of the oil in dishes.

Gum formed in sunlight from a vapor-phase cracked gasoline yields similar products and volatile acids in addition. The gasoline itself contained some volatile and non-volatile acids which could be extracted together with phenols by sodium hydroxide solutions. Acetic and acrylic acids were identified among the low-boiling acids. Acidity and peroxide and gum formation increase with the time of exposure to sunlight, but no direct relation between them could be established. Different rates of acid formation were observed during evaporation of the gasoline in copper and in glass dishes, the former giving the higher rate. Gum itself gives no test for peroxides, and only faint tests for aldehydes and ketones. It was suggested that the mechanism of gum formation is: Olefin → Activated Olefin → Peroxide → Polymerized Acids and Higher Aldehydes and Ketones.[47a]

Freund[47b] found that the gum content of cracked gasolines increases with the length of exposure to ultraviolet radiation. Smaller amounts of gum were formed in straight-run benzines, paraffin, naphthene, and aromatic and simple unsaturated hydrocarbons under the same conditions. This led to the belief that complicated unsaturated hydrocarbons are the gum-forming constituents and that absorption of oxygen plays only a secondary rôle in this type of gum formation. On the other hand, Vellinger and Radulesco[47c] observed that the amount of gum formed on exposure to radiation from a mercury lamp is a function of the speed of absorption of oxygen. Gasolines were exposed in atmospheres of oxygen in closed containers. At the start the quantity of gum formed was nearly proportional to the amount of oxygen absorbed but as exposure continued, absorption of oxygen diminished and gradually approached a limit which depended upon the pretreatment of the sample.

Although the subject of refining is beyond the scope of this book,[48] some of the methods of removing gum are directly pertinent to this subject and deserve brief mention by way of illustrating the methods in general. In Chapter 26 some treatments for the removal of gum-forming constituents by polymerizing them in the presence of various contact materials have already been discussed. Stevens and Gruse[48a] heated gasoline distillates between 700° and 800° C. under a pressure of 1000 pounds per square inch. The undesirable substances polymerize and remain on distillation. Borax may be added to the distillate to cause polymerization.[48b] The distillate in this case is heated above room temperature but is kept below the cracking point. A mixture of ferric sulphate and fuller's earth may also be used in a similar manner.[48c] The addition of an aqueous solution of hydrogen chloride in the presence of aluminum, manganese, zinc, chromium, iron, cadmium, cobalt, nickel, tin, lead, antimony, boron, arsenic, copper or mercury has been suggested by Day,[48d] and Heath[48e] treats gasoline with an aqueous alkaline solution of potassium ferricyanide followed by a treatment with sulphuric acid.

In other proposed methods the vapors of gasoline are brought into contact with materials which induce polymerization and separation of gum-forming constituents. Among the substances suggested are phosphorus pentoxide with the addition of metal halides or organic oxycompounds;[48f] copper;[48g] oxychlorides[48h] of tin, cadmium, copper and zinc; and a hot mixture of water, zinc and ammonium chlorides.[48i]

A preliminary induced oxidation and removal of gum-forming compounds has also been effected in both the liquid and vapor phases. In the liquid phase, oxidizing agents such as permanganates, lead dioxide, peroxides or persulphates[48j] are added to the gasoline. In the vapor phase, oxygen may be mixed with the gasoline vapors and the mixture injected into a closed chamber at a temperature of 150° to 175° C. The oxygen reacts with the undesirable compounds, the reaction products settling out.[48k] Baxter[48l] treats shale-oil gasoline with ozone, forming gum which is eliminated by centrifuging. This can be followed by a light acid treatment or an extraction with methanol. A mixture of sulphur dioxide and oxygen as the oxidizing gases in the presence of ferric sulphate is recommended by Egloff and Morrell.[48m]

Gum formation is prevented by Rather and Beard[48n] by passing an inert gas such as carbon dioxide or nitrogen countercurrent to a thin flow of gasoline. The inert gas removes any occluded air.

OXIDATION OF LUBRICATING OILS

All mineral lubricating oils absorb oxygen. The rate of absorption varies greatly with the nature of the oil, the extent of processing in refining, the temperature, and the presence of metallic catalysts. Most lubricating oils are used under conditions where a temperature rise occurs, and they are nearly always in contact with the oxygen of the air. Failures in lubrication, with accompanying damage to machinery, arise to a large degree from the oxidation of the lubricant, not because of any great loss of oiliness of the lubricant itself, but rather because oxidation yields viscous or solid bodies, or jelly-like emulsions with water, which interfere with the regular distribution of the lubricant at the bearing surfaces. One method of testing an oil for its behavior on oxidation consists of heating it to a given temperature and blowing oxygen or air through it for a specified time.[49] The quantity of asphaltic matter formed is then determined. In comparing eight oils of approximately the same viscosity at 93.3° C. (200° F.) obtained from widely different sources, Moore and Barrett[50] found them to differ greatly.

[49] For a review of methods of testing sludging and gumming characteristics of oils see Kalichevsky and Stagner, *op. cit.*, 341.

[50] *J. Inst. Pet. Tech.*, 1926, **12**, 582; *Brit. Chem. Abs.* **B**, 1927, 132; *Chem. Abs.*, 1927, **21**, 1703.

Large increases in viscosity were found and these were greater with oils having high sulphur contents. Asphalt and acidity formation for each oil were roughly parallel. The methods used were the Michie sludging test (air blowing for 45 hours at 150° C.), and the British Air Ministry test (12 hours blowing at 200° C.).

In examining the fitness of oils for use in internal combustion engines, Hoblyn[51] employed evaporation tests at 250° C. in crucibles over an oil bath rather than blowing with air or oxygen. At regular intervals the loss was noted and the residue tested for soft asphalts, for asphaltenes soluble in carbon tetrachloride, and for "carbenes" insoluble in that reagent. The samples were also examined microscopically and engine tests of all the oils were made in typical automobile engines. When an oil which easily decomposed was subjected to the evaporation test, the soft asphalt content soon reached a constant value of about 3 per cent. The asphaltenes rose to 30 per cent after heating for 28 hours, after which carbenes were found. The carbenes then increased at the expense of the asphaltenes until at the end of 40 hours the content of soft asphalt was 3.28 per cent; of asphaltenes, 23.88 per cent; and of carbenes, 7.85 per cent. Photomicrographs showed early loss of homogeneity in the oil, increasing until the oil assumed a very dark mottled appearance.

Garner,[52] working with a series of lubricating oils from Texas and Pennsylvania crudes, found that oils of similar distillation range have similar evaporation losses at the same temperature, irrespective of their origin, and that carbonization (that is, the formation of asphaltenes) increases on heating much more rapidly than does the evaporation loss.

Chernojookov[53] has pointed out that the sludge from oxidation of refined oils may be formed in three ways:

(1) The unsaturated hydrocarbons, tars, and sulphur-containing substances on oxidation form a sludge consisting of asphaltenes and carbenes.

(2) The saturated hydrocarbons on oxidation form acids of high molecular weight which cannot be dissolved in petroleum ether and which have acid numbers varying between 60 and 110.

(3) Another sludge is obtained by the reaction of the metals with acids in the presence of water.

According to Chernojookov, the Conradson carbon appears to correspond only to the coke or carbon formed from asphaltenes and tars by evaporation of the oil. Saturated hydrocarbons (paraffins and naphthenes) do not form coke. Such carbonization values are, therefore, not representative of the oil in service. More reliable information appears to be obtainable by oxidizing the oil at high temperatures and pressures (150° C. and 15 atmospheres pressure) with air or oxygen. Treatment for 3 hours under these conditions seems to be sufficient.

An oxidation test giving some insight into the probable behavior of lubricating oils in engines was devised by Ehlers.[54] It consists of passing oxygen for 5 hours at the rate of two bubbles per second into 100 cc. of the oil heated to 170° C. Good oils yield no coke and only small quantities of tar.

In studying the deterioration of mineral oils Mead[55] and his collaborators used two methods. In one, the oil and oxygen are introduced into a closed system so designed that the quantity of oxygen absorbed by the oil can be determined by direct measurement. Between 120° and 130° C. the rate of disappearance of the oxygen is proportional to the time of exposure. The rate at 130° C., however, is 2.4 times as great as that at the lower temperature. At 120° C. and over small ranges (0.2 to 0.4 sq. cm. per gram) the surface exposed to the oxygen does not affect the rate of absorption. At higher temperatures, however, it may exert some influence. Sludge formation and acidity develop slowly at first, and the rate of sludge formation increases as oxidation is continued. The acidity developed probably catalyzes sludge formation. The rate of oxidation also appears to depend upon the degree of unsaturation.

In the other method proposed by these investigators, the oil is heated to 150° C. Acidity development is autocatalytic only when the initial acidity is low. Sludge formation is greatly influenced by the initial acidity of the oil, larger quantities of sludge being formed when the initial acidity is high.

Haslam and Frolich[56] investigated the mechanism of oxidation of a highly refined oil. This oil was selected to eliminate, as far as possible, the effect of impurities. The oil (75 grams) was oxidized by passing through it dry oxygen at the rate of 10 liters per hour at 130° and at 140° C. The degree of oxidation, as indicated by the acidity, increases rather rapidly up to 28 hours, and from then on the increase is very slight up to 40 hours. The viscosity of the oil increases as oxidation progresses. The viscosity increases much more rapidly, however, after oxidation has apparently reached a maximum. Preheating the oil in the presence of nitrogen and the addition of the oxides of iron or copper or of various salts of copper catalyze the oxidation of the oil. Only a small proportion of the oxygen in the oxidized oils was found to be present as acids, the remainder being probably in the products of polymerization or condensation. On the basis of Bone's hydroxylation theory and the data obtained; the oxidation steps appear to be: Hydrocarbons → Alcohols → Aldehydes and Ketones → Naphthenic or Fatty Acids, or Condensation and Polymerization Products (Asphaltic Bodies).

That only a small portion of the dissolved oxygen remained in the oil, while the greater portion was present in the insoluble substances precipitated by the addition of petroleum ether, was pointed out by Waters.[57] The following results were obtained before and after exposing an oil for 23 days to the action of light and air:

	Carbon	Hydrogen	Oxygen
		Per Cent	
Original oil	86.37	13.73	—
"Insoluble product"	72.72	7.83	19.45
Filtered oil	84.49	13.42	2.09

The "insoluble product" was assumed to be of an acid character, for it readily dissolved in alcoholic potassium hydroxide.

The effect of metals and metallic oxides on the oxidation of petroleum was also investigated by Waters.[58] Two medium motor oils were used, one from a paraffin-base and the other from a naphthene-base crude. The oils were heated in an open container for 2 hours at 250° C. and the quantities of substances formed insoluble in petroleum ether were determined. It was observed that zinc and aluminum are without effect; steel, cast iron, nickel and cobalt cause a small increase; and phosphor bronze, brass and copper are distinctly active and effect an appreciable increase in the oxidation. Cupric oxide, nickelous and cobaltous oxides, and ferric oxide are also active. The greatest increases, however, are obtained by exposing the oils to air and light for 20 hours before testing. Later, Waters [59] observed that lubricating oils containing relatively high percentages of sulphur compounds are more easily oxidized either by heating or by exposure to air and sunlight than those of low sulphur content.[60]

[56] *Ind. Eng. Chem.*, 1927, **19**, 292.
[57] *J. Ind. Eng. Chem.*, 1910, **2**, 452.
[58] *J. Ind. Eng. Chem.*, 1921, **13**, 901.

The oxidation of saturated paraffin oils which contain no sulphur compounds was investigated by Arditti [61] by bubbling air through them at different temperatures. The degree of oxidation of the oils was followed by measuring the change in the interfacial tension between 0.02 *N* sodium hydroxide solution and the oil, and by titration of the acidity with 0.1 *N* alcoholic potassium hydroxide solution. The first method indicated that no oxidation occurs at 15° or 85° C., but after 16 hours at 110°, 3 hours at 123°, and ½ hour at 150° C., marked changes had taken place in the oil. Great differences between the free and combined acidity of the oil were observed, which pointed to the occurrence of reactions of marked complexity.

The presence of metals often increases the resin content of lubricating oils. The extent of this deterioration appears to depend on the nature of the metals.[61a] It has also been suggested that the easily oxidizable constituents in the oils actually give off oxygen and thus contribute to the oxidation effect of metals. Borodulin [62] found that the oxidation of steel plates in contact with oils of varying resin content bears no relation to the latter, but depends principally on the viscosity of the oil. The protective action of oils on steel plates is enhanced by increasing their viscosity by the addition of resins. Oils from which resins have not been completely removed afford better protection than highly refined oils.

In a study of the effect of ozone on oils, Dover and Cromwell [63] used four unblended neutral mineral oils, two from paraffin and two from asphalt-base crudes. These oils were given a prolonged treatment with ozone after which the changes in their physical and chemical properties were determined. In all cases there was a decrease in the iodine number, an increase in the acid number, and but very slight change in the specific gravity. The viscosity was, however, generally increased by the treatment. The coefficient of static friction of the paraffin-base oils was reduced, but a less regular and pronounced change was observed in the asphalt-base oils. No general relation between any of the properties of the oils and their value as lubricants could be determined. It appeared, however, that an unsaturated oil would be a better lubricant than a saturated one.

In spite of the recognized deleterious effects of oxidation on mineral oils the proposal has been made to prepare certain lubricants by oxidation. For example, lubricating oil may be produced by blowing air or oxygen through a mixture of a hydrocarbon oil in which is dispersed a catalyst consisting of manganese, lead or mercury compounds. The temperature is maintained below the cracking point of the oil and blowing is continued until the acidity reaches about 1 per cent. The volatile products are allowed to escape. The oxidized oil can then be blended with other lubricating stock.[64]

OXIDATION INHIBITORS FOR LUBRICATING OILS

Haslam and Frolich[65] found that certain substances acted as negative catalysts, that is, delayed the oxidation of mineral oils for a period of time. After the catalyst had been eliminated either by oxidation, by decomposition by heating the oil or by evaporation, oxidation took place normally. The delay in hours when 0.01 gram of the negative catalyst was added to 75 cc. of the oil is given in Table 143.

TABLE 143.—*Oxidation Inhibition of Various Substances.*

Catalyst	Delay in Hours
β-Naphthylamine	3
Ethyl-α-naphthylamine	3
Methyl-α-naphthylamine	4.5
α-Naphthylamine	4.5
p-Aminophenol	5
Diphenylamine	5.5
Phenyl-α-naphthylamine	11
Diphenylhydrazine	18

The rate of oxidation of mineral oils and the formation of sludgy deposits can also be lessened by the addition of small quantities of cyclic amines or highly basic compounds[66] such as piperidine, diethylaniline or phenylenediamine.

Mead and his collaborators[67] tested a large number of organic negative catalysts or inhibitors and concluded that no generalization could be drawn as to the most effective type of compound. The substances which showed the greatest effect as inhibitors were sulphur,[68] nitrocresol and nitrobenzene. Small quantities of lead aryl or alkyl compounds (lead tetraethyl) have been suggested for preventing or hindering the partial decomposition and oxidation of mineral oils.[69]

Active inhibitors, according to Smith and Wood,[70] may be divided into two main groups: energetic reducing agents (stannous compounds and sodium thiosulphate) and strong bases (amines). The presence of such inhibitors increases general stability and resistance to oxidation. Their influence, however, is temporary, and their period of activity depends upon the concentration, the temperature, and the nature of the oxidation products formed. After the effect of the inhibitor or antioxidant is lost, the rate of oxidation is the same as that of the original oil. These substances, therefore, control oxidation for definite but limited periods of time. With basic inhibitors, combination probably takes place with the acid oxidation products, which are themselves good oxidation catalysts. The amines, because of the tervalent nitrogen with two partial valences, may form intermediate compounds with the easily oxidized ethylene hydrocarbons. In some instances, alcohols and phenols are effective as inhibitors. With certain of these (for example with eugenol), there is a concentration at which the substance is most active as an inhibitor, and above which it acts as a positive oxidation catalyst.

The inhibiting effects of a large number of nitrogen compounds were investigated by Moureu, Dufraisse and Badoche.[71] The secondary amines, diamines and aminophenols were found to be the most effective inhibitors. *N*-Methyl derivatives of diamines or aminophenols are said to be equally active. Substitution of both the amino and phenolic groups generally yields inactive compounds, but *N*-acyl derivatives, such as o-acetamidophenol, are still active inhibitors. Most amino-acids or amides have little or no inhibiting properties. Cyclic compounds containing a nitrogen atom in the ring (pyridine or quinoline) are only slightly active.

OXIDATION OF TRANSFORMER OILS

The oxidation of transformer oils is very similar to that of lubricating oils, both as to mechanism and products formed. Since some of the work on the oxidation of transformer oils may shed light on the general mechanism of oxidation, it deserves attention here. The decomposition of transformer oil and the formation of sludge and other undesirable constituents can be prevented in actual use by maintaining a blanket of a non-reacting gas, such as nitrogen or carbon dioxide, over the oil.[72] However, as oxygen is soluble in the oil to some extent it is necessary to remove it either by vacuum treatment or by bubbling an inert gas such as nitrogen through the oil before it is charged into the transformer. Vacuum-treated oils undergo no changes when heated for several days in an atmosphere of carbon dioxide, even in the presence of metallic catalysts. Yamada[73] also showed that transformer oils which readily deposit sludge when heated in the presence of air yield no deposit and undergo no color change when heated in a vacuum or in the presence of nitrogen, carbon dioxide, or hydrogen, for 100 hours at 140° C.

Oxidation also depends to a large extent upon the degree of refinement of the oil. Highly refined oils are more easily oxidized than less refined oils. This is substantiated by oxidation tests made either by passing oxygen through the heated oil[74] or by heating a mixture of oil and oxygen under pressure.[75] Addition of unrefined oil or less refined oil to highly refined oil lessens the oxidizability of the latter. The protective action of the less refined or unrefined oils is probably caused by the presence of natural inhibitors which are eventually removed by the refining treatment.

The oxidation of transformer oils can be accelerated by the introduction of either metals or metallic compounds acting as catalysts. Lead and copper are particularly effective, and of these two, the lead is the more active. The rate of acid formation with lead as a catalyst is slow during the first hour of oxidation but thereafter increases rapidly. Various oils differ widely in their sludge-forming properties. Based upon the data he obtained, Butkow[76] suggested the following oxidation test for transformer oils: 100 cc. of the oil are heated to 120° C. in the presence of a piece of copper gauze (70 x 15 mm.) for 70 hours during which time a current of oxygen is admitted at the rate of 6 to 7 liters per hour. The oil is then poured into a graduated cylinder and the volume of sludge noted. The acidity and resin content of the oil are also determined.

Stäger and Bohnenblust[77] investigated the effects of suspending strips of metals and alloys in transformer oils heated to 112° C. for 1000 hours. Sludging is increased by the presence of copper, brass, tin, and zinc. Acid formation is greatly increased by copper and brass. Aluminum, iron and nickel have little effect. Lead, copper and zinc are attacked by the organic acids in the oil. Lead, in particular, tends to produce acids of low molecular weights which are insoluble in the oil. Resinous substances rich in oxygen, which appeared to be monocarboxylic acids, were also formed.

In the oxidation of transformer oils at 120° C. by a stream of oxygen, von der Heyden and Typke[78] observed that the reaction is accelerated by the presence of sodium hydroxide, sodium or potassium carbonate, and ferric oxide. Magnesium oxide or carbonate give low values for both tar and acid. Lead monoxide decreases oxidation and lead dioxide greatly accelerates it, and red lead (Pb_3O_4) has little, if any, effect. Of the organic substances, phenol, starch, oxalic acid and oleic acid accelerate oxidation; and salicylic acid, hydroxylamine hydrochloride and especially pyrogallol and aniline have the opposite effect.

Anticatalysts or inhibitors of the same general type as those used with lubricating oils (that is, principally aromatic phenols and amines) can be used to reduce or prevent the oxidation of transformer oils. For example, Butkow[79] suggested adding 1 per cent of β-naphthol to the oil, and the British Thomson-Houston Co.[80] proposed to protect oils in actual use with quinol suspended in the oil at or near the surface exposed to oxidation. Amino-compounds such as urea, piperidine, diethylaniline or phenylenediamine, are said to protect the oil against both oxidation and polymerization.[81]

Other inhibitors which may be used are metallic soaps and adsorbents. By adding, for example, not more than 2 per cent of a neutral soap of aluminum, calcium, copper, lead, nickel, tin or zinc, the sludging tendency of the oil is reduced.[82] The soaps need not be soluble in the oil. The useful life of the oil may be prolonged two to three times by the addition of about 6 per cent of fuller's earth.[83] Mizushima and Yamada[84] also showed that free sulphur or organic sulphides such as isoamyl sulphide or selenium compounds are antioxidants for transformer oils.[85]

Some interesting information as to the mechanism of the oxidation of transformer oils has been given by Stadnikov and Vozzinskaia.[86] Data obtained by the systematic analysis of the deposit from used transformer oils indicated that sludge results from the condensation of resinous substances with organic compounds formed by oxidation of the oil. In these condensations the sulpho-acids or their sodium salts (present in oils that have been treated with sulphuric acid and imperfectly washed) act as catalysts. Only traces of such catalysts need be present, and they can exist in the oil in the form of emulsions invisible to the eye but visible under the microscope.

This view is further supported by the oxidation of acid-treated oils. One portion was treated with 90 per cent acid and another, with fuming acid (4.3 per cent SO_3). After careful washing, both were oxidized with air for 45 hours at 120° C. in the presence of copper gauze. Both oils showed increased acid and resinification numbers, but these increases were much less for the oil treated with 90 per cent acid. No solid deposits formed in either oil. These same oils were reoxidized after the addition of 0.1 per cent of naphthene sulphonic acids. They soon darkened and yielded considerable quantities of a brown precipitate. Oxidation was repeated in the presence of 0.2 per cent of the potassium salts of sulphonic acids and a much greater formation of the precipitate took place.

A further indication of the condensing action of the naphthene sulphonic acids was obtained by these same workers[87] in the following manner: When the refined oil was heated in an atmosphere of carbon dioxide with acetic acid and cyclohexanol, the reaction was one of saponification only. If, however, naphthene sulphonic acids were present, resin-formation took place. Glacial acetic acid itself yielded resins with the naphthene sulphonic acids. As a test for naphthene sulphonic acids it is suggested that the oil be heated with acetaldehyde and acetic acid. A discoloration of the acetic acid layer indicates their presence.

In refining transformer oils, the oil, after washing with acid, is treated for about 1½ hours with silica gel. Silica gel replaces alkali for the elimination of excess acid, and the stability of the oil is improved because of the absence of alkali salts of organic acids. Air oxidation followed by a similar treatment with silica gel[88] has also been proposed as a substitute for the acid treatment.

Refining transformer oils by oxidation with air followed by precipitation of the oxidized substances by the addition of an alkaline reagent was suggested by Maloney.[89]

Evers,[90] however, believed that the sludge in transformer oils is the result primarily of a reaction of the oil with water and atmospheric oxygen, which is catalyzed by condensation in the capillary spaces of the insulated coils or other parts immersed in the oil. The oxidation products consist mainly of acidic compounds and partly of asphaltenes. These can be removed by treatment with fuller's earth at 60° C. Contrary to Butkow's results, Evers found that these products are not removed with silica gel.

EVALUATION OF TRANSFORMER OILS

The most important property of a transformer oil is its resistance to oxidation. A large number of tests have been devised for ascertaining the extent to which various oils possess this property. Some of the fundamental points which must be considered in making these tests are as follows:[91]

(1) Temperature. This varies between 100° C. and 175° C., but the temperature most generally used is about 110° C.

(2) Heating. A covered thermostat is better than an exposed oil surface on account of the variability of air currents.

(3) Container. Most metals act as oxidizing catalysts to some degree but glass apparently does not. A vessel of the same material should therefore be used in all tests to secure comparable results.

(4) Quantity of oil. This varies from 10 grams in the French method to 1000 cc. in the Swiss method. The ratio of volume of oil to exposed surface determines the speed of the reaction. A small surface is recommended as it prevents too rapid and uneven oxidation.

(5) Catalyst. Copper in the form of a wire gauze or sheet is preferred. The total surface is of secondary importance.

(6) Air. The use of air or oxygen shortens the time but increases the manipulation required. It is unnecessary when copper is used.

(7) Electrostatic field. The obtainable information on this point is somewhat vague.

(8) Time. This varies from 5 hours to 24 days, and is arbitrarily selected. The Italian standard of 300 hours is long enough to yield sufficient quantities of oxidation products for the necessary determinations.

(9) Oxidation Products. The change in color of the oil is no criterion of quality. The total sediment (i.e., material insoluble in standard benzine) and the total acids (the intermediate products) should both be determined.

These oxidation products, in addition to being partially precipitated by the addition of petroleum ether, can also be extracted, because of their acid nature, by a solution of sodium hydroxide in 50 per cent alcohol (Kissling reagent). Kissling[92] suggested the terms "tar-forming value" and "coke-forming value" for mineral oils, effecting the separation of the two with the alcoholic sodium hydroxide reagent.

Numerous methods for making oxidation tests of transformer oils have been suggested. Stäger[93] proposed heating the oil at 112° C. for various periods up to 1000 hours. The sludge which separates is extracted with chloroform and weighed. The asphaltogenic acids in the weighed residue are determined by saponification with standard alcoholic alkali. The sludge insoluble in oil is determined by filtering the hot oil at 80° C. and weighing the residue. No direct relation was found between sludge formation and iodine number, formolite number, or other chemical characteristics.

Oxidation tests have also been devised by Butkow,[94] by Marcusson and Bauerschäfer,[95] and by Evers and Schmidt.[96] Butkow passed oxygen into an autoclave with some Wood's metal on the bottom heated at 150° C. in which glass tubes containing the oil are immersed. Subsequently the oil is treated with sulphuric acid, the acid layer is separated, and determinations are made of the acidity, sludge-formation, and saponification value.

The Marcusson and Bauerschäfer method is a modified sludge test in which sodium hydroxide is used as a catalyst. The oil is heated with pumice saturated with sodium hydroxide at 120° C. for 24 hours. To the mixture is then added alcoholic sodium hydroxide solution, with which it is refluxed for 20 minutes. The soap solution thus formed is separated, acidified, and the acids are extracted with benzene. The benzene extract is washed to remove any mineral acids, and the tarry material obtained by the evaporation of the benzene is weighed.

Evers and Schmidt compared the relative stabilities of various oils by heating them for 2 hours at 150° C. in the presence of silica gel impregnated with vanadium and ferric oxides and then determining their acid values. The test may be modified by heating the oil and oxygen in a closed container at 120° C. in the presence of the catalyst, followed by determination of the oxygen absorption. They expressed the opinion that oxidation is confined to unsaturated constituents.

In the test proposed by Matthis[97] the oil is heated under specified conditions and the time required for the formation of sludge is observed. The useful life of the oil in service is said to increase with the time required for the sludge to appear. By this method an experienced operator can detect the formation of 0.001 per cent of asphalt.

Vanghelovitch[98] extended the method proposed by Hoblyn[99] by determining microscopically the time required for the precipitation of asphalt when the oil is heated at 250° C. The order of oxidation appears to be: Oil → Hard Asphalt → Soft Asphalt → Carbenes (colloidal carbon) → Coke. The heating may be avoided by another method in which the limiting concentration of nitric acid which will precipitate asphalt from the oil is determined. A thin film of the oil is placed under the microscope and a drop of nitric acid is added. This is repeated with solutions of various concentrations until precipitation of the asphalt occurs. The limiting concentration of nitric acid determines the resistance of the oil to oxidation. The results with nitric acid closely agree with those obtained by prolonged heating at 250° C.

According to Ford,[100] unsaturated hydrocarbons and naphthenes are both important in the oxidation of these oils. When over 5 per cent of unsaturated compounds is present, the quantity of sludge formed is independent of the source of the oil, i.e., whether the oil is of paraffin or asphalt base. Naphthene hydrocarbons of high molecular weight are less sensitive to oxidation than those of low molecular weight. Mixtures of the former with paraffins give oils highly resistant to oxidation and to sludging. No general rule can be given concerning the effect of different temperatures on the rate of oxidation of different oils. High temperature tests, however, did not agree with results obtained in actual use. Ford[101] devised a method for the determination of the different types of hydrocarbons in transformer oils.

TURBINE OILS

The oxidation of turbine oils is very similar in many respects to that of lubricating and transformer oils, so that it is unnecessary to discuss it in detail. In general these oils are affected by the same reagents, and oxidation tests can be carried out in practically the same manner as for the other two.

As an oxidizing test, Schmidt[102] recommended bubbling a slow stream of oxygen (2 bubbles per second) through 125 grams of oil heated to 100° C. Superficially oxidized copper gauze is also introduced into the oil and oxidation is continued for 70 hours. At the end of this time the acid number and the quantity of sludge are determined.

Rogers and Miller[103] suggested iron as a catalyst in a similar procedure. Butkow,[104] on the other hand, preferred to heat the oil with oxygen under 15 atmospheres pressure for 4 hours at 150° C. He also found that the highly refined turbine oils oxidize more readily than less refined ones.

The presence of small proportions of lead tetraethyl as an oxidation inhibitor in turbine oils, according to Hatta,[105] materially reduces the darkening of color and sludge formation in paraffin oils. With naphthene oils, however, although the darkening is retarded, the acid and sludge formation are increased. Oxidation tests in both instances were made at 120° C. with moist oxygen passed in at the rate of 150 bubbles per minute.

Chapter 41

Oxidation of Aromatic Hydrocarbons

The conversion of petroleum distillates into other products by vapor phase catalytic oxidation is a reaction of abundant promise and one which has received much attention. Since both aromatic and cyclic compounds have been isolated from petroleum fractions, the vapor phase oxidation of such hydrocarbons is of interest. As pointed out in Chapter 36, the oxidation of the vapors of some petroleum distillates has yielded maleic acid, and Ellis[1] obtained phthalic acid by oxidizing the vapors produced by cracking petroleum distillates.

Many petroleum fractions contain aromatic hydrocarbons and the isolation of some of these has already been described in Chapter 1. Mizuta,[1a] in determining the physical and chemical composition of Japanese gasolines, noted that fractions cut at 97° C., 120° C., and 150° C., contained benzene, toluene and xylene, respectively. Gasolines from crude oils from the southern part of the Japanese Archipelago were rich in aromatics and contained only a small proportion of naphthenes. The reverse was true of gasolines from the northern part. Zelinski and Juriev[2] observed that analytical determinations indicated as high as 16 to 17 per cent of aromatics in Ural benzine. Bruun, Leslie and Schicktanz[3] by careful fractionation have obtained, from an Oklahoma crude, a fraction boiling at 107° to 108° C. containing about 32 per cent toluene. This distillate on nitration yielded dinitrotoluene quantitatively.

Marek[3a] discussed methods and apparatus for the oxidation of hydrocarbons. He states that aromatics require high temperature and a catalyst and that the reaction proceeds in stages, hence a good yield of intermediate oxidation products can ordinarily be obtained. An extensive study of the vapor-phase catalytic oxidation of hydrocarbons has also been made by Wilken-Jorden.[3b]

The catalysts most extensively used in the vapor phase oxidation of aromatic compounds are oxides of the metals of the fifth and sixth groups of the periodic system, especially vanadium, uranium, tungsten and molybdenum. The metallic catalyst generally employed in the oxidation of aromatic hydrocarbons to acids appears to be vanadium. For producing aldehydes, other oxides, such as those of uranium or molybdenum, are used as they seem to be less energetic catalytic agents and hence more appropriate. Often a mixture of the oxides of these latter metals is more effective than the oxide of either metal alone.[4]

Reaction can be secured by passing the vapors of the aromatic compounds with air or oxygen over the heated catalyst, or by mixing a spray of a colloidal suspension of the oxide in the hydrocarbon with air in a heated reaction chamber. By the latter method Caspari[5] produced maleic acid from benzene, and benzaldehyde or benzoic acid from toluene.

[4] For a very complete classification of these catalysts, see Craver, U. S. Patents 1,636,854 and 1,636,855, July 26, 1927; both patents assigned to Barrett Co. For the use of vanadium pentoxide, see Selden, British Patent 170,022, 1921; assigned to Selden Co.

In addition to the oxides, various salts of these same metals can be used, for example, a ferric vanado-chromate[6] or a complex vanadium pentoxide silicate.[7] The latter catalyst is not poisoned by sulphur compounds which may be present in the aromatic substances. "Zeolite" catalysts, or the reaction products of silicates with metallic salts such as potassium vanadate, are employed in the partial oxidation of aromatic hydrocarbons, or in the purification of such hydrocarbons by preferential oxidation.[8] The addition of stabilizers (the neutral or acid salts of the alkali and alkaline earth metals) and also of "stabilizer promoters" (compounds of heavy metals with amphoteric metals, e.g., aluminum, zinc or lead) to these catalysts is also recommended. These zeolites, after being used in oxidation processes, can be revivified by heating to 300° to 500° C. with halogens, non-metallic halides, acids or acid anhydrides, together with air or oxygen. The mass is subsequently mixed with hydrogen peroxide, which is removed later by evaporation. Or the catalytic mass may be heated to 300° C. in a stream of ozonized air.[9]

In catalytic vapor phase processes excessive oxidation of the aromatic compounds can be lessened by the addition of some other substance which is more readily oxidized.[10] For example, in the preparation of benzaldehyde or benzoic acid, methyl alcohol or gasoline vapors can be mixed with the vapors of toluene. Or gasoline vapors may be used similarly in the conversion of acenaphthene to naphthalic anhydride or of cresol to salicylaldehyde and salicylic acid.

Weiss, Downs and Burns[11] investigated the mechanism of the catalytic oxidation of benzene to maleic acid, particularly the oxide equilibria in the vanadium oxide catalyst. At 400° C. the catalyst at the end of the runs consisted of vanadium pentoxide and tetroxide, the proportion of the former increasing rapidly as the ratio of oxygen to benzene in the reacting gases increased. Even when the initial catalyst was a mixture of vanadium trioxide and tetroxide its final composition appeared to depend only on the ratio of oxygen to benzene. Catalytic action, therefore, appears to depend upon an oscillation between vanadium pentoxide and tetroxide, the dissociation of the former compound furnishing the activated oxygen.

At temperatures higher than 400° C., for any given ratio of air to benzene, the proportion of vanadium pentoxide decreased rapidly while complete combustion also increased at the expense of the partial oxidation products. The reverse was true at lower temperatures. Complete combustion is, therefore, not dependent on the ratio of vanadium pentoxide to tetroxide, but on some other factor, perhaps the activation of the reacting substances themselves.

The nature of the products of combustion must also be a function of some property of the catalyst other than the activation of oxygen by dissociation of the oxide. For example, there may be some specific relation between the structure and the dimensions of the metallic atom and the structures and the dimensions of the organic substances being oxidized. This surmise is illustrated in the case of benzene. The best catalyst for bringing about partial oxidation is an oxide of vanadium, though more complex molecules, such as naphthalene and anthracene, are susceptible to a large variety of catalysts. With benzene a mixture of various oxides will often effect partial oxidation, although the individual oxides do not possess this property.

Forrest and Frolich,[11a] however, maintain that with careful control of temperature and concentration of oxygen, aromatic compounds may be converted to partial oxidation products without the aid of catalysts. In their process, the heat of the oxidation reaction is compensated for by the latent heat of evaporation of the reacting material. By regulation of the pressure, thus causing evaporation or condensation, the temperature may be held practically constant. The pressures employed varied from 750 to 2500 pounds per square inch and the temperatures from 200° to 320° C. Toluene, for example, with 4.1 mole per cent oxygen under a pressure of 1000 pounds per square inch at 305° C. was converted after 30 minutes to benzoic acid, benzaldehyde, and carbon dioxide, corresponding to 24.8, 9.9, and 5.4 per cent, respectively, of the oxygen conversion. Other substituted benzene or polynuclear cyclic compounds such as cyclohexane[11b] may be used; with benzene itself, however, the ring is broken.

PRODUCTION OF MALEIC ACID

Kempf[12] was probably the first to obtain maleic acid by the oxidation of an aromatic compound. He oxidized quinone with silver peroxide (made by mixing solutions of silver nitrate and potassium persulphate) and the products were maleic and formic acids, carbon monoxide and dioxide.

Another procedure consists in passing equal weights of benzene vapor and air over a vanadium oxide catalyst at 400° to 450° C. at such a velocity that the time of contact is about 0.25 second.[13] Quinone may be added to the benzene, and the mixture similarly vaporized and catalytically oxidized to maleic acid. Inert gases may be used as diluents to control the reaction.[14] In addition to benzene, other aromatic hydrocarbons, e.g., toluene, can be oxidized to maleic acid in the presence of a vanadium oxide catalyst.[15] The temperature during oxidation may be regulated by passing the reacting materials over the catalyst supported on tubes which contain mercury. Vaporization of the mercury regulates the temperature and thus prevents overheating. The boiling point of the mercury can be adjusted by the application of pressure.[16]

Yabuta and Simose (*Bull. Inst. Phys.-Chem. Research, Tokio*, 1929, **8**, 197; *Chem. Abs.*, 1929, **23**, 3441) made a study of the influence of inert gases, the methods of preparing the catalyst, and the effect of acidic metal oxides in the catalyst on this oxidation.

[15] Weiss and Downs, Canadian Patent 235,972, 1923; assigned to Barrett Co.

Better yields of maleic acid or anhydride can be secured by using a mixed catalyst, for example, one which consists of vanadium pentoxide together with the higher oxides of molybdenum or uranium, or any of the oxides of the metals included in the fifth and sixth groups of the periodic system.[17] Not more than two such oxides should be incorporated in the catalyst. The temperature used with the various catalysts varies from 450° to 550° C. and the time of contact for the gases is about 0.3 second. These catalysts may be deposited on an inert porous carrier containing fused aluminum oxide.[18]

Alternate catalytic oxidation and decarboxylation may be applied to the stepwise degradation of aromatic hydrocarbons in the preparation of maleic acid.[19] For example, naphthalene and air can be passed over vanadium pentoxide at 400° C., then over cadmium oxide at 400° C., and finally over a mixture of cadmium and aluminum oxides at 380° C. At the end of these steps benzene is the principal product. Air is added to the benzene vapors and the mixture led over a vanadium pentoxide catalyst at 410° C. to form maleic acid, together with some benzoquinone.

Maleic acid can be obtained not only from aromatic hydrocarbons but also from other substances containing a ring structure, such as furane. In Chapter 36 it is pointed out that maleic acid is a product of the oxidation of gasoline vapors.[20] This may probably be due to the naphthenes present in gasoline. Ellis [21] showed that this same acid is formed, along with other dibasic acids, by the oxidation of the vapors from cracking kerosene and other petroleum fractions.

In another method, crude furfural was atomized with pure oxygen and passed over zinc vanadate or granulated aluminum at 300° to 350° C. The yield of maleic acid corresponded to about 30 per cent of the theoretical. Yields of about 50 to 60 per cent were secured when pyromucic acid was oxidized.[22] This process was somewhat modified by using furane with a large excess of oxygen or air (20 to 100 times the theoretical quantity) together with steam, the latter assisting in the vaporization of the furane.[23] The gaseous mixture was also passed over the catalyst at a lower temperature (about 180° C.).

By vaporizing furfuraldehyde in a current of air at 40° to 50° C. and leading the vapors over a vanadium oxide-asbestos catalyst at 200° to 300° C., a 14 per cent yield of maleic acid was obtained.[24] Other products formed at the same time are maleic anhydride, formaldehyde, water, and carbon dioxide, but no fumaric acid.

The oxidation of pyrroline derivatives by nitric acid to maleic acid derivatives was described by Ciamician and Silber.[25] Brominated thiophens on oxidation give the corresponding bromomaleic acids.[26]

[25] *Ber.*, 1887, 20, 698, 2594.

[26] Angeli and Ciamician, *Ber.*, 1891, **24**, 77, 1347.

The purification of crude maleic acid, made by the oxidation of benzene or naphthalene, by recrystallization from solvents (e.g., diethyl maleate or mixtures of the esters of maleic acid and hydrogenated polynuclear aromatic hydrocarbons) is described by Jaeger.[27] Iron compounds are removed from the crude acid by sodium cyanide.[28]

Maleic acid is converted to fumaric acid (the isomeric compound) by heating it either alone or in the presence of solvents, such as water[29] or benzene,[30] to temperatures above its melting point. The addition of nitric acid to an aqueous or ether solution of maleic acid produces the same results.[31] Terry and Eichelberger[32] reported that maleic acid, in aqueous solution, is transformed to fumaric acid by heating to 99.2° C. in the presence of hydrochloric or hydrobromic acid as catalysts. The reaction proceeds without the formation of by-products and its velocity is proportional to the concentration of the catalyst and to the second power of the original concentration of the maleic acid.

Both maleic and fumaric acids can be oxidized in aqueous solution to tartaric acid (racemic) by adding a solution of potassium permanganate at such a rate that the temperature does not rise above 50° to 60° C.[32a] On the other hand, in the presence of such acids as sulphuric, phosphoric, acetic and perchloric the principal product obtained on oxidation (with permanganate) is formic acid.[33]

PRODUCTION OF BENZALDEHYDE

Both benzaldehyde and benzoic acid can be produced by the oxidation of the same aromatic hydrocarbon, particularly toluene. In vapor phase oxidation the formation of one of these substances in predominance is dependent upon the conditions of oxidation, such as the rate of flow of the gases through the apparatus, the temperature, the quantity of air or other oxidizing gas, and the catalyst. Generally, high flow rates and a relatively low proportion of air or oxygen favor the production of the aldehyde.

Coquillion[34] obtained benzaldehyde as one of the oxidation products when a mixture of air and toluene vapor was passed over an incandescent platinum or palladium wire. Later Woog[35] used pumice impregnated with a reduced platinum salt, or the oxides of iron, nickel or copper at temperatures varying from 150° to 300° C. In the presence of manganese dioxide complete oxidation of the hydrocarbon was observed. Toluene was also oxidized at 370° C. in the presence of coke, yielding a small amount of benzaldehyde and a large proportion of benzoic acid. Woog considered that the best results were secured with the iron oxide catalyst. The reaction can be controlled by diluting the gaseous mixture with an inert gas, carbon dioxide or nitrogen.[36] Orloff[37] reported a

2.5 to 4 per cent yield of benzaldehyde on passing a mixture of toluene vapor and air over heated copper. Other oxidation products, resembling phenols, were formed at the same time.

Kuznetzov and Stepanenko[38] investigated the following catalysts for the vapor phase oxidation of toluene to benzaldehyde: (1) basic zinc manganate, (2) vanadium pentoxide on asbestos, (3) vanadium pentoxide on pumice, (4) molybdenum trioxide on asbestos and (5) bismuth vanadate on pumice. The best catalyst was found to be molybdenum trioxide. The catalyst was preheated to 375° C., but after oxidation started the temperature rose to 475° C. Somewhat better yields were obtained using small pieces of molybdenum oxide (2 to 3 mm. in diameter) and keeping the temperature of the catalyst at 500° C. Under these conditions 42.3 per cent of the volatilized toluene was oxidized, of which 55.2 per cent was benzaldehyde, 5 per cent benzoic acid, and the remainder carbon dioxide. No carbon monoxide was formed.

Although vanadium pentoxide or vanadates appear to be excellent catalysts for the oxidation of aromatic compounds to acids, benzene to maleic acid or naphthalene to phthalic acid, for example, they do not favor good yields of benzaldehyde.[39] Meigs[40] noted when another metal, such as silver, was incorporated in the catalyst that larger proportions of benzaldehyde were obtained by the vapor phase oxidation of toluene. The temperature of the catalyst was kept at about 250° C., and steam was mixed with the reacting gases. The temperature and the quantity of steam were regulated so that the concentration of carbon dioxide in the exit gases was maintained at about 3 per cent. Good yields of benzaldehyde, however, are obtained by the use of vanadium pentoxide in the catalytic oxidation of benzyl alcohol or benzyl chloride with air.[41]

In the production of benzaldehyde by the catalytic oxidation of toluene vapors with air, Downs[42] controlled the temperature in the reaction zone by the vaporization of sulphur adjacent to but out of direct contact with the catalyst. The boiling point of the sulphur can be varied by changing the pressure on the system.

Several procedures have been developed for the liquid phase oxidation of toluene to benzaldehyde. One of these involves the use of manganese dioxide and sulphuric acid, the latter being in excess.[43] When 65 per cent sulphuric acid is employed, at 18° to 19° C., and the ratio of toluene to manganese dioxide is 4:1, the yield of benzaldehyde (calculated on the basis of the active MnO_2 content) is 55 to 56 per cent.[44] The addition of a small quantity of nitric acid accelerates the reaction, but cupric sulphate or potassium iodide are without effect.[45] Substitution of manganese dioxide by powdered pyrolusite, which had been previously treated with sodium hydroxide (10 to 25 per cent) in an autoclave at 156° to 158° C. under 6 to 6.5 atmospheres, reduced the proportion of aldehyde formed to about 14 per cent.

Other oxidizing agents include sulphuric acid solutions of manganese dioxysulphate[46] (prepared by the electrolysis of a solution of manganous sulphate) at 50° C. or of the ammonium manganic alum, $(NH_4)_2SO_4.Mn_2(SO_4)_3$. The addition of sulphuric acid slowly to a cooled mixture of lead dioxide, water and benzol also yields benzaldehyde.[47] A mixture of cerium dioxide in 60 per cent sulphuric acid at 90° C. is suggested[48] as well as ammonium persulphate in sulphuric acid (containing a small proportion of silver sulphate), at room temperature.[49] Oxidation of toluene with chromyl chloride furnishes the compound $C_6H_5CH(CrOCl_2.OH)_2$ which on hydrolysis gives benzaldehyde. The reaction may be carried out in either carbon bisulphide[50] or chloroform[51] solutions.

[44] Shorigin, Kizberg, Troitski and Smolyaninova, *loc. cit.*

[45] The use of cupric sulphate ($CuSO_4.H_2O$) as a catalyst is described by Evdokimov, *J. Chem. Ind. (Russia)*, 1929, **6**, 207; *Chem. Abs.*, 1930, **24**, 2737.

Toluene can be oxidized indirectly to benzaldehyde. For instance, benzyl chloride (obtained by chlorinating toluene) is hydrolyzed to benzyl alcohol by refluxing with a solution of sodium hydroxide for several hours. The reaction product is treated with aqueous sodium hypochlorite, containing 2 to 3 per cent sodium hydroxide. During the addition of the hypochlorite, the benzaldehyde formed is separated by steam distillation.[52]

Aldehydes can be obtained directly from aromatic hydrocarbons by treating them with carbon monoxide and hydrogen chloride in the presence of aluminum chloride.[53] To illustrate, carbon monoxide and hydrogen chloride are passed for 6 to 8 hours into a solution of benzene in nitrobenzene to which aluminum chloride is added. During passage of the gases a temperature of 50° to 60° C. is maintained. The reaction product is poured onto ice, and benzene, benzaldehyde and nitrobenzene are separated by steam distillation. The benzaldehyde can be further purified by converting it to its bisulphite compound. This method is applicable not only to the production of substituted aldehydes, such as chlorobenzaldehyde or p-toluic aldehyde, but to the preparation of chlorine-free aldehydes which can be used in the manufacture of perfumes and preservatives.

When dissolved in glacial acetic acid saturated with nitrous oxides (N_2O_3) and exposed to light or heated to 120° C., toluene yields a mixture of benzaldehyde, benzoic acid, and a small proportion of unidentified nitrated products.[54] Benzaldehyde and benzoic acid are separated from the mixture by treatment with a concentrated solution of sodium bisulphite and a dilute solution of sodium hydroxide, respectively. Similar results were obtained when nitrogen tetroxide was used as the oxidizing agent. The reactions involved may be represented by:

$$C_6H_5CH_3 + N_2O_3 \longrightarrow C_6H_5COOH + H_2O + N_2$$
$$2C_6H_5CH_3 + N_2O_4 \longrightarrow 2C_6H_5CHO + 2H_2O + N_2$$

One of the characteristic reactions of benzaldehyde is its autoxidation, particularly in the presence of sunlight. This apparently takes place in two stages: (1) the formation of perbenzoic acid from benzaldehyde, and (2) the oxidation of benzaldehyde to benzoic acid by the perbenzoic acid.

$$C_6H_5CHO + O_2 \longrightarrow C_6H_5COOOH$$
$$C_6H_5COOOH + C_6H_5CHO \longrightarrow 2C_6H_5COOH$$

These reactions can be accelerated, particularly when the aldehyde is dissolved in a solvent, by the presence of iron powder. Tin and aluminum powders, however, have no effect. Perbenzoic acid may be isolated from an acetone solution by distilling off the acetone, or by extracting the benzoic acid with dilute sulphuric acid followed by extraction with chloroform.[55] When dissolved in pyridine, benzaldehyde fails to exhibit autoxidation.

PRODUCTION OF BENZOIC ACID

In making benzoic acid by the vapor phase oxidation of toluene, Kuznetzov and Stepanenko[56] used a large excess of air, stannic vanadate as the catalyst, and a temperature of 290° C. About 21 per cent of the vaporized toluene was oxidized, the products consisting of 87.9 per cent benzoic acid and 7 per cent benzaldehyde.

Maxted[57] reported that stannic vanadate can be used in the vapor phase oxidation of toluene and ethylbenzene to benzoic acid. With the former a 50 per cent yield was obtained, and with the latter, a 40 per cent yield. The same catalyst can be employed in the oxidation of benzyl alcohol and benzaldehyde to benzoic acid. Bismuth vanadate yielded results similar to those with the tin compound though the temperature of activity is about 100° C. higher (about 390° C.). Pansegrau[57a] employed hydrated ferric oxide at 150° C. as a catalyst for the conversion of toluene to benzoic acid under pressure in the presence of a liquid aqueous phase.

Other methods for the catalytic oxidation of toluene to benzoic acid involve the use of a zeolite catalyst[58] containing vanadium, tungsten and molybdenum; the spraying of a colloidal solution of vanadium oxide in toluene[59] together with eight times its vapor volume of air into a chamber kept at 200° to 300° C.; and the oxidation of naphthalene in the presence of a relatively large quantity of steam (see Phthalic Acid).

This acid can be made also by heating solutions of phthalic acid or of phthalates to 150° to 300° C. under pressure,[60] or by heating a mixture of solid calcium phthalate and calcium hydroxide.[61]

Several procedures are available for the recovery of benzoic acid from phthalic acid made by the oxidation of naphthalene. The aqueous solution, or dispersion, of these two acids can be continuously leached with a current of an organic solvent, such as gasoline or benzene, in which the benzoic acid is the more soluble.[62] Benzoic is recovered from this solvent and phthalic acid from the water. Mixtures of benzoic and phthalic acids may be treated with the vapors of an organic solvent for benzoic acid at temperatures at which the latter acid is volatile (125° to 150° C.) but below those at which phthalic acid is transformed into the anhydride.[63] This operation can be carried out in the presence of steam and made continuous.

The mixture of acids can also be subjected to the action of superheated steam at temperatures (150° to 175° C.) below which phthalic anhydride is formed. The vapors of steam and benzoic acid are partially condensed and benzoic acid recovered.[64]

Although both the liquid- and vapor-phase oxidation of toluene at ordinary pressures gives mainly benzaldehyde and benzoic acid, Newitt and Szegö[64a] observed that at 50 atmospheres and 210° C., toluene is oxidized by air to hydroxylated compounds, of which benzyl alcohol is the chief product. Small amounts of 2,4-dihydroxytoluene, benzaldehyde and benzoic acid are also formed.

PRODUCTION OF PHTHALIC ACID

Phthalic anhydride, from which phthalic acid can be obtained, is easily produced at a low cost by catalytic oxidation of naphthalene with air. It is an important raw material in the manufacture of anthraquinone or vat dyes and also of synthetic resins.[64b] Esters of this acid are used as plasticizers.

The catalysts most extensively employed in the oxidation of naphthalene are vanadium pentoxide or vanadates. When the vapors of naphthalene or alkylnaphthalenes (e.g., methylnaphthalene) together with air are conducted over vanadium pentoxide at 450° C. about 87 per cent of the hydrocarbon is converted to phthalic anhydride.[65] Other compounds produced at the same time are benzoic acid, carbon dioxide and possibly naphthols. Buylla and Pertierra[65a] observed that o-xylene under similar conditions also yielded phthalic anhydride. The catalyst is best prepared by fusing vanadium pentoxide and then reducing it to a powder. Arsenic trioxide and sulphur dioxide do not affect the catalyst. Sodium salts, however, greatly lower its efficiency. Molybdenum can be used as a catalyst, though it is not as efficient as vanadium pentoxide. The oxidation of naphthalene with air takes place also in the presence of zeolites[66] as well as the vanadates of tin and bismuth.[67] The catalysts may be supported on a smooth or polished metal carrier. For example, a catalyst is prepared by immersing small polished strips of aluminum into molten vanadium pentoxide.[68]

Kusama[69] found that acidic oxides were the best promoters for vanadium pentoxide catalysts, as the basic oxides, including the lower oxides of vanadium, combine with the acid which is produced. He also noted that the presence of water vapor increased the yield of benzoic acid. The addition of steam has been reported by Conover,[70] who obtained a 90 per cent yield of benzoic acid by passing phthalic anhydride vapors and steam over catalysts of zinc, copper or aluminum oxide at 200° to 600° C. Phthalic acid, together with maleic acid, carbon dioxide and water, is obtained by the catalytic oxidation of hydro-aromatic compounds, such as decahydronaphthalene.[71]

Catalytic processes of the kind described above, e.g., the conversion of benzene to maleic acid or naphthalene to phthalic anhydride, depend for their success on the accurate control of temperature. For such control a number of methods have been developed, several of which have already been mentioned.

Downs,[72] for example, immersed the reaction vessel in a eutectic mixture of sodium and potassium nitrates to maintain a constant temperature. The catalyst was coated directly on the walls of the vessel. This mixture of nitrates and a large number of small reaction chambers has been employed by Gibbs.[73]

As heat absorbents, alloys of mercury, cadmium and lead can be used.[74] These three metals are mixed in various proportions to obtain alloys which boil over a wide range of temperatures. Using mercury alone presents some disadvantages, since its boiling point is low, its cost high, and it has a relatively low heat conductivity. Alloys formed from these three metals have low melting points, sufficiently high boiling points, high thermal capacities, and relatively low specific gravities. Various details of apparatus for controlling the temperature have also been described by Jaeger[74a] and Selden.[74b]

Green[75] suggested that the surplus heat generated during the oxidation reactions be absorbed by the injection of a water spray into the spaces between the successive catalyst zones. The evaporation of the water by the hot gases thus reduces their temperature.

Temperature control is also obtained by allowing oxidation to proceed in steps. The gases are first passed over a less active catalyst at a moderate temperature and then over a more active catalyst.[76] The heat of reaction from the first step thus heats the gases to an appropriate temperature for the second step. For example, naphthalene vapors and air are led first over vanadic acid on metallic granules at 320° C. and then over vanadic acid on powdered kieselguhr at 350° to 410° C.

Crude phthalic anhydride can be purified in several ways. The reaction products coming directly from the reaction chamber are brought into contact with large surfaces of solid adsorbents (e.g., silica gel or pumice) which are maintained at a temperature low enough to prevent decomposition of the reaction products.[77] Granulated pumice or bauxite have been suggested for the removal of impurities in a similar manner.[78] In another process the crude solid anhydride is vaporized into a current of air or purified flue gas at a temperature of about 200° C. The gaseous mixture is cooled in successive stages to fractionally crystallize the vaporized substances.[79] The crude acid or anhydride may be freed of impurities by selective steam distillation at temperatures below which the acid distills.[80]

The crude product can also be treated in the solid or liquid phase with reagents which react with the impurities and afterwards the phthalic acid is separated by distillation. These reagents may be condensing agents, for example, manganese dioxide or zinc chloride,[81] an aldehydic material such as trioxymethylene,[82] acid compounds, e.g., sulphuric acid,[83] lactic, mucic, or citric acid[83a] or sodium acid sulphate,[84] or the impurities may be selectively chlorinated to form high-boiling substances.[85] The crude acid is also purified by distillation followed by extraction with toluene or xylene or mixtures of these solvents.[86]

The decarboxylation of phthalic acid to yield benzoic acid has been effected by subjecting the vapors to the influence of splitting catalysts[86a] and to electronic discharges.[86b]

PRODUCTION OF ANTHRAQUINONE

Anthraquinone is of commercial importance because of its use in the preparation of dyes, particularly alizarin, quinizarin and purpurin. One of the earliest methods of preparation on a commercial scale was the oxidation of anthracene by potassium dichromate and sulphuric acid.[87]

Anthraquinone is now, however, produced by the vapor phase catalytic oxidation of anthracene. Thus, Jaeger[88] oxidized anthracene with air in the presence of a zeolite catalyst at 400° to 500° C. Canon and Andrews[89] used molybdenum trioxide at 450° to 550° C. and kept the temperature constant by removing the excess heat generated by means of a cooling medium consisting of an alloy of cadmium and mercury.

Wohl[89a] oxidized anthracene to anthraquinone by passing a mixture of air and anthracene over a vanadium oxide catalyst supported on pumice at about 400° C. Triphenylmethane also yielded anthraquinone, whereas toluene produced benzaldehyde and benzoic acid. Tar fractions containing aralkyl hydrocarbons were found to give a mixture of aldehydes and acids. Unsaturated hydrocarbons of high molecular weight such as those which occur in brown-coal tar were similarly converted to acids.

Craver[90] concluded that the oxides of vanadium were too energetic as catalysts and with them phthalic anhydride was the main product in the oxidation of anthracene. The oxides of molybdenum, uranium, or other metals of the fifth and sixth groups in the periodic system were more satisfactory. Best results were obtained by using a mixture of such oxides. The optimum temperature for oxidation is about 475° C. and the time of contact of the gases with the catalyst about 0.5 second.

Instead of using air alone, the oxides of nitrogen together with air furnish a convenient oxidizing gas. In one process these oxides are absorbed by basic oxides, such as zinc or copper oxide, and the resulting compounds mixed with anthracene. The mixture is heated to 250° to 350° C. and a stream of air passed through the mass. In this manner anthracene is oxidized to anthraquinone.[91]

Nitrogen oxides may be dissolved in nitrobenzene and anthracene added slowly to the solution. After standing for some time the excess oxides are removed by heating to 100° C. On cooling the nitrobenzene, crystals of anthraquinone separate and are freed of the solvent by filtration. Additional anthraquinone is obtained by steam distillation of the nitrobenzene. This method of oxidation is not applicable to anthracene containing a large proportion of impurities, as it is difficult to separate anthraquinone from other substances formed on oxidation.[92]

Small quantities of anthraquinone have also been obtained in the oxidation of toluene vapor, or the vapor of toluene-containing petroleum distillates, using a catalyst consisting of aluminum grains coated with vanadium pentoxide,[93] at a temperature of 400° C.

OXIDATION IN THE LIQUID PHASE

Oxidation of aromatic hydrocarbons can be carried out in the liquid phase as well as in the vapor phase. In the preparation of phenol, benzene is emulsified with an equal volume of 20 per cent sodium hydroxide solution and this emulsion is heated in an autoclave at 320° to 400° C. for one hour, an internal pressure of about 200 atmospheres being maintained.[94] The oxides of uranium, together with the oxides of molybdenum, vanadium or tungsten, are used as catalysts. The oxygen in the air above the liquid in the autoclave is absorbed with the formation of phenol, which dissolves in the alkali. The yield of phenol is small. Amiel[94a] heated 1 mole of benzene with 15 gram-atoms of oxygen at 460° to 490° C. for periods ranging from 1.4 to 2 hours. The maximum yield of phenol was 4.5 milligrams from 25 milligrams of benzene. At the same time, 1.7 milligrams of 1,4-benzoquinone were formed.

Aromatic hydrocarbons with side chains, when heated in an autoclave with air or oxygen under high pressure (60 atmospheres) in the presence of a solution of alkalies produce acids or aldehydes.[95] Good stirring during heating promotes emulsification which, in turn, facilitates oxidation. High temperatures and long reaction periods, however, favor the formation of acids. Aldehydes require lower temperatures and shorter reaction periods and also continuous removal of the hydrocarbon, in which the aldehyde is soluble. Compounds which are oxygen carriers may be used as catalysts.

Alkylbenzenes having a side chain of two or more carbon atoms can be oxidized in the liquid phase with air or oxygen in the presence of catalysts such as the oxides or hydroxides of silver, copper, zinc and other metals, or the acetates, stearates or resinates of iron and manganese.[96] The temperature varies with the hydrocarbon being treated, the range generally being from about 50° C. to the boiling point of the hydrocarbon. As an example of the products obtained by this process, ethylbenzene at 120° to 140° C. is oxidized to a mixture of acetophenone and methylphenylcarbinol.

The oxidation of ethylbenzene in the liquid phase has been studied by Stephens [96a] and King, Swann and Keyes.[96b] The best yield of acetophenone was obtained with manganese acetate as catalyst, although acetic anhydride and to some extent, cerium oxide, also accelerated the oxidation.

Senseman and Stubbs [96c] investigated both the vapor- and liquid-phase oxidation of p-cymene. Vanadium pentoxide supported on porcelain was employed at 300° to 400° C. as a catalyst for the vapor-phase and manganese dioxide at 140° to 160° C. for the liquid-phase oxidation. The products in either case were p-toluic acid, terephthalic acid, acetic acid, formaldehyde, carbon dioxide and water. p-Tolyl methyl ketone was also found in the liquid-phase reaction products. Senseman and Stubbs [96d] also carried out the liquid-phase oxidation of ethylbenzene at temperatures of 102° to 104° C. in the presence of manganese dioxide. Acetophenone, benzoic acid, phenylmethylcarbinol, formaldehyde, carbon dioxide and water resulted.

Oxygenated products of hydroaromatic compounds are made by oxidation at relatively low temperatures in the presence of mild catalytic agents. Thus, α-ketotetrahydronaphthalene and other oxidation products are obtained at temperatures below 130° C. with oxygen or other oxidizing agents with catalysts such as the salts or oxides of manganese or copper.[97]

Aromatic hydrocarbons are oxidized with oxygen under the influence of light in the presence of anthraquinone or chloroanthraquinones.[98] By the addition of acetic anhydride, or acetyl chloride or other substances which react with the final or intermediate oxidation products, derivatives of the oxidation products, such as esters, can be obtained directly.

In the oxidation of aromatic alcohols with gaseous oxygen Stephens [99] noted that three reactions appear to take place: (1) a small proportion of the alcohol is oxidized directly to ketones; (2) high-boiling compounds are formed which correspond to two molecules of the alcohol less one molecule of water, this reaction taking place to the largest extent; and (3) the formation of unsaturated compounds by dehydration. All three of these reactions are completely inhibited by the presence of excess water. The alcohols used in this investigation were methylphenylcarbinol, ethylphenylcarbinol, dimethylphenylcarbinol and others of a similar type.

ELECTROCHEMICAL OXIDATION

Many attempts have been made to utilize the electric current as the oxidizing agent for the commercial preparation of organic compounds. Although this has been done successfully in a number of processes, nevertheless, in many others the results have been disappointing because of low yields and the difficulty of regulating the oxidizing action. A great many organic compounds are oxidized completely in this manner, to yield carbon dioxide and water. Some of the factors regulating these electrolytic oxidation processes have been pointed out by Fichter.[100]

Aromatic hydrocarbons such as benzene are insoluble in aqueous solutions and are non-conductors. They must, therefore, be vigorously stirred with solutions to form exceedingly fine emulsions, which behave like true solutions. The final oxidation product then depends upon the construction of the apparatus, the type of electrodes used, and the choice of the electrolyte. These points can be illustrated by the following brief description of the conditions for the oxidation of benzene.

The construction of the apparatus.—With a platinum electrode and a cell which contains a diaphragm, benzoquinone is obtained, but in the absence of the diaphragm, quinol is formed.

The type of electrode.—The most vigorous oxidation is obtained with smooth electrodes. Peroxidized lead electrodes are next in order of activity. Graphite can be used, but it disintegrates mechanically, and also absorbs the organic substances. Electrodes in operation often become hot and may produce undesirable changes in the organic materials.

The type of electrolyte.—Dilute sulphuric acid is most generally used. It has been suggested that with this electrolyte the reaction is an indirect electrochemical oxidation as the acid is oxidized to persulphuric acid which is then reduced by the organic substance. This may also apply to the use of salts of metals possessing more than one valence state, such as chromium, manganese, or vanadium. Alkaline solutions often yield products entirely different from those obtained in acid solutions. Thus, the electrochemical oxidation of benzene in an alkaline solution does not yield quinones, not because they are not formed but because in alkaline solutions quinones are unstable and are immediately oxidized to hydroxyquinone-like substances.

Anodic oxygen, however, is the strongest of all oxidizing agents. It attacks benzene and its homologues directly in the nucleus, changing them into phenols and quinones. It can also effect the linking together of two molecules by eliminating one atom of hydrogen from each. In addition side-chains are attacked, forming aldehydes and oxides. The latter substances themselves can be further transformed into hydroxy-acids, which in turn can undergo degradation.

Several procedures for the electrolytic oxidation of aromatic compounds have been proposed. Mann and Paulson[101] found that toluene could be oxidized to benzaldehyde by the electrolysis of toluene-acetic acid-nitric acid mixtures. The highest yield was 19 per cent. A diaphragm and electrodes of sheet platinum were used. Acetone, alcohol, and carbon tetrachloride were found to be unsatisfactory as solvents and the principal objection to ether was its low boiling point. The reaction is distinctly electrochemical, since experiments carried out under identical conditions but without the applied electromotive force yielded no traces of benzaldehyde.

Both the indirect and direct oxidation of toluene has been investigated by Mitchell.[102] In the former method toluene was first sulphonated to p-toluenesulphonic acid. The electrolysis of a 40 per cent aqueous solution of this acid at 100° C. yielded p-sulphobenzoic acid in quantities equivalent to 21.8 per cent current efficiency. An anode of lead wool was used. In the direct method, with an emulsion of toluene and a solution of 2N sulphuric acid or sodium hydroxide, practically no oxidation took place. The addition of various emulsifying agents did not help. However, when the toluene was emulsified with 55 per cent sulphuric acid containing manganous sulphate, at a temperature of 55° C., and using sheet lead electrodes, benzaldehyde was produced at a current efficiency of 61 per cent in a continuous system. With chromic sulphate under the same conditions benzoic acid was produced with an efficiency as high as 54 per cent. In these two latter treatments the toluene is oxidized by the manganic sulphate or chromic acid, which are the primary anodic oxidation products. A certain amount of cresol is also produced by the direct anodic oxidation of toluene.

The electrochemical oxidation of xylene yields a variety of products depending upon the conditions during electrolysis.[103] Using a lead oxide anode, a lead cathode, and a diaphragm, the oxidation of toluene suspended in 0.5N sulphuric acid yielded p-toluic acid and aldehyde, p-xylenol, p-xyloquinol and p-xyloquinone. Without a diaphragm the products were about 70 per cent p-hydrotoluoin, 10 per cent iso-p-hydrotoluoin, and some p-tolylmethyl alcohol. Suspending the xylene in a mixture of acetone and 2N sulphuric acid the oxidation products were p-tolualdehyde, a trace of terephthalic acid, and a small quantity of ω-acetylstyrene-p-carboxylic acid. The latter compound was formed by the condensation of acetone with the terephthalic acid formed by the electrochemical oxidation.

Anthracene, suspended in dilute sulphuric acid, is oxidized only to a very slight extent even at 80° C. The use of ceric sulphate as a catalyst increases the current efficiency to only 8 to 9 per cent. With the type of anode developed by Rasch and Lowy,[104] however, a current efficiency of over 26 per cent was obtained. This type of electrode is prepared by inserting a paste of a finely ground mixture of anthracene and lead peroxide (1 : 3) with dilute sulphuric acid into the openings of the grid plate of a lead accumulator, after the grid has been superficially oxidized with nitric acid. This grid is then used as the anode in an electrolytic cell containing dilute sulphuric acid. The addition of ceric sulphate to the sulphuric acid increased the current efficiency to over 40 per cent with this anode.

For the electrochemical oxidation of anthracene and other organic compounds Field[105] suggested a catalyst made from Swedish cerite ore. The ore is treated with concentrated sulphuric acid at 200° C., and then with cold water. The precipitate formed on the addition of oxalic acid, or sodium hydroxide, and which contains metals of the rare earth type, is used as a catalyst.

MISCELLANEOUS OXIDATION REACTIONS

The catalytic oxidation of the nitro and halogen derivatives of toluene proceeds in about the same manner as the oxidation of toluene itself.[106] Thus, in the oxidation of p-nitrotoluene with air at 270° to 300° C. in the presence of granulated tin vanadate as a catalyst a 14 to 16 per cent yield of p-nitrobenzoic acid was obtained. Under the same conditions o-bromotoluene yielded about 24 per cent of o-bromobenzoic acid, and o-chlorotoluene about 14 per cent of o-chlorobenzoic acid. o-Nitrotoluene, however, decomposed to such an extent that very little or practically none of the corresponding acid could be obtained.

[106] Maxted and Dunsby, *J.C.S.*, 1928, 1439.

Acenaphthene vapors when mixed with 9 to 12 volumes of air and passed over manganese dioxide or an oxide of vanadium or molybdenum at about 400° C. yielded a mixture of acenaphthylene, acenaphthenequinone, and naphthalic anhydride. The products could be separated by fractional condensation.[107] Among the catalysts employed by Jaeger[107a] for the vapor-phase oxidation of acenaphthene are compounds of alkali and alkaline earth metals, molybdenum, tungsten, uranium, chromium, iron, silver, manganese, aluminum, nickel, and cobalt.

β-Naphthol heated to 300° C. in contact with air in the presence of either tungsten or molybdenum trioxides gave 2,2′-dinaphthyl ether.[108] Under similar conditions but employing vanadium pentoxide, *β*-dinaphthol was obtained. At 340° C., 1,1′-dinaphthylene-2,2′-oxide was formed, though in the absence of air only the 2,2′-dinaphthyl ether was produced. When titanium dioxide was used, the product was mainly 2,2′-dinaphthyl ether together with some 1,1′-dinaphthylene-2,2′-oxide.

Lucas and Bibb[109] have shown that a mixture of benzene vapor and air, containing a small quantity of nitric acid vapor or oxides of nitrogen as catalysts, passed through a tube at 600° to 750° C. yields some phenol. By regulating the conditions, such as rate of flow, concentration of the catalyst, and temperature of the tube, 5 to 5.5 per cent of the benzene was oxidized to phenol.

Benzoic acid and p-nitrobenzoic acid are the main products if toluene is boiled with nitric acid.[110] Some o-nitrotoluene, carbon dioxide and traces of picric acid are also formed. No p-nitrotoluene was obtained as this substance is comparatively easily oxidized to p-nitrobenzoic acid. Little difference was noticed in the results obtained by oxidizing under 10 and 15 atmospheres pressure.[111] Reaction proceeds slowly at 150° C., much faster at 180° to 185° C., and above 190° C. there is a tendency to explode. Benzoic acid was recovered almost quantitatively when toluene was heated with 22.5 per cent nitric acid at 180° to 185° C. under 10 to 20 atmospheres of oxygen.

Oxidation of hydroaromatic compounds can be effected with nitric acid. Cyclohexanol, for example, may be oxidized with 50 per cent nitric acid at 50° C. in the presence of a small quantity of ammonium vanadate.[112] This operation yields principally adipic acid, together with small proportions of both glutaric and succinic acids. The vapor phase oxidation of methylcyclohexanol with air at 300° to 400° C., using vanadic acid as a catalyst, also gives adipic acid.[113] A mixture of cis- and trans-hexahydro-o-phenylenediacetic acid, with some octahydrocinnamic-o-carboxylic acid, results from the treatment of decahydronaphthol with 60 per cent nitric acid at 50° C. in the presence of ammonium vanadate.[114]

[113] Deutsche Hydrierwerke A.-G., German Patent 473,960, 1926; *Chem. Abs.*, 1929, **23**, 2988. The action of free oxygen on hydroaromatic compounds has been discussed by Chavanne, Miller and Cornet (*Bull. soc. chim. Belg.*, 1931, **40**, 673; *Brit. Chem. Abs.* **A**, 1932, 372) and by Wienhaus (*Z. angew. Chem.*, 1928, **41**, 617).

Binapfl[114a] treated tetrahydronaphthalene at 100° C. for 9 hours with air or oxygen in the presence of nitrocellulose and benzyl nitrate, the products being α-ketotetrahydronaphthalene and α-hydroxytetrahydronaphthalene. The oxidation of side chains of aromatic compounds such as methylbenzanthrone has been effected by heating them with selenious or selenic acid.[114b] The aromatic ring is said to be unattacked by this treatment and the oxidation proceeds to the formation of aldehyde, carboxyl or ketonic groups.

Benzene and its homologues absorb ozone like unsaturated compounds.[115] This absorption, however, is not complete, even though ozone is present in large excess.[116] Compounds such as styrene and phenylcyclohexene add ozone at the ethylenic linkage and when this addition is complete the nucleus is attacked. Acetylenic hydrocarbons, in their behavior towards ozone, are intermediate between ethylenic and benzenoid hydrocarbons. Ozonization curves can be used to distinguish sharply between these three types of hydrocarbons.

Instead of air or oxygen, carbon dioxide can be employed in some instances as an oxidizing agent. For example, toluene and anthracene are oxidized to benzaldehyde and anthraquinone, respectively, by conducting the vapors of these compounds mixed with moist carbon dioxide over vanadic acid deposited on pumice at 480° to 500° C.[117]

The treatment of coal with potassium permanganate at 70° to 130° C. to yield aromatic carboxylic acids, of which mellitic acid is the chief constituent, has been described by Bone and Quarendon.[117a]

Kinney and Langlois[117b] observed that, with catalysts of the zinc-copper-chromium oxide type, benzene was directly carboxylated to benzoic acid at about 300° C. under a pressure of 30 atmospheres. The yield of acid was low, however, but was increased in a further study by Kinney and Ward[117c] by the use of a similar catalyst prepared in a different manner. In this later investigation, diphenylmethane, triphenylmethane, styrene, phenol, anisol (phenyl ethyl ether) bromobenzene, dimethylaniline, nitrobenzene, catechol, resorcinol and quinol, but not phenol, were also carboxylated by this treatment. Similar treatment of diisopropylbenzene or cuminol with carbon dioxide in the presence of aluminum chloride, cuprous chloride or hydrogen chloride has been said to yield diisopropylbenzaldehyde.[117d]

Chapter 42

Production of Acids from Petroleum Hydrocarbons

Methods of producing acids from hydrocarbons by oxidation may be classified roughly into three main divisions:

(1) The oxidation of hydrocarbons by air, oxygen, nitrogen dioxide, or other gaseous oxidizing agents. This type of reaction may be accelerated by catalysts, and the hydrocarbons can be gases, liquids or solids. This method appears to be most promising from an industrial point of view.

(2) The oxidation of hydrocarbons by ozone. The low yields generally obtained by this method appear to limit its application materially.

(3) The conversion of halogen derivatives of the hydrocarbons, particularly chlorides, to unsaturated compounds and subsequently to acids by oxidation. This method is perhaps too complicated for any extensive industrial adaptation.

In this chapter the production of acids from both gaseous and liquid hydrocarbons by vapor and liquid phase oxidation is discussed. Some oxidation processes which yield acids and a variety of other products have also been mentioned in a preceding chapter (36). The oxidation of solid hydrocarbons (such as paraffin wax) is described in the next chapter. The acids obtained from heavy petroleum distillates resemble, more or less, the "wax acids" produced from paraffin wax.[1]

OXIDATION OF GASEOUS HYDROCARBONS

Methane can be oxidized to formaldehyde, as described in Chapter 38, and formaldehyde to formic acid. Numerous attempts have been made to produce formic acid by reaction between carbon monoxide and water, thus:

$$(1)\quad CH_4 + O_2 \longrightarrow CO + H_2O + H_2$$

$$(2)\quad CO + H_2O \longrightarrow HCOOH$$

Reaction (1) is, of course, that involved in the partial oxidation of methane to produce hydrogen from natural gas.[2] Reaction (2), however, is a reaction not particularly pertinent to this chapter. Syntheses with carbon monoxide[3] are too far removed from the scope of this volume, hence only a few which pertain to the production of formic acid are given.

Nielsen[4] proposed to effect the partial oxidation of methane to formic acid in the presence of a copper suboxide catalyst at temperatures which are said to range from 250° to 800° C. The process is not continuous since the catalyst becomes reduced and requires reoxidation.

---

[1] Danaila and Boltus-Goruneanu (*Bul. chim. soc. romana stiinte,* 1929, 31, 133-200; *Chem. Abs.*, 1930, 24, 2282; *Chem. Zentr.,* 1931, 1, 1393) believed that only the acids from paraffin wax can have practical application—those from mineral oils being semi-solid acids resembling humic acids, of objectionable odor and color, which they state are useless in the manufacture of soap. These investigators reviewed the literature from 1855.

[2] This reaction is discussed more completely in Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., Inc., New York, 1930, 771; see also Chapter 8 of this book; Marek and Hahn, "Catalytic Oxidation of Organic Compounds in the Vapor Phase," Chemical Catalog Co., Inc., New York, 1932, 259.

[3] For detailed information on this subject see Ellis, *op. cit.*, 652, *et seq.*

[4] U. S. Patent 1,665,175, Apr. 3, 1928; *Chem. Abs.*, 1928, 22, 1832. See also Nielsen, U. S. Patent 1,672,081, June 5, 1928; British Patent 198,385, 1921; *J.S.C.I.*, 1923, 42, 760A.

Dreyfus[5] stated that when methane together with carbon monoxide or carbon dioxide is passed under pressure over heated catalysts, a mixture of acetic acid, acetaldehyde, and acetone is formed. The temperature during the reaction can range between 120° and 350° C., and the pressure from 12 to 500 atmospheres. The catalysts may be (1) copper, iron, nickel, cobalt, platinum, palladium, platinum or palladium black, ferrites, ferrates, cobaltites or cobaltates of alkali or alkaline earth metals used in conjunction with zinc, magnesium, calcium, aluminum, chromium, molybdenum and vanadium or (2) carbonates which dissociate below 500° C., as for example nickel carbonate.

The reactions involved in this process have been known for a long time.[6] Moldavski,[7] by thermodynamic calculations[8] and by experiment, showed that this procedure is not feasible economically. In his tests, Moldavski obtained an acetic acid yield of 0.00001 per cent on passing the gases once over a catalyst made by heating nickel formate to 200° to 250° C.[9]

Acetaldehyde, which is one of the partial oxidation products of gaseous hydrocarbons (see Chapter 38), can be further oxidized to acetic acid by passing its vapors together with air over copper or platinum at 150° to 200° C.[10] The oxidation of acetaldehyde or its solutions can also be effected by conducting the vapors countercurrent to a stream of air through a series of towers maintained at gradually increasing temperatures.[11]

In a study of the oxidation of acetaldehyde with oxygen, Pease[12] came to the following conclusions: (1) Peracetic acid is the largest product except when the reaction vessel is coated with potassium chloride; (2) the reaction is accelerated by broken glass packing, and by coating the vessel with potassium chloride; (3) the reaction is inhibited by ethyl alcohol vapor but not by water vapor. Nitrogen, hydrogen and ethane are without effect on the rate. (4) The initial rate is proportional to the square of the acetaldehyde concentration and independent of the oxygen concentration. (5) The reaction is auto-accelerated and is believed to be of the chain type, with chains starting on the walls and ending in the gas phase.

Butyraldehyde may also be oxidized by oxygen producing butyric acid.[13]

The indirect oxidation of ethylene to acetic acid can be effected by converting it to ethyl alcohol (see Chapter 13) which can then be oxidized to acetic acid either (1) electrolytically, (2) with chromic acid or potassium permanganate, or (3) by air.[14] Strache[15] described a method in which unsaturated hydrocarbons, obtained from a variety of sources, are esterified with a mineral acid, such as sulphuric acid, and then oxidized with potassium dichromate. Volatile acids can be separated from the products by steam-distillation.

Acetic acid may be produced from acetylene[16] by passing this gas together with hydrogen and air, the latter being added in stages, over the vanadates of tin, silver, or mercury at 200° to 250° C.

OXIDATION OF LIQUID HYDROCARBONS IN THE LIQUID PHASE

One of the earliest investigators of the production of organic acids from petroleum hydrocarbons was Schaal.[17] His work included the oxidation of not only petroleum hydrocarbons but also those resulting from the distillation of coal, shale and peat. In the oxidation air was passed into a mixture of hydrocarbons and alkalies, such as the carbonates or hydroxides of the alkali or alkaline earth metals, heated under pressure. Additional alkali was added from time to time during the heating so as to maintain always a slight excess. Copper was found to be a good catalyst. Pumice, infusorial earth, sodium chloride and sulphate also aided the reaction. After the oxidation, the soluble materials were removed with as little water as possible, leaving the acids dissolved in the petroleum. These acids were then extracted with alkalies and afterwards liberated by the addition of mineral acids.[18]

In several instances the hydrocarbons were difficult to oxidize, in which event oxidation was started by the use of bleaching powder. With this reagent the hydrocarbon mixture had to be cooled frequently to avoid too violent a reaction. At the end of the oxidation the lime was removed with hydrochloric acid and the organic acids were extracted from the oil with alkalies. The residual oil could then be oxidized further with air.

Löffl[19] oxidized petroleum fractions at 115° to 120° C. under 3 atmospheres pressure in the presence of water.[20] Lead and mercury compounds were recommended as catalysts. The products were acids together with some aldehydes and ketones, which were fractionated by distillation up to 200° C. with superheated steam and then by steam distillation *in vacuo.*

Zerner[21] produced acids by the oxidation of liquid hydrocarbons obtained on the distillation of petroleum in the following manner: the hydrocarbon was treated with liquid sulphur dioxide, to remove unsaturated compounds, and then blown with air or other oxygen-containing gases, in the presence of bases. Fuming sulphuric acid can be used in place of liquid sulphur dioxide to remove constituents which form resinous or asphaltic substances. This preliminary refining, however, may be eliminated in one of two ways: (1) the reaction-promoting agents which are formed by blowing the liquid hydrocarbons in an acid medium are added to the hydrocarbons before treating in the presence of a base, or (2) the liquid hydrocarbons may be blown first in the presence of an acid and the treatment afterwards continued in the presence of a base.[22] The refining may be eliminated entirely if oxidation is carried out in steps in the presence of a base and detrimental reaction products are removed between steps by filtration.[23] Luther and Harder [23a] suggested a preliminary purification of paraffin or naphthene hydrocarbons by treating with dilute nitric acid at 80° to 100° C., and subsequently with concentrated sulphuric acid. Pressure hydrogenation in the presence of metals of groups IV to VII have been proposed for the removal of sulphur compounds prior to oxidation of hydrocarbons by air with a manganese stearate catalyst.[23b]

Oxidation of Caucasian oil at 140° C. by air in the presence of fuming sulphuric acid yielded about 5 per cent crude acids.[24] Of the crude acids approximately 60 per cent was soluble in benzene and the remainder, acids and resins, was insoluble.[25]

The work of Tuichinin and Ivanov [26] indicated that treatment with liquid sulphur dioxide or with 50 per cent alcohol increased the oxidizability of a Baku gas oil more than did anhydrous sulphuric acid. Poor results were obtained with oleum, however.

In comparing the catalytic action of various metals, Petrov, Danilovich and Rabinovich [27] oxidized petrolatum oil at 100° to 105° C. in the presence of powdered lead, iron and zinc. Of these metals, lead proved to be the best, yielding about 2.6 to 3.6 per cent acids. With the other metals the yields were less or no more acids (0.41 to 0.7 per cent) than were produced in the absence of the catalyst. The oil, however, after being refined with sulphuric acid and alkali, was not oxidized when exposed to a current of air for 49 hours at 100° C., either in the presence or absence of zinc or iron. Lead catalyzed the formation of hydroxy-acids which were insoluble in benzene.

Arditti [28] observed that with zinc and lead, oxidation of paraffin oil at 130° C. is faster at first but after some time it becomes even slower than in the absence of a metallic catalyst. Copper and nickel definitely hasten the reaction but sulphur retards it.

In the oxidation of paraffin oils, Tütünnikoff [29] used manganic oxide, manganese dioxide, and red lead oxide as catalysts. The lead oxide was found to be the best catalyst. By long passage of air it was possible to oxidize 90 per cent of the oil. The paraffin oil yielded chiefly saturated acids.

Metallic salts of organic acids are also used as oxidation catalysts. For example, Teichner [30] oxidized Galician spindle oil which had been freed of unsaturated compounds by treatment with 20 per cent oleum, with air or oxygen at 110° C. in the presence of zinc stearate.

Liquid petroleum hydrocarbons are oxidized under a pressure of 100 to 320 pounds per square inch, at temperatures of about 120° to 130° C., with manganese stearate or oleate as a catalyst, in a method developed by Burwell.[31] If oxidation is carried on until about 20 per cent of the hydrocarbons are oxidized, the products are principally the simple carboxylic acids. Hydroxy-acids predominate when the oxidation is conducted to the extent of about 80 per cent. The type of distillate being oxidized also determines to some extent the kind of acid which will be present in the larger proportion. The two types of acids may be separated[32] in several ways: In one method, fresh oil is added to the oxidized mixture. The simple carboxylic acids are thus dissolved and the hydroxy-acids can then be withdrawn. The mixed acids can also be separated with concentrated sulphuric acid, which dissolves the hydroxy-acids but not the simple carboxylic acids.[33] It is also possible to partially oxidize the hydrocarbons, withdraw the products insoluble in the hydrocarbon mixture, and then continue oxidation. The products obtained by the oxidation of a 42° Bé distillate from Pennsylvania crude oil by Burwell's procedure were: 5 per cent formic acid, 5 per cent of acids varying from $C_7H_{14}O_2$ to $C_{12}H_{24}O_2$, and 90 to 95 per cent of liquid acids having an average molecular weight greater than 345.

Dietrich[34] destroyed hydroxy acids by heating the oxidation products of high molecular hydrocarbons in the presence of catalysts which have a dehydrating effect. For instance, the crude product obtained from the oxidation of gas oil was heated for 4 hours at 250° C. and under 50 atmospheres pressure in the presence of naphthalenemonosulphonic acid, nickel and hydrogen. The solubility of the initial substance in petroleum ether changed from 58.2 to 91.8 per cent, and the iodine value from 17.8 to 46.7.

In addition to the metallic salts of fatty acids, Petrov and his collaborators[35] showed that metallic salts of naphthenic acids also can be used for the oxidation of oils. With an acid-treated Caucasian oil the yield of acids on oxidation was considerably increased by the presence of cobalt naphthenate. This same substance also produced a much higher yield of acids than did lead, which had proven to be the best metallic catalyst.[36] The activities of various naphthenates were compared by these same investigators. Manganese naphthenates were the most and zinc naphthenates the least active. Copper and lead naphthenates were intermediate in activity.[37] The manganese salts of sulpho-acids of high molecular weight were the most active catalysts. It was observed that oils refined with sulphuric acid were oxidized to about the same extent as unrefined oils. The former, however, yielded the larger quantity of soluble acids and the latter gave more hydroxy-acids. Distilled oils which were highly refined with sulphuric acid were not oxidized in the absence of a catalyst but darkened as a result of decomposition. The oxidizability of an acid-treated oil, however, can be increased also by the addition of the lithium, sodium, potassium, or iron salts of naphthenic acids.[38]

[32] Stetzenko and Buman (*Masloboino-Zhirovoe Delo,* 1932, No. 9, 18; *Chem. Abs.*, 1933, **27**, 3354) found that the detergency of hydroxy-acids which form in the oxidation of solar oils is about equal to that of the carboxylic acids, hence, this separation may not be necessary in many cases in which the acids are to be used in soap manufacture. The acids had about one-half to one-third the detergent power of fatty acid soaps and were similar in properties to the soaps of naphthenic acids. Dietrich and Harder[38a] obtained high-molecular oxygenated compounds by oxidizing Pennsylvania middle oil with a five-stage air treatment at 160° C. in the presence of manganese naphthenate. The mixture obtained was first treated with sodium hydroxide to remove the acids formed and then the residue hydrogenated at 200° C. with a nickel-kieselguhr catalyst. On shaking the resulting mixture with liquid sulphur dioxide, two layers formed, the upper containing hydrocarbons of hydroxyl number 1.3, and the lower, alcohols of hydroxyl number 95.

In oxidizing mineral oils to acids, Zerner[39] used, among other catalysts, manganese resinate and turpentine. Only catalysts containing a metal, especially manganese, were found to start the oxidation at low temperatures, and variations in the quantities of catalyst used, from 0.1 to 5 per cent, made little difference. He considered the disagreeable odor of the products to be a disadvantage in their use for soap making.

As catalysts for the oxidation of mineral oils to acids, acetylacetonates of manganese, cerium, nickel, cobalt, or zinc have also been suggested.[40] Metallic oxides may be added at the same time.

Luther and Klein[40a] suggested the use of aliphatic saturated carboxylic acids containing up to four carbon atoms in the molecule. They subjected the hydrocarbons in the liquid phase, to which had been added from 2 to 20 per cent of formic, acetic, or propionic acid, to treatment with oxidizing gases at 80° to 200° C. under pressures as high as 50 atmospheres. Resinates or oleates of alkali or alkaline-earth metals, aluminum, magnesium or manganese, and solid bodies of aluminum, or inert bodies such as glass and porcelain, may be employed as catalysts. Explosions are prevented by controlling the ratio of oxidizing gas to the hydrocarbon liquid by dilution with an inert gas, such as carbon dioxide. In this method esters are formed by the reaction of the resulting alcohols and the added acids. The esters are not attacked by the oxidizing agents and no resinification or polymerization takes place.

Activated carbon, obtained from vegetable raw material in such a manner that the structure of the raw material is retained, has also been proposed as a catalyst for the oxidation of oils.[41] The carbonized material may be used in one of three ways: (1) It is mixed with the liquid and the mixture under pressure is treated with the oxidizing gas. (2) The liquid and gas can be passed, countercurrently, through a column filled with the granular carbon. Or, (3) the carbon can be made to adsorb the oxidizing gas, for example, at low temperatures under pressure, and the liquid is then treated with the charged carbon.

Yamada[42] studied the effect of oxidation at 130° C. on the acid saponification and acetyl values of a petrolatum and a switch oil. These values increase almost linearly with the time, but the acetyl value of the unsaponifiable fraction shows a definite maximum.

OXIDATION OF LIQUID HYDROCARBONS IN THE VAPOR PHASE

The vapor-phase oxidation of light distillates has been discussed in Chapter 36. Examples are described by Ellis,[43] in which a petroleum distillate is cracked by being passed through a heated zone and the vapors are mixed with air, or oxygen, and conducted over a heated catalyst. Both mono- and di-basic acids, such as formic, acetic, maleic and phthalic, are obtained. Shimose[44] also showed that vapor-phase catalytic oxidation of both saturated and unsaturated hydrocarbons leads to the production principally of maleic acid, together with carbon dioxide and formaldehyde.

Schill and Seilacher[45] dispersed heated grease or oil in the form of a spray with a hot blast of air. Part of the spray condenses immediately, but the greater portion is passed through a series of chambers, allowing longer contact for oxidation. Ozonized air or a mixture of ammonia and air can be used. The products may be employed in the manufacture of leather and soap, and in dyeing as a substitute for tournante oil.

In a process developed by Walter[46] the petroleum distillate, boiling above 300° C., is sprayed into a current of air mixed with steam. After being conducted over a catalyst, consisting of asbestos coated with finely divided copper oxide, which is kept at a red heat, the mixture is cooled in a condensing apparatus. By regulating the proportions of air and steam it is possible to keep the catalyst at a red heat without the application of heat from an outside source. The aqueous layer of condensed products contains acetic acid and its homologues. From the oily top layer it is possible to extract the water-insoluble acids with alkaline solutions. Aldehydes can be separated from the organic acids with sodium bisulphite.

This method of oxidizing liquid petroleum distillates has been modified as follows:[47] The liquid is sprayed through atomizers into the top of a tower which is kept at 80° C. and is packed with pumice impregnated with nickel oxide. At the bottom of the tower either oxygen or oxygen diluted with nitrogen is introduced. The gases leave the tower at the upper end and, after passing through condensers and scrubbers, can be used over again with the addition of fresh oxygen. The hydrocarbons pass out of the lower end of the tower into reservoirs, and from there through the apparatus again until sufficient oxidation has been effected. This method of oxidation favors the production of high molecular weight, water-insoluble acids. Blowing of the distillate results in the formation of considerable quantities of alcohols, esters, and low molecular weight, water-soluble acids.

To oxidize low-boiling aliphatic hydrocarbons to acids Wiezevich and Tannich[48] circulated the gases together with air through a non-catalytic partial oxidation zone under pressures[49] of 300 to 3000 pounds per square inch at temperatures of 200° to 600° C.

Aldehyde-acids have been found to form as the principal products when liquid hydrocarbons are oxidized at high temperatures. To produce aldehydes and aldehyde-acids,[50] the vapors of the liquid hydrocarbons together with air, or other oxygen-containing gas, are passed over metallic oxides at 500° C. Oxides of molybdenum, especially the "blue oxide," appear to be the best catalysts. The quantity of oxygen actually present in the gas is generally slightly in excess of that required stoichiometrically, and steam can be added to lessen the risk of explosion. The condensed products contained, as a typical example, about 70 per cent aldehyde-acids, 25 per cent aldehydes, and about 5 per cent unchanged hydrocarbons together with undetermined substances.

The aldehyde-acids can be separated from the other materials by precipitation as insoluble salts, such as those of aluminum.[51] The solution of the aldehydes and aldehyde-acids is agitated with the hydroxide of the metal and the insoluble salt thus formed is removed by filtration or decantation. Or the mixture containing aldehyde, aldehyde-acids, and hydrocarbons can be heated to 100° C. with the carbonate or hydroxide of the metal. On cooling, the soap separates from this mass and can be easily removed. Numerous derivatives of these oxidized products have been proposed.[52]

Efforts have been made to eliminate the disagreeable odor associated with the soaps of the aldehyde-acids by converting these acids to dibasic acids.[53] The oxidation can be carried out with nitric acid or with nitrogen dioxide in the presence of vanadium pentoxide or molybdenum trioxide or the acids, dissolved in water, may be oxidized with chlorine in the presence of cobalt chloride. The soaps themselves can also be oxidized with chlorine provided the medium is kept alkaline. In some instances the aldehyde-acids can be oxidized to dibasic acids in the vapor phase with air or oxygen in the presence of a uranyl molybdate catalyst.

OXIDATION OF LIQUID HYDROCARBONS BY OTHER OXIDIZING AGENTS

Acids, as well as esters, are obtained when petroleum benzines which boil below 180° C. are oxidized at temperatures varying from 80° to 200° C., under 50 atmospheres pressure, with oxides of nitrogen.[54] Resinates, oleates, and enolates of the alkali and alkaline earth metals, magnesium, aluminum or manganese can be used as catalysts. The products from the oxidation of hexane, for example, under these conditions contained the lower members of the fatty acid series with 2 to 6 carbon atoms and their esters.

Ozone can be used as an oxidizing agent for the preparation of either acids or aldehydes and ketones.[55] For example, lignite-tar oil is treated with liquid sulphur dioxide which removes the highly unsaturated compounds but leaves the less saturated compounds. This oil is then cooled until partial solidification takes place and the liquid portion is separated and fractionated. The fraction which boils between 100° and 250° C. at 10 mm. pressure is treated with ozone until the increase in weight amounts to 8 to 12 per cent. This ozonized oil is next hydrolyzed with steam and the acids thus formed are separated with hot concentrated potassium hydroxide solution. On hydrolysis of the resulting soaps, principally palmitic and stearic acids are produced. The oil, after the removal of the acids, is recycled. The total yield of acids amounts to about 18 to 20 per cent of the oil.

Aldehydes and ketones formed on treating ozonized oil with steam can be recovered by extraction with potassium hydroxide and then with sodium bisulphite solution. The crystalline bisulphite compounds are treated successively with sodium carbonate and sulphuric acid and the resulting liquid is steam-distilled. Better yields of aldehydes and ketones (up to 80 per cent) may be obtained if the bisulphite treatment is carried out in the presence of potassium bisulphate.

The following method has been suggested[56] for mineral oils which are oxidized only with difficulty. The oils are first refined with sulphuric acid or with liquid sulphur dioxide and then treated with ozone. The ozonides thus formed are removed by adsorption and on treatment with steam, are hydrolyzed to acids.

The electrochemical oxidation of mineral oils to produce acids has been described by Atanasiu,[57] but this is described more completely in Chapter 43.

For converting kerosene and spindle oil to acids, Schrauth[58] proposed to chlorinate the oil to monochloro-derivatives. These are then subjected to fusion with alkalies. The temperature during fusion is first maintained at 200° to 230° C., but during the latter part of the operation, is allowed to rise to 300° C. The product obtained after 6 to 8 hours is a mixture of dry, odorless soaps which are soluble in hot water and lather freely. The excess alkali may be neutralized with hydrochloric acid or fatty acids, or after remelting, the soap may be extracted with steam and water. Hydrogen is evolved during fusion.

For the photochemical oxidation of paraffin oils to fatty acids, a transmission catalyst such as anthraquinone together with an auxiliary catalyst, for example, sodium or potassium hydroxide, calcium hydroxide, adsorptive charcoal which may be impregnated with metallic salts or oxides, or inorganic gels has been proposed.[59]

Acids, together with ketones, have been produced by heating either aliphatic or aromatic hydrocarbons under pressure with carbon monoxide.[60] The catalysts used were the anhydrous chlorides of aluminum and boron. In the presence of aluminum chloride temperatures of 30° to 60° C. are required, but with boron chloride, 180° C. Normal pentane, for example, when treated with carbon monoxide yielded a ketone, boiling at 114° to 116° C., a mixture of ketones boiling at 116° to 250° C., and hexanoic together with other acids.

Alleman[61] obtained acids, melting below —30° C., from the alkali used in washing acid-treated lubricating distillates. The alkali is freed of oil and resins by extraction with gasoline, and the acids are then liberated by hydrolyzing with steam under pressure or by the addition of mineral acids. Further purification results on distilling under reduced pressure. Insoluble salts of these acids can be made by adding soluble metallic salts, such as calcium chloride or nickel sulphate, to the solution of the acids in alkali.

Luther and Klein[61a] produced unsaturated aliphatic acids by distilling the crude oxidation products of higher paraffin hydrocarbons under a pressure of about 8 mm. at 100° to 300° C. in the presence of sulphuric acid, thereby converting the hydroxy fatty acids present into unsaturated acids. The operation may be facilitated by passing an inert gas through the mixture during the distillation.

Chapter 43

Oxidation of Paraffin Wax. Production of Synthetic Fats

It has long been known that when higher paraffins are heated in the presence of air for considerable periods of time they absorb oxygen and become brown in color. Such observations were made at an early date by Bolley[1] and also by Jazukowitsch.[2] The effect of other oxidizing agents on paraffins has also been investigated. Gill and Meusel,[3] for example, studied the action of chromic acid mixtures and Hofstädter[4] and Pouchet,[5] that of nitric acid. Various investigators noted the formation of acetic and other organic acids when air was passed through hot mineral oils.[6]

Schaal[7] was among the first to derive oxidation products in any quantities from petroleum hydrocarbons. He passed a stream of air or oxygen through the heated hydrocarbon in the presence of sodium hydroxide or calcium oxide and thus obtained the salts of the acids. Later, Byerley and Mabery[8] described a process for manufacturing "artificial asphalt" which consisted of blowing air through high-boiling petroleum residues for several days at a temperature of about 230° C. However, as the reaction is exothermic, the temperature often rose much higher. Because of these high temperatures, the final product contained very little oxygen. The oxidation was also probably accompanied by polymerization and condensation of oxygen compounds, such as alcohols and aldehydes. At lower temperatures, however, small proportions of both aliphatic and naphthenic acids were formed.

The production of acids and esters was effected by Gray[9] in "deblooming" petroleum distillates and other hydrocarbons. The process involved the passage of air through the heated hydrocarbons in the presence of ultraviolet light. Various metals or their salts, or porous materials which had been previously impregnated with such substances, were used as catalysts. Ellis[10] also debloomed petroleum distillates by the use of ultraviolet light. In this method, however, oxidation is minimized by the presence of an inert gas such as nitrogen. If the inert gas is not used and oxidation does take place, the oxidation products may be removed afterwards by employing any of the usual methods.

The oxidation of higher paraffins appears to offer a method for the production of high molecular weight aliphatic acids which may be used for the synthesis of fats or in the manufacture of soaps. Oxidation may be effected with air or other oxidizing agents, and with the formation of alcohols and aldehydes very probably as intermediate products. As pointed out in the chapter on the oxidation of methane (Chapter 37), oxidation of high molecular weight hydrocarbons proceeds in steps which seem to be in accord with the hydroxylation theory. In this chapter the oxidation of such hydrocarbons is considered in greater detail.

The term "wax acids" appears to be a better designation for these acids than "fatty acids," for it indicates (1) that wax is the source instead of fats, and (2) that these acids differ slightly in their chemical constitution from the true fatty acids. This difference so far as is recognized will be pointed out later.

OXIDATION WITH AIR

Benedix[11] was able to oxidize petrolatum by intimately mixing it with sodium peroxide in the presence of water or with hydrogen peroxide diluted with alkalies or alkaline salts. The reaction was promoted by the presence of alcohol and was completed by heating to 80° C. under pressure. The hydrocarbons were believed to oxidize to acids and these reacted with the alkali present to form soaps.

By passing a current of air through paraffin wax which was kept at a temperature of 290° to 300° C., Schulz[12] obtained principally aldehydes, together with some carbon monoxide and dioxide, and a small quantity of acids.

The use of lower temperatures (100° to 120° C.) during oxidation is recommended.[13] Melted wax is oxidized by a blast of air until a deep yellow color is obtained. Oxidation is then stopped and the product is separated into its oxidized and unoxidized portions. In this way about 70 per cent of the wax was oxidized to oleic and other acids, a ceresin-like wax, aldehydes, and other substances. From the volatile products aliphatic acids and aldehydes were separated. The unoxidized portion may be retreated. A catalyst, such as paraffin wax which has previously been oxidized or mercuric oxide may be used.

Wax acids were obtained by Bergmann[14] by passing air for 15 to 18 days through paraffin wax heated to 130° to 135° C. At the end of that time the product was a brown, unctuous mass, which had an acid number of 132 and formed soaps with alkalies. The acid products were separated from the mass by forming the barium salts. These acids, after being liberated by the use of hydrochloric acid, were further separated by fractional distillation under reduced pressure. The fraction distilling between 270° and 310° C. at 100 mm. pressure was identified as lignoceric acid. From the fraction boiling between 230° and 270° C. two acids were isolated: one melted at 53.7° C., and had the formula $C_{11}H_{22}O_2$ and was unidentified; the other melted at 38.4° C. and was thought to be isopalmitic acid, $C_{16}H_{32}O_2$.

The production of acids from paraffin wax by a similar process of oxidation has also been described.[15] If oxidation is very prolonged a brown resinous substance is obtained which has a possible use in varnish manufacture.

Dovanov[16] treated Grozny paraffin at 160° to 170° C. with air at the rate of 60 to 80 cubic meters per hour for a period of two and one-half hours. He found that the oxidation products had an acid number of 45 to 50, and contained about 10 per cent of water-soluble acids. The larger part were in the form of ethers and could be separated only by saponification followed by fractionation. The dry distillation of their calcium soaps yielded about 22.7 per cent of ketones, of which the largest portion boiled between 65° and 100° C.

Fischer, Schneider, and Jantsch[17] studied the pressure oxidation of paraffin wax. Their oxidation experiments were carried out in an autoclave equipped with an agitator. Two hundred grams of paraffin wax and 800 cc. of 2.5N sodium carbonate solution were heated to 170° C. while a current of air (200 liters per hour) under 30 atmospheres pressure was passed through the mixture. Oxidation was continued until one-half of the alkali had been neutralized by the wax acids which were formed. The average molecular weight of the acids was 250 and these were found to be insoluble in water and satisfactory for making soap. A considerable quantity of carbon dioxide was formed during the reaction and some decomposition of the sodium salts of the higher wax acids was noted. Light paraffin oils were obtained at the same time.

The influence of various factors was found by these investigators to be as follows: Increased temperature affected the color of the products as well as the speed of oxidation. Increased air pressure accelerated the reaction, and the quantity of air influenced the molecular weights of the acids. Undue prolongation of oxidation resulted in a secondary decomposition. The use of lime instead of sodium carbonate was found to be desirable. Speed of stirring and quantity and concentration of the alkali had little effect. Iron, manganese, and copper were found to be the best catalysts, though cerium, titanium, fuller's earth and charcoal yielded the best-colored products. When the apparatus was lined with lead or glass, the rate of oxidation was retarded although better-colored products were obtained. The addition of aromatic hydrocarbons, such as toluene and xylene, resulted in a greater yield of acids, although neither of these compounds was oxidized under the same conditions in the absence of paraffins. Paraffin wax appeared to be more extensively oxidized when alkalies were not present. Other paraffins, such as those obtained from lignite, coal or peat could be oxidized, though the first two were the more resistant. The yield of wax acids was nearly 75 per cent of the paraffin oxidized.

The solid soaps could be obtained by evaporation of the aqueous solution, or by separating the paraffin and water layers and allowing the latter to stand overnight. During this time the soaps of high molecular weight acids separated as solids. Brown soaps were bleached with sodium hypochlorite or by further treatment in the autoclave at 160° C. The free wax acids were liberated by the addition of a mineral acid or by heating the soap solution with carbon monoxide under pressure. Under such conditions the carbon monoxide acted as formic anhydride, liberating the free acids and forming sodium formate. The wax acids could be further purified by distillation with superheated steam or *in vacuo*. Potassium or mixed potassium and sodium soaps were prepared and all soaps lathered well.

Although the solutions of the sodium salts of lower-molecular weight acids lather well, the presence of such soaps imparts a disagreeable odor to the crude product and makes it hygroscopic. Separation from those of the higher-molecular weight acids is accomplished, as mentioned above, by cooling the alkaline solution and filtering off the solid soaps which precipitate. Evaporation of the filtrate yields soaps of the lower-molecular weight acids. On liberating these from their salts it was found that about one-half, ranging from capric to lauric acid, was insoluble in water.

---

[17] Fischer, *Ges. Abhandl. Kennt. Kohle*, 1919, 4, 35; Fischer and Schneider, *ibid.*, 1919, 4, 48; Schneider, *ibid.*, 1919, 4, 101; Schneider and Jantsch, *ibid.*, 1919, 4, 118; Schneider, *ibid.*, 1919, 4, 132; Fischer and Schneider, *ibid.*, 1919, 4, 94; *Chem. Abs.*, 1921, 15, 2736, 2737.

At the same time Schneider observed that oxygen-containing compounds, such as alcohols, aldehydes, and ketones, were carried over by the compressed air leaving the autoclave. Such substances were also noted in the cake of residual paraffin. The solid portion of the cake resembled a true wax rather than paraffin.

Attempts were made to identify and separate the wax acids by means of their ethyl esters. The acids all appeared to conform to the general formula $C_nH_{2n}O_2$, and for a large proportion of the acids n was an odd number. On the other hand, the acids from natural fats and oils generally contain an even number of carbon atoms. Schneider also observed that oxidation at ordinary pressure in glass vessels yielded 2 to 3 per cent of acids insoluble in water, but in iron vessels the yield of insoluble acids was 64 per cent. Mercuric oxide showed little catalytic effect.[18] The reaction velocity was much less than that of oxidations conducted under increased pressures. There was some indication that acid anhydrides were formed.

Varmalov[19] also investigated the oxidation of paraffin wax under pressure. One to two hundred grams of Grozny paraffin, melting at 52° C., were mixed with 500 to 1000 cubic centimeters of 2N sodium carbonate solution, and oxidized in an iron autoclave at a temperature of 160° to 180° C. and a pressure of 15 to 30 atmospheres. Air was supplied at the rate of 200 to 400 liters per hour. The results obtained were: (a) the rate of oxidation was directly proportional to the pressure; (b) 20 to 74 per cent of the paraffin was oxidized; (c) wax acids insoluble in water were formed to the extent of 53 to 78 per cent, and soluble acids, 7 to 8 per cent; and (d) the hydroxy-acids were equivalent to 10 per cent of the oxidized paraffin. Wax acids had acid numbers of 172 to 210, and the hydroxy-acids, an ester number of 66.

Holde[20] has shown that the oxidation of paraffins with air at 135° to 145° C. results in the formation of acid anhydrides which are insoluble in 94 per cent alcohol. These anhydrides reacted with 72 per cent alcohol to yield ethyl esters. Possible substitution of esters of glycol and glycerol for natural fats and oils has been suggested.[21]

Montan wax likewise has been oxidized under pressure.[22] This wax was more inert than paraffin wax and the acids formed appeared to undergo decomposition, hence the yield was lower. The soaps from such acids did not lather as well as those made from paraffin wax acids.

By partially oxidizing wax, good yields of alcohols of high molecular weights may be obtained.[23] Catalysts for such oxidations include organic acids of relatively low molecular weight (e.g., formic, acetic, maleic or benzoic acid), or of weak inorganic acids, such as boric acid, antimony pentoxide, or stannic acid. Best results are secured when 5 to 10 per cent of acid is used and the reaction is continued for 2 to 3 hours at temperatures between 100° and 200° C. As an example, hard paraffin wax containing boric anhydride (50 grams per kilogram of wax) is heated to 175° C. and air is passed into the mixture at the rate of 1 cubic meter (containing 16 grams of acetic acid vapor) per hour. At the end of 3 hours a pale-colored oxidation product is obtained which consists of about

44 per cent by weight of alcohols. The alcohols can be separated by distillation with steam under pressures less than 100 mm.[24] Mixtures of these alcohols or their boric or stearic esters may be used in coating and polishing compositions.[24a]

Other methods described for the separation of the products obtained by the air oxidation of paraffin wax include that of Pungs.[25] After the oxidation step he warms the mass so that the oxidized portion is obtained as a liquid while the unoxidized portion remains solid. The oxidized portion is further divided into waxes and acids by means of alcohol, the acids being soluble in this solvent. Pataky and Nellensteijn,[26] however, add superheated steam to the air or oxygen and thus distil off the wax acids as they are formed. The distillate separates into a solid layer of wax acids of high molecular weight and a liquid containing soluble acids of low molecular weight.

Besides the catalysts already mentioned, others have been used in the oxidation of paraffin wax. By employing a reduced nickel catalyst, Goswami and Chatterjee[26a] obtained about 20 per cent of higher aldehydes. Kelber[27] converted paraffin wax (m.p. 50° C.), to the extent of about 60 per cent, into wax acids by oxidizing it with air at 130° to 135° C. in the presence of manganese compounds such as the oxide, dioxide and silicate. Osmium trioxide and platinum gauze also accelerated oxidation. Of the wax acids obtained, about 60 per cent were insoluble in water. Some of the water-soluble acids found in the distillate which came over during oxidation were identified as propionic, butyric and valeric, and the insoluble acids contained hexanoic, octanoic, nonanoic, and higher acids. The non-volatile residue was also examined for wax acids. Among the acids isolated from this latter portion were decanoic, myristic, palmitic, stearic and arachidic. Kelber observed that if oxygen was passed in while the paraffin was being heated to 150° to 160° C. some time elapsed before the reaction started, which was accompanied by the evolution of heat. On the other hand, if the paraffin was heated at that temperature for some time and oxygen then passed in, reaction began immediately. This appeared to indicate that oxygen takes no part in the action until a breaking down of the hydrocarbon sets in, whereupon it reacts with the decomposition products.

Franck[28] used 0.5 to 5 per cent of various compounds of lead, mercury, vanadium and chromium as catalysts. He carried out oxidation in an autoclave filled with oxygen at a temperature of 150° C. A series of wax acids, which ranged from acetic to arachidic, was obtained. Upon esterifying a sample of the mixed acids with ethylene glycol, in the presence of 3 per cent of sulphuric acid, a solid fat was formed which possessed the odor of coconut oil. After refining, this product was pale yellow in color.

Contrary to the results of other investigators, Grün, Ulbrick and Wirth[29] found that the oxidation reaction was inhibited by calcium or barium oxides or other compounds having alkaline properties. They believed, however, that acidic substances, such as stearic acid, may be helpful, or at least not show marked inhibitive properties. If the conditions of oxidation are not carefully chosen one carbon atom after another of the intermediate products may be oxidized away, thus producing a whole series of acids which range from formic acid, or even carbon dioxide, to high molecular weight acids. The use of pure oxygen is likely to lead to the formation of explosive peroxides as intermediate products. When oxidation is not too vigorous the product consists of waxes, free acids, alcohols, and unsaponifiable matter. Any hydroxy-acids formed probably react to give esters or estolides[30] or yield unsaturated acids by loss of water. The unsaponifiable matter consists of unchanged paraffin and higher alcohols together with probably aldehydes and ketones. The absence of water appears to promote the formation of acid anhydrides.

Collin[31] was unable to identify any of the acids in paraffin wax which had been oxidized on a "commercial scale." He concluded, however, that it contained about 80 per cent saturated acids ranging in molecular weight from 145 to 300, and that probably half of the acids had a molecular weight corresponding to acids of 14 carbon atoms or less. No one acid was present in any predominating quantity.

Despite the fact that the presence of certain alkaline substances may be detrimental to the oxidation, certain processes have been developed which depend upon the use of such substances. Paraffin, petrolatum and naphthenes can be oxidized with air at 150° C. for 24 to 36 hours in the presence of about 2 per cent of a light metal such as sodium, potassium or magnesium.[32] Over 20 per cent of the hydrocarbons are converted into acids, the salts of which can be employed as soaps. Plauson and Vielle[33] obtained soaps by oxidizing paraffin at 125° to 150° C. with air or oxygen under 5 to 10 atmospheres pressure in the presence of an alkali. The volatile products, amounting to 16 to 18 per cent of the paraffin, are withdrawn and condensed. About 60 to 70 per cent of the paraffin is changed into saponifiable matter, and the remaining non-volatile portion can be emulsified in the soap. When air is the oxidizing agent it should be free of both moisture and carbon dioxide.

The salts of organic acids also appear to function well as catalysts. These include salts of the alkaline earth metals, such as barium stearate or calcium cinnamate, in the absence of free alkalies or alkaline earths.[34] Similarly, manganese and zinc stearate,[35] manganese acetylacetonate,[36] or naphthenate[36a] or other metallic enolates have been used. Nitrogenous bases,[37] e.g., hexamethylenetetramine, aniline and butylamine, may be used in conjunction with such salts as manganese or cerium stearate.

---

[30] Estolides are the esters formed by the interesterification of high molecular weight hydroxy-acids. For example, an estolide has been obtained from 12-hydroxy-stearic acid by the interesterification of three molecules.

$$3C_{17}H_{34}\genfrac{}{}{0pt}{}{\diagup OH}{\diagdown COOH} \longrightarrow C_{17}H_{34}\genfrac{}{}{0pt}{}{\diagup OH}{\diagdown COOC_{17}H_{34}COOC_{17}H_{34}COOH} + 2H_2O$$

Among the inorganic catalysts, metallic borates,[38] cupric oxide[39] and manganites and manganates[40] have been mentioned for the oxidation of paraffin wax with either oxygen or air. Neutral or acid alkali halides or oxalates (sodium chloride or sodium oxalate) have been suggested, particularly for the oxidation of montan wax.[41]

USE OF OTHER OXIDIZING AGENTS

Paraffin wax, melting at 50° to 52° C., can be oxidized with air containing 2 per cent nitrogen dioxide[42] at temperatures which range from 110° to 150° C. Complete conversion of the paraffin into oxidation products is possible in all cases, the time for such action, however, varying inversely with the temperature. The products were not excessively discolored, and consisted of a mixture of acetic, butyric and higher acids and about 15 per cent of unsaponifiable oil. With pure nitrogen dioxide at 140° C., oxidation was complete in a much shorter time, and the exit gas consisted principally of nitric oxide, together with small quantities of nitrogen, hydrogen cyanide, and carbon monoxide. As the alkaline solutions of the oxidized wax were red when nitrogen dioxide was used, this was taken as evidence that some nitro-compounds were formed.

Gränacher observed that when pure n-undecane was treated with nitrogen dioxide at 140° C., the product was a mixture of acids, none of which was higher than nonanoic acid. Only about 60 per cent of the hydrocarbon was oxidized. Since paraffin waxes were more completely and quickly changed to acids than was undecane (a straight-chain hydrocarbon), Gränacher concluded that paraffin wax consisted chiefly of branched-chain hydrocarbons.

In some further work on the oxidation of paraffin with nitrogen dioxide, it was impossible to detect either stearic or palmitic acid.[43] The crude acids were extracted with sodium hydroxide solution, converted into the barium salts to remove neutral products, and the free acids were then liberated. The ethyl esters of these acids were made and separated by distillation into two fractions, the first boiling at 37° to 240° C. (at 23 mm), and the second at 240° to 300° C. (at 23 mm). From the second fraction the acid $C_{22}H_{44}O_2$ (m.p. 59° to 60° C.) was obtained. This acid differed greatly from behenic acid ($C_{22}H_{44}O_2$), which further substantiated the belief that paraffin wax contains considerable quantities of hydrocarbons other than normal straight-chain ones. In a second experiment the esters were separated into fractions which boiled at 90° to 135° C. and 135° to 155° C. at 12 mm pressure. From the first fraction was obtained the acid $C_{14}H_{28}O_3$ and from the second, the acid $C_{15}H_{30}O_3$. These were saturated, liquid hydroxy-acids, and probably contained a naphthenic or branched-chain structure.

The oxidation of melted paraffin wax at 60° C. with liquid nitrogen tetroxide under 4 atmospheres pressure leads to a product containing only 12 per cent unsaponifiable matter.[44] During oxidation the nitrogen tetroxide is reduced to nitric oxide. This gas, however, may be mixed with oxygen to re-form the tetroxide which can be used again. By making the working conditions milder as the reaction proceeds the formation of hydroxy-acids[45] can be largely prevented. Thus, crude paraffin may be oxidized with a mixture of nitrogen oxides in three stages at 110°, 90°, and 60° C., respectively, and the product will have less than 10 per cent hydroxy-acids. The gases, together with the partly oxidized wax, are passed from one autoclave to the next. The first autoclave is fed with nitrogen dioxide and this subsequently becomes diluted with nitric oxide as the reaction proceeds. Decreasing the pressure or velocity of the gases is of aid. Zinc or aluminum stearate, or metallic phosphates may be used as catalysts.

Other catalysts which have been used in the oxidation of paraffin wax with the oxides of nitrogen are barium stearate, calcium and barium cinnamate, and similar organic compounds of the alkaline earth metals, magnesium and aluminum,[46] and also barium and manganese acetylacetonates.[47]

After paraffin wax has been oxidized with the higher oxides of nitrogen, the crude acids can be purified by heating or distilling below 300° C. with carbon monoxide or hydrogen in the presence of a hydrogenating catalyst[48] or by treatment with alkalies.[48a] In this way the nitrogen-containing fatty acids are either reduced or the nitrogen is split off.

Schaarschmidt and Thiele[49] obtained acids by oxidizing unsaturated compounds (made from the chlorine derivatives of paraffin) with potassium permanganate. Chlorine was passed into molten paraffin at 160° C. through a Witt stirrer which was rapidly rotated. Reaction proceeds almost to completion without the aid of external heat. Hydrogen chloride was then eliminated either by heating the products to 300° C. or with alcoholic potassium hydroxide, the latter method yielding olefins of higher iodine number. The olefins thus obtained were then oxidized with potassium permanganate. For example, an olefin having a bromine number of 24 and derived from a chloroparaffin containing 10.6 per cent chlorine, on oxidation with potassium permanganate yielded the acid $C_{14}H_{29}COOH$. The more unsaturated the olefin, the greater and quicker the absorption of oxygen.

Since the ease with which these water-insoluble unsaturated compounds can be oxidized depends on their state of subdivision, the following modifications of the oxidation procedure were tried: (1) The olefin was emulsified with an aqueous solution of sodium palmitate and an aqueous solution of permanganate was added. Oxidation was stopped when the weight of permanganate used was about six times the weight of olefin. (2) The reaction was started with a small quantity of sodium palmitate and olefin, and further additions of the latter were made as the permanganate became reduced. The quantities of acids and of unsaponifiable material were about the same by both methods. The acid values of the products obtained by the second method, however, were greater than those obtained by the first. Oxidation by means of permanganate apparently does not stop with the splitting of the double bonds, but also further changes a large portion of the cleavage products, as a quantity of water-soluble acids was formed, and also a large portion of the olefin was oxidized to carbon dioxide.

Ozone is readily absorbed by the olefins, the amount corresponding closely to the quantity of hydrogen chloride split off in the preparation of the olefin. The ozonides can be decomposed with water and the non-acid aldehyde portions further oxidized with ozone. In this manner, 105 grams of higher fatty acids, together with a considerable amount of water-soluble acids, were obtained from 150 grams of olefins. The latter were made from a chloroparaffin (containing 19.4 per cent chlorine) by means of alcoholic potassium hydroxide.

The electrochemical oxidation of paraffins (which melted from 38 to 53° C.), after thorough refining with 98 per cent sulphuric acid, was studied by Atanasiu.[50] The apparatus used consisted of a cylindrical container of sheet lead, which served as the anode, and a porcelain cell into which dipped a lead cathode. The electrolyte was 20 per cent sulphuric acid (d. 1.2). The paraffins are relatively easily oxidized, particularly in the presence of a catalyst such as 5 per cent potassium dichromate or better, 4 per cent ceric sulphate. Since the oxidation proceeds slowly, the higher yields are obtained with low current densities. The reaction appears to be essentially chemical as the catalyst is alternately reduced and electrochemically reoxidized. The products are wax acids, unsaponifiable matter, water and carbon dioxide. The character of wax acids so obtained varies with the nature of the paraffin, the acid value of the products being about 150 for a paraffin which melted at 37° C. and about 200 for one which melted at 50° C. Soft paraffins are generally the more easily oxidized, but the products contain a large quantity of unsaponifiable material and resins which are difficult to separate.

Grün and his collaborators[51] found that oxidation of paraffin at 160° C. took place to about the same extent in the presence or absence of ultraviolet light. On the other hand, an increase in the quantity of air used, or in the time, gave a large yield of acids. The presence of moisture appears to affect the yield also, though the data on this point were not conclusive. Carbon monoxide, however, retards oxidation. With air diluted with carbon dioxide it was shown that oxidation takes place even when the mixture contains as little as 1.3 per cent by weight of oxygen.

The action of ozone on paraffin and montan waxes was investigated by Fischer and Schneider.[52] The wax was dissolved in acetylene tetrachloride and ozonized for 24 hours at 50° to 60° C. and the quantity of acid products insoluble in water was determined. From preheated montan wax, hard paraffin wax, or lignite tar very little wax acids were obtained. On the other hand, the yields of such acids from paraffin wax of low-temperature tar, from montan wax (not preheated), and from ozokerite were large. These differences were ascribed to the relative proportions of straight- and branched-chain hydrocarbons in the waxes, the latter class being more easily attacked by the ozone.

MISCELLANEOUS OXIDATION REACTIONS

The three constituents of lignite tar, namely, tar oil, paraffin and montan wax, have been oxidized with oxygen in the presence of dilute sodium carbonate solution by Schneider.[53] The tar oil, after the removal of phenols and solid paraffins, consisted of approximately 50 per cent unsaturates, 30 to 40 per cent naphthenes, and 10 per cent paraffin hydrocarbons. When oxidized with air at 200° C. under 30 atmospheres pressure, in the absence of carbonate solution, about half was precipitated as solid asphalt and the remainder gave on distillation a light yellow liquid. In the presence of the carbonate solution no solid product was formed, but about 55 per cent was changed to an alkali-soluble, syrupy liquid (insoluble in petroleum ether) which had a specific gravity greater than 1.0. This seemed to indicate that the product was not an aliphatic acid, but something similar to Charitschkov's polynaphthenic acids.[54]

Oxidation of the lignite paraffin, which melted at 53° C., led to the following conclusions: (1) deep-seated oxidation with the formation of low molecular weight acids does not take place; (2) alcohols and aldehydes are formed only in traces while acids are formed almost exclusively; (3) the acids are monobasic wax acids, and their solubility in petroleum ether indicates the absence of any appreciable quantities of hydroxy-acids; (4) dibasic acids, such as oxalic, are formed only in minute quantities; and (5) the oxidation seems to consist of the formation of acids of high molecular weight, the loss of carbon dioxide, followed by re-oxidation. In this way a homologous series of acids is formed.

As found with paraffin wax from other sources, an increase in temperature of 10° C. appeared to double the reaction velocity and an increase in the oxygen concentration also speeded up the reaction. At a given temperature the quantity of wax acids produced increased with the time allowed for oxidation. Salts of iron, copper and manganese accelerated the reaction, but the salts of nickel, cobalt, chromium, lead, mercury, cerium, titanium and vanadium and also charcoal appeared to have no effect. The acids which were isolated varied from $C_{13}H_{26}O_2$ to $C_{19}H_{38}O_2$, all apparently having an odd number of carbon atoms. The sodium soaps, which separated directly from the reaction products, possessed good lathering and detergent qualities.

Fischer, Schrader and Friedrich[54a] subjected lignin dissolved in dilute sodium carbonate to prolonged oxidation with air at 200° C. under a pressure of 55 atmospheres, obtaining an orange-colored solution which contained 12.8 per cent of the carbon originally present. This liquid on acidification and distillation with steam, gave fatty acids and 0.06 per cent of benzoic acid. The non-volatile acids were extracted with ether and their barium salts were separated by fractional crystallization. Acids from the more soluble barium salts consisted of isophthalic and benzenetricarboxylic acids. The slightly soluble barium salts yielded anhydrides of succinic, phthalic and trimellitic acids and the insoluble salts on acidification yielded oxalic and fumaric acids in solution and benzenetri- and benzenepentacarboxylic, mellitic, prehnitic and hemimellitic acids as precipitates. A yield of 8.28 per cent of aliphatic acids and 3.12 per cent of benzenecarboxylic acids was obtained.

Langer[55] carried out some experiments, which were rather qualitative than quantitative, on the oxidation of petrolatum oils and liquid and solid paraffins. Although some indications were obtained that acids were formed, no individual acid was identified. The oxidizing agents used were: potassium permanganate in alkaline and acid solutions, sodium hypochlorite, manganese dioxide and hydrochloric acid, nitric acid, and potassium dichromate with hydrochloric acid.

The oxidation product from solid paraffin resembled a salve. With litharge it formed lead salts which were soluble in ether. This indicated that acids of the oleic type were formed. From petrolatum, hard and soft resins were produced, the latter containing no substances of an acid character. The yield of saponifiable matter was less than with petrolatum oil and no soluble lead salts were formed.

Yellow petrolatum oils on oxidation yielded a supernatant liquid and a sludge. From the solution of this sludge in dilute sulphuric acid was obtained an oil only slightly soluble in dilute sodium carbonate or hydroxide solutions. When heated on a water bath with concentrated sulphuric acid, sulphur dioxide was evolved and a crystalline mass insoluble in all ordinary solvents was obtained. Despite careful removal of all sulphuric acid, this latter product gave sulphur dioxide on burning. The supernatant liquid from the oxidation of petrolatum oil showed a similar behavior.

On heating liquid paraffin with oxygen under pressure Tschernozhukov[56] obtained oxygenated compounds which were free of sulphur. Neither asphaltenes nor carbenes were formed. Crude Balakhani, Grozny, and Emba oils, under the same conditions, however, yielded asphaltenic sediments, having formulas such as $C_{136}H_{142}O_{12}S$ and $C_{172}H_{176}O_{14}S$. Asphalt-like substances were also obtained when the white oils from Baku and Emba crudes were heated with sulphur and then oxidized. When the sulphur-treated oils were heated with sulphuric acid, sulphur dioxide was liberated. Tschernozhukov concluded from these experiments that asphaltenes were formed from crude oil by unknown sulphur compounds in the various stages of oxidation.

In the oxidation of ordinary paraffin wax in the presence of manganese dioxide or fuller's earth only normal aliphatic acids are obtained. This indicates that paraffin contains only normal aliphatic hydrocarbons which is in direct contrast to Gränacher's[57] conclusion. If ceresin (protoparaffin) contained naphthenes, then naphthenic acids, which could be separated from the aliphatic acids, should be produced also. To verify this, Marcusson[58] oxidized ceresin (melting point 68° to 71° C.) with oxygen for 35 hours at 125° C., and then for 55 hours at 150° C., with manganese dioxide deposited on fuller's earth as a catalyst. The product was separated into saponifiable and unsaponifiable portions according to the method of Hönig and Spitz,[59] and the acids were divided into solid and liquid fractions by the application of Varrentrapp's[60] lead salt method. The unsaponifiable material, which amounted to about 44 per cent of the ceresin used, consisted largely of saturated and unsaturated hydrocarbons, ketones and alcohols. The liquid acids were obtained as a thick oil, with an acid number of 115, iodine number of 11 and a density less than 1. They were considered a mixture of polymerized unsaturated acids. The solid acids melted at 60° to 62° C., had an acid number of 146, and an apparent molecular weight of 346. They were extremely soluble in the usual solvents, such as benzene and alcohol, which is typical of branched-chain compounds. It was therefore concluded that ceresin consists principally of branched-chain hydrocarbons.

A mixture of various paraffinic substances can also be oxidized to yield acids which may be employed in the manufacture of soaps. Thus, Schrauth and Friesenhahn[61] used a mixture of 300 kg. of paraffin wax, 350 kg. of beeswax, 300 kg. of ceresin, 30 kg. of sodium hydroxide, and 100 liters of water. The mixture was heated for 8 hours at 160° to 180° C., with brisk agitation, and a pressure of 10 atmospheres of air or oxygen was maintained. A catalyst was not necessary. The use of sodium carbonate in place of sodium hydroxide is to be avoided, as the former gives rise to the formation of anhydrides, lactones, or waxy substances, all of which reduce the detergent property of the soap. After heating, the product is withdrawn and mixed with water, coloring matter and perfume. This finished product lathers freely, and contains only 15 to 25 per cent unsaponifiable material, which however is readily emulsified.

OTHER METHODS FOR OXIDIZING PARAFFINS

A brief review of some other industrial methods for oxidizing the paraffinic hydrocarbons and also for separating the products of oxidation follows:

By spraying the liquid hydrocarbons into the top of a cylindrical vessel and injecting oxygen or air at the bottom, thus securing an intimate mixture of the two reacting materials, the time required for oxidation can be greatly reduced. In one process, the vessel is kept at 80° C., and packed with a filling material such as pumice stone, which may also be impregnated with a catalyst. Substances which can be used as catalysts are the oxides of copper, nickel, and manganese.[62]

Instead of spraying the paraffin into air, Reid and Burke[63] oxidized molten paraffin by treating it with air comminuted and disseminated throughout the mass in such an extreme degree of subdivision as to approach molecular dispersion. In this way the speed of the reaction at any given temperature is greatly accelerated. This subdivision of the air is accomplished by high-speed stirrers, such as a Witt stirrer. As an example, a 60 per cent conversion of paraffin wax to wax acids was obtained by oxidizing at 175° C. under 150 lbs. per sq. in. pressure and with the stirrer rotating at 3000 r.p.m. The use of solutions of alkalies, such as sodium carbonate or hydroxide, is also recommended.

Molten paraffin, or hydrocarbons such as ceresin, petrolatum, or paraffin oils, which have been refined with liquid sulphur dioxide, are oxidized[64] with a current of air in vessels containing some filling material. This material may consist of rings or cones of a non-porous nature and may or may not be catalytic. For non-catalytic material, glass or porcelain can be used, and iron or manganese serve as catalytic materials. The use of aluminum or its alloys as filling materials is said to aid in controlling the temperature. The filling extends far above the liquid level so as to help the oxidizing action of the air on the foam or spray carried over by the air. The temperature is maintained between 160° and 180° C. In this manner there is obtained a partial separation of oxidized and unoxidized hydrocarbons. A clear, yellow oxidation product results which is of use in soap manufacture. The process can also be carried out under pressure, or in the presence of inert solvents. Montan wax,[65] either alone or mixed with paraffin hydrocarbons, can be oxidized in the same manner.

Another method for the production of wax acids, anhydrides, aldehydes, alcohols and ketones from paraffins provides for the purification of the hydrocarbons by treatment with hydrogen at 5 to 500 atmospheres pressure at 150° to 450° C.[65a] Sulphur compounds are thus removed and any unsaturated compounds hydrogenated.

Utilization of the heat developed during the reaction for the preheating of a fresh charge of hydrocarbon has been proposed by Luther.[66] A process developed by Luther and Goetze[67] provides that the foam drawn off at the top of the reaction vessel be further oxidized by returning it to the bottom of the same vessel or by passage through other vessels connected in series.

Mathesius[68] recommended the use of relatively large quantities of water, high pressures, and also alkalies to unite with the acids and prevent further decomposition. Schaffner[69] found that emulsifying the hydrocarbon with a water solution of an aliphatic or aromatic sulphonic acid, aids in the oxidation of the hydrocarbon. Luther and Wille[70] prevented the formation of resinous by-products in the oxidation of paraffin oils and waxes by stopping the reaction before all of the initial products have been oxidized. They extracted the oxidized portion with methyl alcohol, and resubjected the unoxidized residue to oxidation. Fresh unoxidized material can be added after each extraction with alcohol.

In another method for the oxidation of hydrocarbon waxes only a portion of the initial material is oxidized and reaction is stopped before discoloration occurs.[71] The oxidation products can then be removed by distillation. The non-oxidized portion is mixed with fresh material and oxidation repeated. Such a process can be operated in a continuous manner. Scanlin[72] proposed to oxidize paraffin wax at 290° to 330° F. (140° to 165° C.) until the product has an acid value of 35. The oxidized and unoxidized portions are then separated by sweating. The unoxidized portion is added to fresh stock and oxidized again. The oxidized portion is used for making soaps, or for compounding with lubricating oils.[73] By this process the formation of gummy oxidation products insoluble in hydrocarbon oils is avoided.

The hydroxy-acids present in the crude oxidation products of paraffin and montan wax, when distilled under reduced pressures in the presence of carbon dioxide or steam, are converted into long-chain unsaturated acids.[74] Catalysts such as red phosphorus, metallic oxides, or sulphuric acid can be employed in the distillation.

Light-colored products may also be obtained from paraffin and montan wax by oxidizing with air or oxygen at 120° to 180° C. in the presence of small quantities of aqueous non-oxidizing strong acids, or of an ansolvo-acid.[75] Such catalysts may be, 0.1 per cent of 45 per cent sulphuric acid, 0.1 per cent oxalic acid, or 0.3 per cent of the ansolvo-acid obtained from zinc chloride and acetic acid, $(ZnCl_2.2C_2H_3O_2)H_2$. These products can be used as substitutes for beeswax.

Schmidt and Grün,[76] on the other hand, produce a light-colored wax from paraffin by shortening the time of heating. For example, paraffin wax which melts at 50° C. is mixed with a little stearic acid and heated for 6 to 8 hours at

150° to 155° C. Contact substances such as the oxides or salts of lead, manganese, nickel, cobalt, cerium or thorium may also be used. At the end of the operation the mass is extracted with alcohol and the wax is obtained as an insoluble product. The wax is a light yellow, opaque substance which melts at a temperature just slightly higher than the original material.

Another method of making light-colored products consists in reducing the temperature, pressure, rate of flow of gas, or concentration of oxidizing agent as reaction proceeds.[76a]

SEPARATION OF OXIDIZED FROM UNOXIDIZED MATERIALS

In the preceding text, reference has been briefly made to procedures for the separation of oxidized from unoxidized wax. From this it has been seen that a number of methods are available. These may be roughly classified as (1) sweating, (2) extraction with alkalies, (3) separation with solvents. Combination of the methods may of course be used.

Attention has already been called to sweating as a method of separating the crude acids, as liquids, from the unoxidized solid products.[77] The crude acids, moreover, can be further purified by sweating or pressing them at temperatures slightly below their melting points.[78]

The use of alkalies, however, permits a much greater variation in the separation of the products of oxidation. For example, the crude products may be saponified with sodium hydroxide, and after extracting with water the acids can be set free by the addition of a mineral acid;[79] or, after saponification, the unsaponifiable bodies may be obtained by sweating and pressing operations.[80]

The soap solution obtained by the saponification of the crude oxidation product may be treated before the free acids are liberated to separate the saponifiable from the unsaponifiable matter. This may be done by emulsifying it with light petroleum or other solvent and then centrifuging[81] or the solution may be cooled to 15° C. or lower to effect separation of the unsaponifiable portion.[82] A similar method consists in treating the saponified products with a methanol-water mixture, to which is then added benzine. Two layers are formed, one of which is a soap solution of water-alcohol, and the other a solution of unsaponified material in benzine.[82a]

The acids in the oxidation products can be saponified with the alkaline earths, magnesia,[83] anhydrous sodium carbonate[84] or ammonium carbonate.[84a] The salts thus obtained are dried and purified by extraction with benzine. The free acids may then be liberated by the addition of sulphuric or other mineral acid. These free acids can be further purified and decolorized by subjecting them at 12° to 13° C. to a pressure of 100 atmospheres in a hydraulic press.[85]

A method of partially separating the acids was devised by Luther,[86] in which the crude acids are first neutralized with about one-third of the theoretical quantity of alkali. After separating the acids and soap solution, complete neutralization is effected. The first step removes the acids of low molecular weight, the high molecular weight acids being obtained in the second step.

Beck and Kremp[87] used concentrated acetic acid to effect a separation of acids and unsaponifiable material. After the oxidation of the paraffin wax, the crude product is treated at 60° C. with 95 per cent acetic acid, and the insoluble portion separated. The solution is allowed to cool, and the unsaponifiable material which separates is filtered off.

The same investigators suggested heating the crude oxidation products under pressure with ammonia, thus converting the acids to amides and ammonium salts.[88] The ammonium salts separate during the reaction and can be removed later. The amides are separated from the unchanged paraffins by extraction with petroleum ether. Both the amides and ammonium salts are then converted to the free acids by any convenient method.

James[88a] found isopropyl alcohol to be superior to methyl, ethyl or normal butyl alcohol in extracting the more highly oxidized portion (alcohols, esters, ethers, aldehydes and ketones) from the heavier fractions of oxidized oils. By employing an isopropyl alcohol-water mixture for the extraction of the fraction boiling above 200° C., two layers form. The top layer consists of a highly concentrated hydrocarbon portion and the lower layer, a mixture of the solvent and highly oxidized products. Another process employs liquid sulphur dioxide as an extraction solvent.[88b] The wax acids are thus dissolved, leaving the unsaturated hydrocarbons.

Distillation may be employed in effecting separation.[89] At a temperature of 150° to 300° C. and under a pressure of 10 to 50 mm., the product may be treated with a mist of finely divided inert liquid. One which boils below 105° C. is best. Water, benzene, tetrachlorethane, carbon tetrachloride, alcohol, toluene, or acetic acid together with inert gas carriers such as steam, carbon dioxide or nitrogen can be employed; or the crude material can be saponified to obtain an aqueous mixture consisting of magnesium, calcium and potassium soaps.[90] The soaps should be present in such proportions that the melting point of the crude product in the anhydrous condition is less than 150° C. The unsaponifiable matter can then be removed by distillation.

Low-boiling benzines have been employed by Hellthaler and Peter[91] to effect the separation of hydroxy acids from wax acids which do not contain hydroxyl groups. The process depends upon the solubility of the non-hydroxy wax acids in the benzines, as compared with the relative insolubility of the hydroxy acids. In a sample of oxidized paraffin wax, these investigators found 30 per cent of hydroxy acids.

According to Dovankov,[91a] however, the method of separation of hydroxy and non-hydroxy carboxylic acids by extraction with naphtha is impractical on a technical scale on account of the large amounts of solvent required. He reduced the amount of naphtha used to 3 to 5 times the weight of the acids by two methods. In one, concentrated sulphuric acid was added in small portions to a 3 to 1 solution of the acids. With each addition of sulphuric acid some hydroxy acids were precipitated. In the second, 0.3 to 0.8 per cent by weight of gaseous hydrochloric acid was introduced into a 5 to 1 naphtha solution of the wax acids, the separation of hydroxy acids being complete after 12 hours.

Varlamov[92] freed saponifiable matter from unsaponifiable in the following manner: the oxidation product is dissolved in benzine (boiling from 120° to 160° C.) and the calculated quantity of aqueous sodium hydroxide (1:5) is then added. The saponifiable portion was extracted leaving the unsaponifiable dissolved in the benzine.

Beck and Diekmann[92a] reduced the content of unsaponifiable material in wax acids by extraction with hydrocarbons which are themselves capable of being oxidized to fatty acids. The resulting mixture of hydrocarbon solvent and unsaponified constituents may then be oxidized to fatty acids. A sample of soap solution (saponified constituents) containing about 8 per cent of unsaponifiable substances was heated and passed countercurrent to the extracting hydrocarbons. The resulting soap solution contained 3 to 4 per cent of unsaponifiable substances.

The material obtained by oxidizing wax with nitric acid, or the oxides of nitrogen, may be refined by heating (under pressure) with dilute aqueous solutions of alkali or acid.[93] The volatile nitrogen compounds formed are removed by blowing with steam.

Mono- and dicarboxylic acids of high molecular weight can be separated from each other by treating oxidized wax with aliphatic hydrocarbons of low boiling point.[94] Organic solvents soluble in water can also be used. To such solvents is added enough water to effect solution of the dicarboxylic acids leaving the monoacids as insoluble residues.

Mention has been made of decolorizing the acids by pressing at high pressure and low temperatures. Other methods for bleaching and deodorizing such acids include both oxidation and reduction. Thus, the crude acids may be oxidized with nitric acid,[94a] chromic acid, potassium permanganate or hydrogen peroxide at temperatures around 105° C., or in an electrolytic cell containing oxygen-transferring agents, such as chromic or ferric sulphate;[95] or the mixture of acids may be treated with a metal and an acid which react to liberate hydrogen, as for example, zinc and sulphuric acid.[96] Active carbon has also been used for decolorizing.[96a]

MECHANISM OF THE OXIDATION OF PARAFFIN

The influence of the elements of the oxygen group on paraffin wax was investigated by Siebeneck,[97] whose findings correspond somewhat to those of other investigators. The wax can be oxidized when heated to 135° C. by either air or oxygen, the rate of oxidation being somewhat slower with air. At the end of 10 hours, acid vapors are evolved, and at the end of 22 hours a product was obtained which contained 30 to 40 per cent of saponifiable material. Longer oxidation increased the quantity of saponifiable material in the product. The acids produced were saturated aliphatic acids and the volatile product consisted of acids of lower molecular weight of the same series together with some water. The volatile material corresponded to about 7 per cent of the paraffin used.

With hard paraffin and sulphur the reaction appears to be a dehydrogenation, as hydrogen sulphide is obtained in large quantities together with carbon disulphide. After heating for 72 hours at 230° C., a fat-like, black mass was obtained. On extraction with carbon disulphide followed by ether, a black amorphous substance was obtained, whose composition corresponded closely to the formula $(C_8S)_x$. This substance was rather indifferent towards alkalies and organic solvents, but was attacked by concentrated sulphuric or nitric acid. Reaction between the paraffin and sulphur takes place at slightly higher temperatures than with air or oxygen, the reaction starting at 150° C. and proceeding rather rapidly at 230° C.

Selenium and tellurium react similarly but require higher temperatures (300° to 700° C.). No selenium or tellurium compounds analogous to the sulphur compound were obtained. Small quantities of either sulphur or selenium seem to inhibit the action of oxygen on paraffin.[98]

In another study, brown-coal paraffin, melting at 54° C., was oxidized for 55 hours at 135° C., and analyses were made at various time intervals.[99] During the first 10 hours there was a rapid absorption of oxygen accompanied by the formation of formic acid and other low molecular weight acids. Ester formation, according to Siebeneck, appeared to be the primary reaction, the acids resulting from the decomposition of the ester. The second stage in the oxidation was reached in about 12 hours when the evolution of carbon dioxide began. During the second stage the ester value and saponification value both increased while the acid value more than doubled. The third stage occurred after 33 hours, during which the ester value decreased, the saponification value remained about constant, and the acid value increased. The products formed in the second stage, between 12 and 33 hours, are the ones which are most likely to find commercial use. They are waxy, of a light color, and can be recovered by steam distillation.

At a slightly higher temperature (183° to 184° C.) Kailan and Olbrich[100] found that oxidation of paraffin wax proceeded more rapidly in the second period of 25 hours than during the first period of the same length. The quantity of carbon dioxide evolved was proportional to the time of the reaction, and the quantity of saponifiable matter increased from 1.46 per cent at the end of 25 hours to 8.04 per cent at the end of 100 hours.

This latent period has also been observed by other workers. The time required for a paraffin wax to reach a given oxygen content (7 per cent) was determined by Francis and his collaborators, who obtained the following values.[101] For wax at 100° C., oxidized with oxygen, the time required was 1060 hours. With air at the same temperature the time was too long to be determined, but at 120° C. it required 285 hours. With wax containing 5 per cent turpentine, the time required with air at 100° C. was 800 hours, and with oxygen, 320 hours. When the temperature was increased to 135° C., the time required with air was 285 hours, but with oxygen only 46 hours were necessary. On the other hand, wax from lignite, which contained 0.7 per cent oxygen, reached a 7 per cent oxygen content after 24 hours at 135° C.

It was further observed that the latent period could be reduced by (1) heating the wax[102] before oxidation in a vacuum, (2) employing catalysts, and (3) pretreating with sulphuric acid at 100° C. Heating the wax in a vacuum did not alter its physical constants, but it did slightly increase its solubility in chloroform or acetone. When this heated wax was recrystallized from acetone it again showed the same latent period as the untreated wax, the acetone evidently extracting a substance which catalyzed the oxidation. The latent period may therefore be ascribed to (1) formation of a positive catalyst, (2) destruction of a negative catalyst present in the original material, or (3) isomeric changes brought about by the action of heat, particularly the formation of unsaturated compounds.

In investigating the composition of paraffin wax, Francis[103] found that oxidation did not take place on passing a rapid current of air for 280 hours at 110° C., nor by oxygen in 700 hours at 100° C. With oxygen at the end of 1276 hours at 100° C., a product containing 74.7 per cent carbon, 11.6 per cent hydrogen, and 13.7 per cent oxygen was obtained. Above 130° C., however, paraffin could be easily oxidized with air. In the presence of a small quantity of turpentine a selective oxidation takes place at 100° or 110° C. and apparently only one class of constituents is attacked. The resulting products are therefore less numerous than those obtained at higher temperatures and are close in molecular weight to the hydrocarbons which occur in the wax. The part played by the turpentine is not well understood.

Since two synthetic normal hydrocarbons, n-hexadecane ($C_{16}H_{34}$) and n-dotriacontane ($C_{32}H_{66}$), were not oxidized in the presence of small quantities of turpentine, it would appear that there were some constituents of wax other than normal aliphatic hydrocarbons which were oxidized. This view was further strengthened by the fact that when paraffin wax was distilled in a high vacuum it was possible to obtain certain fractions which were more easily oxidized than others.

In addition to the volatile reaction products obtained in the above oxidations, the substances remaining in the reaction vessel consisted of unattacked hydrocarbon, non-acid oxidized materials, and some acids of high molecular weights. The acidic substances were divided into four groups, α, β, γ, and δ. The α- and β-acids, which amounted to 32 per cent of the total, are the principal products of air oxidation. The α-acids are insoluble in water or aqueous alcohol, and possess low melting points and high molecular weights. The β-acids possess higher melting points and lower molecular weights. The γ-acids are liquids which are slightly soluble in aqueous alcohol. The δ-acids are rather soluble in water. Oxidation with pure oxygen yields principally β- and γ-acids.

[102] *Cf.* Kelber, *Ber.*, 1920, **53**, 66, 1567.

[103] Francis, Pope, Coysh, and Gauntlett, *J.C.S.*, 1922, **121**, 496; *J.C.S.*, 1926, **128**, 2377; Gutt and Plotko (*Azer. Neft. Khoz.*, 1930, No. 9, 108; *Brit. Chem. Abs.* B, 1931, 284) found 150° C. to be the optimum temperature for air oxidation.

The non-acid products consisted of secondary alcohols and ketones and probably some dihydric alcohols, hydroxyketones and diketones. These non-acid products also decrease in quantity as oxidation proceeds, as they are converted to acids. The ketones and secondary alcohols had chains of 26 to 29 carbon atoms. The secondary alcohols are first formed and these are then oxidized to the ketones. As shown by x-ray examination of the ketones, the point at which the carbon chain is attacked seems to be the third or fourth carbon atom from the end.

Later, however, it was found that triacontane ($C_{30}H_{62}$) could be oxidized at 95° C. by air in the presence of turpentine and that the nature of the products and the velocity of reaction were both similar to that of paraffin wax.[104] The acid products isolated were succinic acid; cerotic acid, $C_{26}H_{52}O_2$, which was identical with that prepared from beeswax; a small amount of the acid, $C_{24}H_{48}O_2$, which was identical with that formed by oxidizing paraffin; and three acids of the following formulas, $C_{16}H_{32}O_2$, $C_{20}H_{40}O_2$, and $C_{22}H_{44}O_2$. The inert products included a ketonic alcohol or dihydroxy-compound of the formula $C_{30}H_{60}O_2$, and a ketone $C_{30}H_{60}O$. The point of attack was again indicated to be the third or fourth carbon atom from the end of the chain.

The failure to oxidize triacontane in the first instance was traced to impurities, particularly iodine which was not removed completely in the synthesis of the substance. These greatly prolonged the period of time during which no oxidation occurred. Later this same compound, triacontane, was synthesized by the electrolysis of sodium palmitate, and the product so obtained was not contaminated with halogens which inhibit oxidation.

In Chapter 37 the work of Landa on the oxidation of paraffin wax was mentioned. His results led to the conclusion that slow oxidation of the homologues of methane took place according to Bone's hydroxylation theory and that the presence of alcohols and ketones among the oxidation products indicated the presence of branched-chain hydrocarbons in paraffin wax. His further work on the oxidation of triacontane, which is a straight-chain compound, appeared to substantiate this.[105] This product was made both from Japanese wax and by the electrolysis of an alcoholic solution of potassium palmitate. The oxidation products included aliphatic acids (formic, butyric and valeric), aldehydes (hex- and hept-aldehydes) from which acids were formed, and a small amount of unsaturated hydrocarbons and carbon monoxide and dioxide, but no alcohols or ketones. The oxidation of this substance was carried out at 290° to 310° C. and no preferential catalyst (such as turpentine) was used. Both of these factors, no doubt, explain why he obtained products of lower molecular weight than did Francis and Wood.

Landa has also suggested that slow oxidation, or gradual combustion of petroleum oils may be used as a test for the presence of paraffin. Oils containing paraffin give a positive aldehyde test with Schiff reagent after oxidation.

In attempting to get a clearer insight into the nature of the reactions taking place during the oxidation of paraffins, Salway and Williams[106] studied the oxidation of two pure compounds, hexadecane and stearic acid. The former was chosen as representative of paraffin hydrocarbons. Since the higher acids produced by oxidation of paraffin hydrocarbons subsequently undergo further change as the action is continued, stearic acid was chosen to represent an oxidation product. The oxidation was carried out for 24 hours at 120° to 130° C. in a current of oxygen with 2 per cent of manganese stearate as a catalyst.

From the hexadecane were obtained 4 per cent of volatile acids, carbon dioxide, formic and acetic acids. The rest of the reaction product consisted of about 70 per cent acidic substances and 30 per cent unchanged hexadecane. The acidic substances, after extracting with sodium hydroxide, consisted of a pale yellow oil, about 20 per cent of which was volatile with steam, and appeared to be principally hexanoic and nonanoic acids. The non-volatile portion was largely lactonic acids similar to those produced by the oxidation of stearic acid.

These investigators found that the oxidation of stearic acid yielded about 5 per cent of volatile acids, principally carbon dioxide and formic acid together with some acetic and higher acids and about 8 per cent of water-soluble acids, of which about 35 per cent were volatile with steam and proved to be formic, acetic, and butyric, and the remainder, dibasic acids of the malonic acid series. The main product of the reaction, however, consisted of hydroxy-acids and their lactones, none of which could be isolated in a pure condition.

The results obtained by Salway and Williams are in agreement with the earlier findings of Zerner.[107] The latter oxidized stearic acid under practically the same conditions. In addition to the volatile acids, he also obtained an alcohol of the formula $C_{12}H_{20}O$. Among the dibasic acids formed, succinic and pimelic were identified. The main product, however, was a mixture of hydroxy-acids which formed soaps that lathered well in water but could not be salted out. The results of the oxidation of ethyl stearate under the same conditions did not seem to indicate, because of the disappearance of the ethoxy-group, that stearic acid was preferentially oxidized at either end of the carbon chain. Compounds containing eight or less carbon atoms were not oxidized under the same conditions.

Pflugk[107a] investigated the influence of various factors upon the oxidation of paraffins to acids. The optimum temperature for air oxidation was 160° C. Lengthy incubation periods were observed at lower temperatures. The yield of fatty acids increased to a limit with increase in air-current velocity, the most favorable rate being 1100 to 1300 liters per hour per 300 grams of paraffin. A small moisture content (1.2 per cent by volume) increased the yield slightly. According to Pflugk, the mechanism of formation of fatty acids is as follows: Unsaturated compounds are formed by elimination of 2 hydrogen atoms as hydrogen peroxide. Fracture of the chain and anhydride or acid formation then takes place. Peracids and peroxides were found in the products, which was accounted for by reaction of hydrogen peroxide with the wax acids or anhydrides. Acid substances, when present, acted as catalysts but alkalies did not.

SUMMARY

The paraffin waxes from petroleum or similar products can be oxidized to organic acids. The acids thus produced may be roughly divided into two classes: (1) volatile acids of the type of acetic acid, and (2) water insoluble acids which contain ten or more carbon atoms. The term "wax acids" has been used to describe these water-insoluble acids. A large proportion of these acids often contain an uneven number of carbon atoms in the molecule, in contradistinction to the typical "fatty acids" which contain an even number of carbon atoms. Francis[108] and his co-workers have pointed out the difficulty of identifying the acids obtained by the oxidation of paraffin wax or of the alcohols from Chinese and carnauba wax. It arises from the fact that the mixed crystals of acids of two different carbon contents show properties corresponding to those of pure compounds of higher carbon content. The products from the oxidation of natural compounds, purified by the customary procedures, may therefore really be mixtures. These wax acids, however, can be used in the production of soaps, and also, no doubt, in the production of synthetic fats.

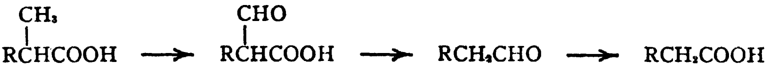
For producing wax acids on a commercial scale, air appears to be the best and cheapest oxidizing agent. Other oxidizing agents (pure oxygen, ozone, oxides of nitrogen) as well as electrochemical methods can be used. The optimum temperature for oxidation is about 150° to 180° C. At higher temperatures, more vigorous oxidation takes place, and a higher percentage of lower molecular weight products are obtained. At lower temperatures, the time required for oxidation is excessive. Oxidizing under increased pressures, at least in some instances, aids in speeding up the reaction.

The oxidation is preceded by a latent period during which oxygen is absorbed with the formation of only a small quantity of acids. This period may be shortened by the use of catalysts, particularly organic acids such as stearic or cinnamic or their salts. Turpentine has been mentioned as a catalyst for the selective oxidation of certain constituents of paraffins. The use of alkalies as catalysts appears to be questionable.

Other products in addition to acids and alcohols are aldehydes and ketones. It seems to be a general rule that aldehydes are the principal products if the hydrocarbon consists for the most part of straight-chain compounds. Alcohols and ketones are more likely to be obtained from the branched-chain hydrocarbons. In some instances, the presence of hydroxy-acids, lactones, and even diketones, has been reported.

Three general theories have been suggested for the mechanism of the oxidation of paraffin: (1) that oxidation proceeds according to the hydroxylation theory; (2) that the hydrocarbons during heating lose hydrogen and become unsaturated, and oxidation then takes place at the double bond accompanied by a breaking up of the molecule; and (3) that the formation of esters takes place first, followed by the oxidation of these substances to acids.

For any α-substituted acids that might be present or formed, the oxidation mechanism suggested by Raper[109] may be applicable. This mechanism is based on Knoop's rule of β-oxidation, which states that the carbon atom of the methyl group present in such acids in the β-position to the carboxyl group, is oxidized in preference to the β-carbon atom in the main chain, thus:



$$\underset{\text{R}\overset{|}{\text{C}}\text{HCOOH}}{\text{CH}_3} \longrightarrow \underset{\text{R}\overset{|}{\text{C}}\text{HCOOH}}{\text{CHO}} \longrightarrow \text{RCH}_2\text{CHO} \longrightarrow \text{RCH}_2\text{COOH}$$

The whole problem of the oxidation of paraffins is a complicated one. Apparently contradictory results have been reported, probably because of the lack of definite methods of determining the composition of the various components of different oxidized waxes.[110] When improved methods become available, many of the apparent discrepancies in the results of various workers will no doubt disappear.

Chapter 44

Oxidation from the Standpoint of Detonation

GASEOUS EXPLOSIONS. LIMITS OF INFLAMMABILITY

For each pair of gases forming a combustible mixture there is both an upper and a lower limit of inflammability. The lower limit corresponds with the minimum quantity and the higher, or upper, limit with the maximum quantity of combustible gas capable of conferring inflammability on the mixture. For example, at ordinary pressures and temperatures the limiting concentrations of methane-air mixtures are approximately 5 and 14 per cent methane.[1]

One factor which affects the limits of inflammability is the direction of the propagation of the flame. Generally these limits are slightly wider for upward propagation than for downward or for horizontal propagation. Other factors which influence the limits of inflammability are the diameter and length of the vessel, and whether it is open or closed. Over small ranges, variations in temperature or pressure do not appear to have much effect on the limits. Over great increases of temperature, however, there is generally a widening in the limits. Pressure decreases are usually accompanied by a narrowing of the limits. This may not be perceptible for a decrease of a hundred millimeters or so in pressure, but as the pressure is further diminished, the upper and lower limits begin to approach one another and finally coincide. An increase in pressure is not invariably accompanied by a widening of the limits. In many instances, a narrowing of the limits of inflammability is brought about by this change. Turbulence also appears to be specific in its effect. For example, the lower limits of inflammability of both methane and ethane in air are lowered by turbulence, although the range of inflammability of ether-air mixtures is widened.

The figures in Table 144 give the limits of inflammability in air of some of the more common gases or vapors. These limits were obtained in tubes of about the same diameter (7.5 centimeters) and with upward propagation of the flame.[2]

TABLE 144.—*Limits of Inflammability in Air (Upward Propagation of Flame).*

Gas or Vapor	Gas Per Cent	Gas or Vapor	Gas Per Cent
Hydrogen	4.15–75.0	Ethylene	3.0–34.0
Carbon Monoxide	12.8 –75.0	Propylene	2.2– 9.7
Methane	5.35–14.9	Butylene	1.7– 9.0
Ethane	3.12–15.0	Acetylene	2.6–80.5
n-Pentane	1.42– 8.0	Benzene	1.4– 7.5
		Toluene	1.3– 6.8

The variations in the limits of inflammability with the direction of the propagation of flame for acetylene in air are as follows:

---

[1] See Coward and Jones, Limits of Inflammability of Gases and Vapors, *U. S. Bur. Mines Bull.* 279. 1928. This is an excellent summary of this subject and gives the limits for a large number of gases and vapors. An extensive bibliography is included.

[2] White, *J.C.S.*, 1922, 121, 1244; *ibid.*, 1924, 125, 2387.

2.60–80.5	Upwards
2.68–78.5	Horizontal
2.78–71.0	Downwards

The upper and lower limits of inflammability for flame propagation upwards, horizontally, and downwards have been determined by White[3] for mixtures of air with hydrogen, hydrogen sulphide, carbon monoxide, and various saturated and unsaturated hydrocarbons containing up to five carbon atoms. In making these determinations closed tubes of various diameters were used. It was observed that, with tubes of 7.5 centimeters diameter, wall-cooling exerted very little influence on the values of the lower limits, but the results for the upper limits occasionally differed appreciably from those obtained with a 5-centimeter tube, probably because of convection. In many instances, the lower limits of the mixtures could be calculated with a reasonable degree of accuracy from the calorific value of the gas. With several mixtures it was possible to obtain similarly a rough approximation of the upper limits. The type of bond which must be ruptured or broken when the gas or vapor is burned seemed to greatly influence these values.

This work was extended[4] to include gaseous mixtures, such as methane and hydrogen, ethylene and hydrogen, and others. The results show that a fair approximation to the limiting values of the mixtures can be secured by the application of the law developed by Le Chatelier,[5] which states that a mixture of any two limit mixtures (both upper or both lower) will itself be a limit mixture. These approximations were usually closer to the experimental values for the lower rather than for the upper limits, and for downward rather than upward flame propagation. For both gas and vapor mixtures the type of flame started often determined whether or not propagation would occur.

White[6] also showed the effect of temperature on the upper and lower limits for downward propagation of the flame. In all instances the limits were widened, and the degree, or percentage change in the limits, differed with the various gases studied.

The upper and lower explosive limits of more complicated gas mixtures, such as those encountered in the manufacture of city gas, have been determined by Yeaw.[7] A small quantity of illuminating constituents was found to reduce the upper limits from about 70 per cent of the gas to 30 per cent, but the lower limit was affected to a much smaller degree. The upper limit was unaffected by large changes in the ratio of hydrogen to carbon monoxide, as they both have ap-

TABLE 145.—*Analysis and Explosive Limits of Various Gas Mixtures.*

								Limits (Gas in Air)	
Gas	CO_2	Illuminants	O_2	CO	H_2	CH_4	N_2	Lower	Upper
	Per Cent								
Oven	1.9	3.9	0.4	6.3	54.4	31.5	1.6	5.0	28.4
Coal	2.4	2.7	0.4	9.7	44.9	28.9	11.0	5.6	30.8
Mixed	2.5	3.2	0.5	10.5	47.0	25.8	10.5	5.6	31.7
Carbureted blue	4.6	7.3	0.3	36.0	37.0	9.6	5.2	6.4	37.7
Blue	6.2	0.0	0.3	39.2	49.0	2.3	3.0	6.9	69.5
Producer	6.2	0.0	0.0	27.3	12.4	0.7	53.4	20.7	73.7

[3] White, *J.C.S.*, 1924, 125, 2387.
[4] White, *J.C.S.*, 1925, 127, 48.
[5] *Ann. mines*, 1891, (8) 19, 388; see Coward and Jones, *op. cit.*
[6] *J.C.S.*, 1925, 127, 672.
[7] *Ind. Eng. Chem.*, 1929, 21, 1030. For the inflammable limits of exhaust gases from automobiles see Jones, *Ind. Eng. Chem.*, 1928, 20, 901.

proximately the same upper limits. The upper limit of the gas mixture was lowered by increasing the methane content. These changes are illustrated by the data in Table 146.

The upper or lower explosive limit (L) of a gas mixture can be calculated by the use of the formula[8]

$$L = \frac{100}{\frac{a}{A} + \frac{b}{B} + \frac{c}{C} + \ldots}$$

in which a, b, and c are the relative proportions of the components of the mixture (in parts per hundred of the mixture) and A, B, and C are their respective inflammability limits. In applying this formula to such complicated mixtures as those just mentioned above, it is better to follow a modification suggested by Jones.[9] This is illustrated by taking the analysis of the producer gas given in the preceding data, and grouping together the carbon dioxide and monoxide, and the nitrogen and hydrogen.

Mixtures	Total	Ratio of Inert Gas to Combustible Gas	Limits of Inflammability[a] Lower	Upper
	Per Cent		——Per Cent——	
(1) 27.3% CO 6.2% CO_2....	33.5	0.2	17.0	70.0
(2) 12.4% H_2 53.4% N_2.....	65.8	4.3	23.0	76.0
(3) 0.7 CH_4	0.7	0.0	5.5	14.5

[a] For these values and methods of obtaining them see Jones, *Ind. Eng. Chem.*, 1928, **20**, 901.

Substituting these values in the formula,

$$\text{Lower Limit} = \frac{100}{\frac{33.5}{17.0} + \frac{65.8}{23.0} + \frac{0.7}{5.5}} = 20.2\%$$

$$\text{Upper Limit} = \frac{100}{\frac{33.5}{70.0} + \frac{65.8}{76.0} + \frac{0.7}{14.5}} = 71.8\%$$

For gases containing illuminants, the limits of inflammability of the illuminants, for the purposes of calculation, may be taken as 2 and 8 per cent, respectively. The calculated values in most instances are in good agreement with the observed values, but generally slightly lower.

It has been pointed out by Jones and Perrott[10] that, although the explosive limits of hydrocarbon vapors from petroleum and its products when mixed with air range from about 1 per cent (lower limit) to 12.5 per cent (upper limit), such mixtures can be made non-explosive by the addition of sufficient inert gases such as nitrogen, carbon dioxide, or flue gas. Jorissen and Meuwissen[11] showed that explosions of methane-air mixtures can be inhibited by the addition of non-inflammable vapors of organic liquids such as carbon tetrachloride or trichloroethylene. Crouch and Carver[12] found that methyl alcohol-air and acetone-air mixtures are rendered non-explosive when nitrogen is added to the mixtures in proportions sufficient to reduce the oxygen content to less than 11 per cent.

---

[8] This formula was derived by Coward, Carpenter, and Payman (*J.C.S.*, 1919, **115**, 27) and its derivation was based upon the theoretical considerations of Le Chatelier (*Ann. mines*, 1891, (8) **19**, 388).

[9] *Loc. cit.*

[10] *Quart. Natl. Fire Protect. Ass.*, 1930, **23**, 385; *Chem. Abs.*, 1930, **24**, 6018.

[11] *Rec. trav. chim.*, 1924, **43**, 591; *Chem. Soc. Abs.*, 1925, **128** (2), 53.

[12] *Ind. Eng. Chem.*, 1925, **17**, 641.

These investigators also observed that Le Chatelier's law held for the mixtures studied.

Jorissen[13] called attention to the fact that a vapor added to a hydrocarbon-air mixture may act either as a positive or a negative catalyst. For example, 1.75 per cent of isobutyl chloride vapor added to a 10 per cent methane-air mixture renders it non-inflammable, but a non-inflammable 2.2 per cent methane-air mixture is rendered inflammable by this same proportion of isobutyl chloride. Propyl bromide, silicon tetrachloride, and sulphuryl chloride behave in a similar manner.

Ignition of Gases by Heated Surfaces

Mason and Wheeler[14] mentioned that the exposure of inflammable mixtures to heated surfaces was one of the earliest methods of determining ignition temperatures.[15] Determinations by this method, as usually made, however, do not give absolute values since the results are affected by the nature and the extent of the solid igniting surface. By modifying the usual method, Mason and Wheeler were able to obtain what they called the relative ignition temperature and also the composition of the most readily ignited mixture of methane and air. Briefly, they introduced known mixtures of methane and oxygen into a small quartz cylinder (81 cc. capacity) which had been heated to a predetermined temperature. The temperature to which it was necessary to heat the walls of the bulb in order that a given mixture would ignite was taken as the ignition temperature. Table 146 gives some of the data which were obtained:

Table 146.—*Relative Ignition Temperatures of Methane-Air Mixtures.*

Methane in Air Per Cent	Relative Ignition Temperature ° C.	Methane in Air Per Cent	Relative Ignition Temperature ° C.
2.00	711	8.00	701
3.00	700	8.80	707
3.95	696	10.00	714
5.85	695	11.75	724
7.00	697	14.35	742

The "pre-flame period" or "lag on ignition" was defined as the time interval between the introduction of the gas into the hot cylinder and the appearance of the flame. For methane-air mixtures containing between 2.5 and 13.0 per cent methane the lag varied from 10 to 15 seconds when the vessel was just at the relative ignition temperature. This period decreased with decreasing concentrations of methane and as the temperature of the cylinder was increased beyond the relative ignition temperature. It was also noted that ignition was accompanied by a sudden rise of pressure within the quartz vessel.

Continuing their work on ignition temperatures, Mason and Wheeler[16] determined these values for various mixtures of paraffins and air. Their data, some of which are given in Table 147, showed, however, that the relative ignition temperatures for hydrocarbon-air mixtures of approximately the same concentration decreased as the molecular weight of the hydrocarbon increased.

2.80% Ethane	571
2.50% Propane	552
2.60% Butane	531
2.75% Pentane	520

The duration of the lags on ignition for all mixtures of methane and air when oxygen was in excess was between 10 and 16 seconds. As the methane concentration was increased, the lag decreased, being about 6.6 seconds (at 720° C.) for a 12.8 per cent methane mixture. With ethane the reverse appeared to take place, as the lag was 28 seconds for a 1.9 per cent ethane mixture at 594° C. and 144 seconds for 10.6 per cent ethane at 534° C. Propane and butane behaved similarly to ethane. The lags for the former varied from 20 to 56 seconds and for the latter from 22 to 25 seconds. Pentane, on the other hand, resembled methane. The lags for the mixtures containing 1.5 to 3.75 per cent pentane were about 15 seconds, and for a 7.65 per cent mixture, about 5 seconds.

These pre-flame periods or lags on ignition, however, are a measure of the relative ignitibility when the gaseous mixtures were introduced into the quartz cylinder heated to a temperature well above the relative ignition temperature. With a temperature, for example, of 600° C., the lag decreased with increasing concentration of hydrocarbon, and with increasing molecular weight. This was true for all the hydrocarbons except methane, the relative ignition temperature of which is well above 600° C.

When mixtures of methane and oxygen, which in turn were mixed with an inert gas, were admitted to a quartz reaction vessel, those reactions which resulted in the production of a flame were thermal reactions catalyzed by the products of an initial slow and flameless combustion.[17] The total amount of heat acquired by the reacting gases depended upon the thermal properties of the inert gas, which absorbs a portion of the heat developed by the oxidation processes. For example, when the nitrogen in methane-air mixtures was replaced by argon, which has both a lower specific heat and lower thermal conductivity, the ignition temperatures of the mixtures were decreased. Replacement of the nitrogen by helium, a gas of high thermal capacity, on the other hand, raised the ignition temperatures. Among the oxidation products formed during the lag on ignition were formaldehyde and carbon monoxide.[18] Addition of either one of these products (about 0.02 per cent) to a methane-air mixture lowered its ignition temperature and shortened the period of lag. Formaldehyde was more effective than carbon monoxide, however. Other substances, such as ethyl iodide or bromide, carbon tetrachloride, traces of iodine, and lead tetraethyl, raised the ignition temperatures of methane-air mixtures and also decreased the speed of the reactions which occur below the ignition temperatures. The inhibiting action of these substances appeared to take place on the surfaces of the reaction vessel.

---

[17] Naylor and Wheeler, *J.C.S.*, 1931, 2456.

[18] Among the intermediate products of the combustion of methane and oxygen which have been identified are formaldehyde, hydrogen peroxide, and ozone. (Riesenfeld and Gurian, *Z. phys. Chem.*, 1928, 139, 169; *Brit. Chem. Abs.* **A**, 1929, 289.) In the combustion of methane in oxygen the yield of ozone increases as the quantity of excess oxygen increases, although the yields of hydrogen peroxide and formaldehyde decrease. When oxygen burns in methane the yield of hydrogen peroxide again decreases but that of formaldehyde increases as the quantity of excess methane increases. No ozone is formed. The mechanism of the formation of these products was considered to involve the decomposition of the methane into methylene (CH_2) and atomic hydrogen. The atomic hydrogen forms mainly molecular hydrogen and some hydrogen peroxide. The methylene burns partly to carbon monoxide and formaldehyde. Further oxidation of these products gives water and carbon dioxide.

Lewis[19] showed that for paraffin hydrocarbon-air mixtures there is a critical temperature at which chemical reaction takes place readily with an increase in the number of molecules. This was demonstrated by slowly heating a given quantity of the liquid hydrocarbon in a large cylindrical bulb while the pressure on the bulb was slowly increased so as to keep the gas volume constant. If no chemical change took place the temperature-pressure curves should follow approximately the gas laws. In the case of the hydrocarbon-air mixtures a sudden rise in pressure, or inflexion, was always noted, thus indicating chemical reaction. The temperature at which this rise occurred was called the critical inflexion temperature (C. I. T.) and was dependent upon the molecular weight of the hydrocarbon. For example, the critical inflexion temperatures of some paraffins are as follows: pentane, 253° C.; hexane, 232° C.; heptane, 212° C.; octane, 198° C. These values were slightly lower for the normal hydrocarbons than for the isohydrocarbons. Thus the critical inflexion temperature of n-pentane is 253° C. but that of isopentane is 259° to 260° C. These values were only slightly affected by the concentration of the hydrocarbon vapor in the apparatus. Once the inflexion temperature was passed the gas mixtures then appeared to be stable up to about 450° C.

In considering the mechanism of the oxidation it appeared that the first step was a primary dehydrogenation, followed by oxidation of the hydrogen to water. This would account for (1) an increase in the number of molecules at the critical inflexion temperature, (2) the presence of water among the products of oxidation, and (3) the formation of unsaturated hydrocarbons at temperatures near the critical inflexion temperature.

Metallic catalysts were divided by Lewis into two classes: (1) promoters of detonation and (2) "antiknocks." To the former class belong such catalysts as platinum which promotes the reaction $2H_2 + O_2 \rightarrow 2H_2O$. To the latter belongs lead tetraethyl which actually retards either this reaction or the action of oxygen on the hydrocarbons. Unsaturated compounds are effective as antiknocks since they have a smaller hydrogen content, hence, are less likely to be dehydrogenated and because they have a tendency to combine with the hydrogen evolved from the saturated hydrocarbons. The latter explanation may also account for the action of aromatic amines. For example, with aniline, the reaction may be represented as

$$C_6H_5NH_2 + 2H \longrightarrow C_6H_6 + NH_3$$

Later, while investigating the ignition temperatures of some hydrocarbons in oxygen, Lewis found that the conditions which were necessary for the explosion of such mixtures on progressive heating were sufficiently rapid rise in temperature and an adequate concentration of oxygen, and a concentration of oxygen above a certain minimum, which minimum value increases rapidly with the molecular weight of the hydrocarbon. To obtain ignition with unsaturated hydrocarbons it is necessary that they be present in high concentrations and be heated rapidly. With a bulb of 225 cc. capacity a heating rate of about 1° C. per minute was usually sufficient, though at this rate all concentrations of diisoamyl failed to ignite. Increasing the rate of heating tended to raise the ignition temperature by "superheating", particularly in the case of the paraffins, though the effect was much less marked with the olefins. As shown by the data in Table 148, no distinction was observed between the minimum ignition temperature and the critical inflexion temperature.

---

[19] *J.C.S.*, 1927, 155; *ibid.*, 1930, 58.

TABLE 148.—*Relation of the Minimum Ignition Temperature to the Critical Inflexion Temperature.*

Hydrocarbon	Minimum Ignition Temperature ° C.	C. I. T. ° C.
n-Pentane	255–257	255
n-Hexane	232–233	230
n-Heptane	218–220	209
n-Octane	203–204	197
Amylene	241–242	240

It was also suggested that the successive stages in the combustion of paraffins were: (1) primary dehydrogenation, to yield unsaturated hydrocarbons, (2) combination of the unsaturated hydrocarbons with oxygen to form unstable peroxides, and (3) decomposition of peroxides to yield aldehydes which could be further oxidized to water and the oxides of carbon.

Powdered glass and pumice or metals such as platinum, silver, lead and copper increased the ignition temperature of the hydrocarbons. Tin, zinc or aluminum had no effect. Charcoal caused an increase for the paraffins but a decrease for the olefins. Lead tetraethyl caused a marked increase in every case, though its effectiveness rapidly reached a maximum, about 3 to 4 per cent in the case of octane.

Masson and Hamilton[20] used what might be termed the crucible method for the determination of ignition temperatures. A circular platinum plate containing an indentation is welded to the hot junction of a platinum-platinum 10 per cent rhodium thermocouple. The cold junction is placed in a thermos bottle filled with ice to maintain a temperature of 0° C. Heavy platinum wires are welded to the plate and serve as conductors for the alternating current employed in heating the plate. The plate is placed inside the furnace, also heated with alternating current. There is a nickel coil through which dry air is delivered to the plate to remove the products of combustion. The furnace is closed with an alundum top containing a "look tube" with a magnifying glass focused on the platinum plate, and a quartz tube through which the liquid was allowed to drop. An ordinary hypodermic needle was used to obtain drops of constant size.

In making measurements the furnace was first heated until a flash appeared 1 second after the drop of liquid fell on the plate. The temperature of the furnace was then lowered about 10° F. and held constant. The temperature of the plate was raised very slowly until ignition again took place. The temperature of the plate was next raised 15° to 20° F. above this value and then slowly decreased until ignition again just took place. In this way it was possible to obtain readings which could be duplicated within 1° F. Readings were made also of the cooling effect of a drop of liquid on the plate and the rise in temperature which results from surface combustion. A stream of dry air was used to remove the products of combustion after each experiment, but during an actual determination no movement of air over the plate was permitted.

[20] *Ind. Eng. Chem.*, 1927, 19, 1335; *ibid.*, 1928, 20, 813.

With this apparatus the ignition temperatures of about 80 organic substances were determined. These substances included aromatic and aliphatic hydrocarbons, alcohols, aldehydes, ketones, acids, esters, ethers, amines, and halogen and other derivatives. For a particular class of compounds, normal paraffin hydrocarbons, for example, the ignition temperatures generally decreased with the molecular weight but this decrease was not progressive. Substances of widely different structures and compositions exhibited similar ignition temperatures.

The surface was found to have an effect on the ignition temperature. Surfaces of materials which are known to be catalytically active, contrary to expectations, except in a few instances, gave higher ignition temperatures. This was brought out particularly by the comparison of platinum with glass surfaces, though silver and gold ones were also used.

Bridgeman and Marvin[21] showed that the ignition temperature of a liquid fuel depends upon the material and volume of the vessel used, the concentration of oxygen in the mixture, the lag on ignition, the pressure in the system, and the composition of the fuel. As no test has been devised yet which is standardized with respect to all these variables, results obtained with the same substance by different investigators may vary widely.

Experiments carried out by Bridgeman and Marvin in a bomb indicated that the time required to produce firing depended upon the rate at which heat is received from or lost to the container. Ignition temperatures which involve a lag before ignition, are composite functions of several properties of both the fuel and the apparatus. Actual firing is usually caused by an increase in the temperature of the charge above that of the container, as a result of heat generated in the charge itself. Such ignition temperatures are appropriately called auto-ignition temperatures. The temperature at which instantaneous ignition (without any lag) occurs is the true ignition temperature and is a fundamental property of a given fuel under definite conditions of pressure and concentration.

Compression methods appear to be best adapted to the study of such ignition temperatures. When the charge is adiabatically compressed, the heating is very uniform throughout the charge and the resulting mean temperature can be calculated from the initial conditions and the compression ratio. Ignition in a mixture immediately following adiabatic compression should therefore permit a close approximation to the true ignition temperature.

Closely allied with the ignition of gases by hot surfaces is that produced by heated wires, metallic bars, and similar heated units. The extent to which the glowing filament of a 2-volt miner's electric lamp might be the source of danger in coal mines when the bulb was broken in such a manner as to leave the filament intact has been investigated by Shepherd and Wheeler.[22] The thicker the wire, the lower is the temperature to which it must be heated to cause ignition of mixtures of air and methane.

Mixtures of natural gas (93.2 per cent methane) and air are more easily ignited by wide metallic bars, when heated, than by narrow bars.[23] With platinum it was necessary to heat to a higher temperature than with nickel.[24] This temperature difference in some instances amounted to several hundred degrees. With nickel, tungsten and certain steels, the ignition temperature rose regularly with increasing natural gas content, but with platinum the most explosive mixtures required the highest temperatures. With molybdenum the ignition temperatures of the gas mixtures decreased with increasing natural gas content. This abnormality, however, was probably associated with the burning of the metal, as dense clouds of molybdenum oxide were observed.[25] Moderate turbulence of the gas decreased the ignition temperature, probably by bringing the inflammable gas into the zone of the burnt-out gases and thus raising its temperature. When turbulence was sufficiently great, however, the opposite result was produced.

Hot-wire ignition curves were obtained by Schaad and Boord [26] for n-propyl, n-butyl, and isoamyl alcohols, toluene, isoamyl acetate, kerosene, diethyl maleate, and diethyl fumarate between the lower and upper limits of inflammability. The fuel-air mixtures were produced by bubbling air first through the liquid fuel kept at definite temperature (the saturator) and then through the same fuel in the bottom of an ignition tube. Both the saturator and ignition tube were kept at the same temperature. The fuel-air mixture then passed directly in contact with a hot wire.

Curves for ignition amperage plotted against the temperature of the saturator first decreased rather rapidly until a minimum was reached, and then rose again as the upper limit (higher saturator temperature) of inflammability was approached. This minimum temperature differed with the individual fuels. The addition of knock suppressors, such as lead tetraethyl, selenium diethyl, and aniline, increased the lowest temperature required for normal ignition. This increase, measured by current flow, varied from 9.5 to 2.0 amperes, depending upon the knock suppressor added. On the other hand, knock inducers, such as nitrobenzene or isoamyl nitrite, lowered the amperage required for ignition. This lowering varied from 0.15 ampere for nitrobenzene in isoamyl acetate to 1.0 ampere for propyl nitrite in toluene.

Pre-ignition combustion curves were obtained also by using filament currents less than that required for ignition and plotting these against the quantity of carbon dioxide formed. Very little if any carbon monoxide was produced. Without exception, the addition of knock suppressors to the fuels effected a decrease in the pre-ignition combustion, but the addition of a knock inducer caused a marked increase.

IGNITION BY ELECTRICAL DISCHARGE

The relative ease of ignition of a series of methane-air mixtures was measured by Wheeler.[27] He determined the minimum current required to ignite the mixtures.[28] In testing 28 mixtures of methane and air, which contained from 5.85 to 11.50 per cent methane, it was found that the relative igniting current varied from 1.2 amperes for the 5.85 per cent mixture to a minimum of 0.585 ampere for an 8.20 per cent mixture and then rose again to 1.56 amperes for the 11.50 per cent mixture. A plot of the percentage of methane against current yielded a smooth curve. Mixtures of methane and air in which the initial speed of flame propagation was fastest contained from 9.5 to 10 per cent methane, and the most easily ignited mixtures contained 8.2 to 8.3 per cent methane.

The relative ease of ignition of methane-air mixtures with induction sparks (low tension "break-flashes" or momentary arcs) was also investigated.[20] An induction spark differs from a capacity spark principally in its longer duration.

---

[25] *Cf.* these results with molybdenum and tungsten with those obtained by Shepherd and Wheeler (*loc. cit.*) with tungsten.

[26] *Ind. Eng. Chem.*, 1929, **21**, 756.

[27] *J.C.S.*, 1920, **117**, 903.

[28] *Cf.* Thornton, *Phil. Mag.*, 1920, **40**, 305; *Chem. Abs.*, 1920, **14**, 3796; Paterson and Campbell, *Proc. Phys. Soc.*, 1919, **31**, 193; *Chem. Abs.*, 1919, **13**, 1970.

[29] Wheeler, *J.C.S.*, 1925, **127**, 14.

This difference was great enough to make it important to determine whether induction sparks were to be regarded as momentary sources of heat or as sustained sources, such as heated surfaces. The results of an extensive investigation indicated, however, that as far as paraffin hydrocarbons were concerned, inductance sparks could be considered similar in effect to capacity sparks, in spite of the wide difference in the two types, both as regards duration and volume. The longer duration and larger volume of the inductance sparks apparently mask small differences in the ease of ignition of those mixtures which are most readily ignited.

Some information regarding the chemical action which takes place during the ignition of methane by the electric spark discharge was obtained by Coward and Meiter.[30] They observed that the spark from an induction coil starts the general inflammation of readily ignitible mixtures of methane and air (8 to 9 per cent methane) when discharged between bluntly pointed platinum electrodes, 0.5 mm. apart. This spark was of sufficient strength to inflame just over 0.5 cu. mm. (measured at ordinary temperatures and pressures) of the mixture. With other mixtures this quantity varied, ranging from 1.5 cu. mm. for a 6.2 per cent mixture to 1.0 cu. mm. for an 11.2 per cent mixture. The spark from an air condenser, which consisted of but one flash, had to inflame only about 0.9 cu. mm., of the most readily ignitable mixtures, to induce general inflammation.

For any given methane-air mixture, with a current of the primary of the induction coil which was less than that required for ignition, it was observed that the extent of the reaction which took place was very nearly proportional to the square of the current. The reaction products contained a large quantity of carbon monoxide and hydrogen, even when a large excess of oxygen was present. It was therefore concluded that the methane-air flame, started by a spark discharge, was propagated from the vicinity of the spark by the heats of reaction of

$$CH_4 + O_2 \longrightarrow CO + H_2 + H_2O\text{ (gas)} + 65{,}000\text{ cal.}$$
$$2H_2 + O_2 \longrightarrow 2H_2O\text{ (gas)} + 116{,}000\text{ cal.}$$

The methane flame appeared to have a small thickness, the first lamina of which included chiefly the formation of carbon monoxide and water vapor and the last lamina, principally the formation of carbon dioxide.

The observed volumes of gas which must be ignited in order to start general inflammation were shown to agree approximately with the known facts concerning the energy of the igniting spark, and the thermal conductivity and ignition temperature of the mixture. Hence, it appears as if the electric spark acts mainly, if not entirely, as a source of thermal energy in igniting a gas mixture.

With a new apparatus of the make-and-break type, developed for the ignition of gaseous mixtures at high temperatures and pressures, Cooper and Wiezevich[31] investigated the upper explosive limits of oxygen-methane mixtures at total pressures from 1 to 229 atmospheres, and at temperatures between 10° and 530° C. It was found that the lower the oxygen concentration, the higher the pressure required for successful ignition. For example, at 20° C., as the total pressure was increased from 1 to 170 atmospheres, the proportion of oxygen in the limit mixture decreased from 39 to 11 per cent. Similarly, rise in temperature was accompanied by a decrease in the proportion of oxygen required for ignition. Spontaneous reactions occurred above 400° C. for the pressure ranges investigated. Complete consumption of the oxygen in the mixture did not take place during explosions at high pressures.

---

[30] *J.A.C.S.*, 1927, 49, 396.
[31] *Ind. Eng. Chem.*, 1929, 21, 1210.

In extending their work to the use of break-spark ignition, Schaad and Boord[32] obtained curves similar to those with hot-wire ignition. The minimum currents required to ignite various fuel-air mixtures were not as great with the break-spark ignition as with the hot-wire ignition. The minima of break-spark ignition curves were very close to those temperatures required for combustion to carbon dioxide, but the minima of the hot-wire ignition curves corresponded very closely to the calculated temperatures at which combustion of the fuel would yield principally carbon monoxide. The presence of knock-suppressors or knock-inducers had very little effect. This seemed to indicate that with hot-wire ignition a burn-out occurred in the vicinity of the heated wire before the current required for ignition was reached, and that this effect was practically absent when ignition was effected by a break-spark. Since this burn-out apparently took place when the amperage was less than that required for ignition it might be considered as preliminary or "pre-ignition" combustion. Knock-suppressors, therefore, seemed to hinder this pre-ignition combustion, but knock-inducers promote it.

INCREASE OF PRESSURE DURING COMBUSTION

The pressures developed with mixtures of air and the first five members of the paraffin series when ignited centrally in a spherical bomb have been measured by Maxwell and Wheeler.[33] In all instances, the pressure rise increases with increasing quantities of hydrocarbon in the gas mixtures, reaching a maximum with mixtures containing slightly more hydrocarbon than that required for complete combustion. Beyond this maximum, the rise in pressure decreases with increasing hydrocarbon content.[34] Similar observations were made of the time required for the pressure to develop after ignition and the time required for the maximum pressure to develop. Some of the data obtained by Maxwell and Wheeler with methane-air and butane-air mixtures are given in Tables 149 and 150:

TABLE 149.—*Pressure Developed in Ignition of Methane-Air Mixtures.*
Theoretical mixture for complete combustion: 9.74% CH_4.
Approximate limits of inflammability: 5.6 to 13.6% CH_4.

Methane Per Cent	Time from Ignition to First Indication of Pressure Sec.	Time from Ignition to Maximum Pressure Sec.	Maximum Pressure (Atmos.)
6.05	0.167	0.545	2.67
7.35	0.058	0.119	5.69
10.20	0.020	0.067	7.43
11.90	0.045	0.102	6.54
13.40	0.166	0.368	4.23

Calculated pressures were always higher than observed pressures, the closest agreements being obtained with maximum-pressure mixtures. The discrepancies were believed to result principally from errors in the values of the specific heats of the gases formed during combustion. The mean temperature of the explosion was considered as the principal factor in determining the mean rate of the development of pressure. There was a general agreement between

[32] *Loc. cit.*

[33] *J.C.S.*, 1927, 2069.

[34] Fenning (*Phil. Trans.*, 1926, **225A**, 331; *Brit. Chem. Abs.* **B**, 1926, 258) reported that under an initial pressure of 95 pounds per square inch and a temperature of 100° C. a maximum pressure was obtained with a 9.7 to 10.5 per cent methane-air mixture and a minimum of "explosion time" with 9.7 per cent methane.

TABLE 150.—*Pressure Developed in Ignition of Butane-Air Mixtures.*
Theoretical mixture for complete combustion: 3.12% C_4H_{10}.
Approximate limits of inflammability: 1.65 to 5.7% C_4H_{10}.

Butane Per Cent	Time from Ignition to First Indication of Pressure Sec.	Time from Ignition to Maximum Pressure Sec.	Maximum Pressure (Atmos.)
2.05	0.078	0.149	5.20
3.00	0.027	0.059	8.15
3.75	0.027	0.057	8.59
4.40	0.041	0.080	7.78
5.15	0.136	0.221	5.83

the composition of the maximum-speed mixtures of hydrocarbons and air, i.e., mixtures of paraffin hydrocarbons and air which give the maximum speed of uniform movement of flame, as determined by Mason[35] and those found by Maxwell and Wheeler. It was concluded that the law of speeds as applied to flame movements in tubes was also applicable to the rate of spread of the flame in a closed spherical container.

Results obtained with mixtures of the olefins, ethylene, propylene or butylene, with air were similar to those obtained with paraffins.[36] This can be seen from the figures in Table 151 which were taken from the data given by Maxwell and Wheeler for propylene-air mixtures.

TABLE 151.—*Pressure Developed in Ignition of Propylene-Air Mixtures.*
Theoretical mixture for complete combustion: 4.44% C_3H_6.
Approximate limits of inflammability: 2 to 8% C_3H_6.

Propylene Per Cent	Time from Ignition to First Indication of Pressure Sec.	Time from Ignition to Maximum Pressure Sec.	Maximum Pressure (Atmos.)
3.18	0.059	0.098	5.69
3.82	0.023	0.060	7.20
4.64	0.023	0.044	7.48
5.67	0.026	0.046	7.66
6.89	0.056	0.113	7.05
7.65	0.115	0.380	5.18

A study of the oxidation of pentane with air under pressure and between the temperatures of 20° C. and 300° C. was made by Dumanois and Mondain-Monval.[37] The air and pentane were introduced at a pressure of 5.3 kg. per sq. cm. into a rotating steel bomb of 700 cc. capacity. The pressure-temperature curves indicated that ignition did not take place below 300° C. if the quantity of pentane was 5 to 10 per cent less than that theoretically required for complete combustion, though a slight increase in pressure[38] was noted at 250° C. With a volume of pentane equivalent to the theoretical quantity required for complete combustion (0.5 cc.), the pressure-temperature curves were almost linear, though a slight break was noted at 120° C. Beyond this and up to about 10° to 15° C. below the ignition temperature, the pressure increased rapidly. The ignition temperature decreased from 238° C. to about 220° C. with increasing proportions of pentane. The explosions also became less violent with increasing quantities of pentane. The pressure-temperature curve for pentane-nitrogen mixtures was steeper but showed no break.

[38] *Cf.* Lewis, *loc. cit.*

The presence of 0.11 per cent lead tetraethyl in the pentane-air mixtures caused spontaneous ignition below 300° C. only when the proportion of pentane was greater than that required for complete combustion. Ignition was preceded by a slight increase in pressure and took place at temperatures which were somewhat higher than in the absence of the lead tetraethyl. The curves for benzene under the same experimental conditions failed to exhibit any breaks, and ignition did not take place below 300° C.

When gasoline was substituted for pentane four types of reaction were noted. No spontaneous ignition took place when less than 0.35 cc. was used. With 0.35 to 0.8 cc., violent explosions, accompanied by marked rises in temperature, occurred when the temperature of the bomb reached 220° to 225° C. With 0.8 to 3.6 cc. of gasoline the sudden increases in pressure occurred at gradually decreasing temperatures, although the magnitude of the effect at first diminished, passed through a minimum, and then again increased rapidly. In this third phase it was noted that carbon deposition took place in the bomb. When more than 3.7 cc. of gasoline were used the pressure and temperature increases fell to an even lower value, and were approximately constant for the higher concentrations of hydrocarbons. No carbon deposit was noted in the bomb. These stages corresponded to a discontinuity in the composition of the combustion gases, and also to the different appearances of the flame in the bomb.

To obtain some information with regard to the mechanism of the reactions, hydrocarbon-air mixtures were passed at atmospheric pressure through a heated tube and the oxidation products examined. Reaction began at 160° C. and proceeded rapidly at 300° C., with the production of carbon dioxide, alcohols, aldehydes, and acids. No true ignition was observed even at 360° C. It was concluded that the initial reactions in the bomb were of a similar nature, were exothermic, and were unaccompanied by a flame. Because of their exothermic nature, the temperature of the mixture rises and, if the concentration of the hydrocarbon is sufficiently high, ignition takes place.[39]

When a mixture of pentane and air was heated under pressure at constant volume, Dumanois and Mondain-Monval[40] observed that the sudden rise in temperature and pressure was accompanied by the formation of carbon dioxide and aldehyde. At 230° C. spontaneous explosion of the mixture occurred. The aldehyde was still present in appreciable quantities but the carbon dioxide was not. Analogous results were obtained with hexane, octane, and commercial gasoline. With gasoline it was noticed that unsaturated hydrocarbons were formed during the stage in which no deposition of carbon took place in the steel bomb.[40]

On passing a gaseous mixture of air and pentane (less than 2.5 per cent) at the rate of 6.5 liters per hour into a glass receiver which was heated progressively to 800° C. in such a manner that the products of oxidation were not removed, Prettre, Dumanois and Laffitte[41] observed that a luminescence appeared at 250° to 300° C., and ignition took place at 670° C. With a larger proportion of pentane (up to 13 per cent) luminescence was noticed at 259° to 263° C., depending upon the composition of the gas mixture, and ignition occurred at 670° to 680° C. It was concluded by them, from the changes in the nature of the luminescence that two spontaneous ignitions occur, one at 260° to 300° C.

and the other above 660° to 670° C. In the interval 300° to 600° C. the mixtures do not ignite but only luminesce.

Brown, Leslie and Hunn[42] showed that the rate of increase of pressure in a gaseous explosion is dependent not only on the rate of the chemical reactions, but also on the initial temperature of the mixture. The fuel used in their investigations was a petroleum fraction boiling between 66.9° and 67.4° C., and consisted principally of isohexane. A measured quantity of the fuel together with the desired amount of oxygen and nitrogen was placed in a constant-volume bomb, and the mixture heated to a given temperature. The mixture was then ignited by an electric spark and the changes of pressure with time were recorded photographically by a camera (Midgley indicator[43]). When the fuel was present in excess, increases in initial temperatures resulted in increases in the rate of rise of pressure until a temperature of 75° C. was reached. Above this temperature the rates decreased. When the air or oxygen was in excess no such critical temperature was noticed at room temperature or above.

Carr and Brown[44] determined the rate of pressure increase of explosive mixtures of different types of hydrocarbons containing varying amounts of lead tetraethyl. The effect of this compound was found to be essentially independent of the chemical structure of the fuel but was governed by the type or rate of combustion of the explosive mixture. When the rate of reaction or rise in pressure increased, the retarding action of the lead tetraethyl decreased and an accelerating effect on the combustion was noted. A similar effect was observed on varying the quantity of lead tetraethyl added to the explosive mixture. Small quantities of this substance tended to retard slow combustion. Larger quantities had no retarding action, but produced, in many instances, an actual accelerating effect.

In attempting to explain this action, Carr and Brown assumed that, in slow-burning mixtures, the decomposition products of lead tetraethyl were the active agents. In rapid-burning mixtures, the rate of inflammation is greater than that of the decomposition of lead tetraethyl, the latter therefore does not have time to form those products which retard the flame. The accelerating action of the lead tetraethyl may be due to the explosive decomposition which occurs in the flame front or possibly to the positive catalytic action of some intermediate decomposition products such as free ethyl radicals.

This accelerating effect resulting from the addition of large proportions of antidetonating substances was pointed out also by Grebel.[45] When iron carbonyl, ethyl fluid (50 per cent lead tetraethyl and 50 per cent ethyl bromide), or aromatic compounds such as benzene or nitrobenzene, were added in small quantities to gasoline, ignition temperature increased, but when added in large amounts, the ignition temperature decreased.

FLAME PROPAGATION

While investigating the mechanism of the ignition of gases by means of an electric spark Wheeler[46] observed that the most readily ignitible mixture of methane and air contained a greater percentage of air than was required for complete combustion, but the reverse was true for mixtures of the higher paraffins and air. Some of the results obtained are given in Table 152.

[46] *J.C.S.*, 1924, 125, 1858. In an addendum to this work, S. C. Lind has pointed out that the rate of reaction between a combustible gas and oxygen increases with the concentration of whichever gas has the greatest stopping power for the radiant energy which will activate it, and its stopping power depends upon the density of the gas.

TABLE 152.—*Ignition Characteristics of Hydrocarbon-Air Mixtures.*

Gas	Mixture in Which Speed of Uniform Movement of Flame is Fastest	Mixture for Complete Combustion	Mixture Most Readily Ignited by Secondary Discharge
	Per Cent		
Methane	9.65	9.45	8.3
Ethane	6.05	5.64	6.7
n-Propane	4.45	4.02	5.1
n-Butane	3.65	3.13	4.2
n-Pentane	2.90	2.56	4.0
n-Hexane	—	2.15	3.2

For the propagation of flames in such mixtures it was found that a minimum volume of the mixture must be burned.

It was also observed that mixtures of air and methane varied as regards their sensitiveness to ignition by various means. For example, mixtures most readily ignited by contact with the walls of a heated vessel contained 5 to 6 per cent methane, but those most readily ignited by an electric spark contained 8.25 to 8.50 per cent methane.[47] The ignition temperature was defined as the lowest temperature under the conditions of the experiment at which inflammation took place, regardless of how long the surface remained in contact with the mixture. The ease of ignition of gases by a momentary source of heat, such as an electric spark, was dependent on the normal speed of propagation of flame in the mixture. It had been observed previously that flames spread away from the path of an electric discharge most readily in those mixtures in which the speed of propagation normally is fastest.[48]

With a standardized flame projected vertically downward from a silica jet as a source of ignition, Walls and Wheeler[49] determined what mixtures of hydrocarbons and air were most readily ignitible, the relative speed of the flame, and the relative duration of exposure of the mixture to the source of heat. The data obtained (see Table 153) indicate that ease of ignition corresponds with the ability of the flame to travel through the mixture after the source of ignition is withdrawn.

TABLE 153.—*Characteristics of Hydrocarbon-Air Flames.*

Gas	Mixture in Which Speed of Uniform Movement of Flame is Fastest Per Cent	Relative Speed of Flame (Cm. per Sec.)	Mixture Most Readily Ignited Per Cent	Relative Duration of Exposure to Flame Required (Milliseconds)
Methane	9.65	91	9.8–10.0	4.3
Ethane	6.05	127	6.8–7.0	2.7
Propane	4.45	114	4.8–5.0	3.2
n-Pentane	2.90	115	3.1–3.3	3.5

Wheeler and his collaborators also showed that the time required for the development of the maximum pressure after combustion of gaseous mixtures in a closed system decreases as the flame speed increases.[50] By application of the law of speeds it was possible to calculate the time required for the development of the maximum pressure for various gaseous mixtures.[51]

[49] *Loc. cit.*
[50] Maxwell, Payman and Wheeler, *J.C.S.*, 1927, 297.

By means of photographs of moving flames, taken at intervals of 4.58 milliseconds, Ellis and Wheeler [52] showed that flame propagation takes place in regular concentric spheres. These results verified the assumptions previously made by Wheeler,[53] and also the deductions of Mallard and Le Chatelier [54] from time-pressure curves. The rate of propagation of flame was affected by cooling at the walls of the vessel. The pressure at any time is smaller when the point of ignition is at the bottom than at the center of the vessel.

The movement of the flame in a given combustible gaseous mixture is dependent upon several factors: the length and bore of the tube, the position of the spark gap, the initial mechanical turbulence, the intensity of the spark, and the initial temperature and pressure.[55] At any given point in the tube the velocity varies with the length of the tube. With central ignition, flame propagation is symmetrical, but if the ignition is not central, the flame front approaching the nearer end is slower than the other. The speed of the flame increases almost rectilinearly with the width of the spark-gap up to a certain point which is dependent chiefly on the strength of the current in the primary circuit and the winding ratio of the induction coil.

Flame propagation can be divided into two phases: one of which is characterized by regular acceleration and the other by a slow and almost perfectly constant speed. In heated mixtures the initial phase is faster and ends nearer the spark, and the flame is less luminous. Maximum speed is attained at 1 atmosphere pressure. Pressures greater or less than 1 atmosphere are accompanied by decreasing speeds. This is shown by the data in Table 154 for a 6.5 per cent ethylene-air mixture:

TABLE 154.—*Effect of Pressure on Ethylene-Air Flame Speed.*

Pressure Atmos.	Flame Speed Meters per Sec.
0.9	8.79
1.0	8.95
1.1	8.76
1.2	8.38

The influence of an inert gas, such as nitrogen, on the speed of the flame has been studied by Campbell and Ellis [56] and by Ellis and Stubbs.[57] Experiments were made by the former with various oxygen-nitrogen mixtures together with the appropriate quantity of fuel, such as methane, ethylene, carbon disulphide, pentane, hexane, alcohol or ether. The speed in all instances was decreased as the dilution with nitrogen increased. The speed of the flame, however, was proportional to the calorific value of the gas mixture. The latter investigators used mixtures of the type $xC + yE$, in which $C = 1$ molecule of carbon disulphide to 3 molecules of oxygen and $E = 2$ molecules of hydrogen to 1 molecule of oxygen. Ellis and Stubbs observed that when the calorific value of the mixture was constant, the speed of the flame was proportional to the thermal conductivity of the mixture. The thermal conductivity was a product of three quantities: the density, the viscosity and the specific heat.

---

[51] The law of speeds is stated by Payman and Wheeler (*J.C.S.*, 1922, **121**, 365) as follows: "Given two or more mixtures of air or oxygen with different individual gases, in each of which the speed of propagation of flame is the same, all combinations of the mixtures of the same type propagate flame at the same speeds, under the same conditions of experiment."

Stevens[58] examined the rate of flame propagation in mixtures of carbon monoxide and oxygen. A mixture of these gases, in which the individual partial pressures were known, was employed to blow a soap bubble. Through the aperture from which the bubble was blown was inserted an ignition gap which was extended as near the center of the bubble as possible. After firing, the volume of the bubble was photographed at regular intervals on a continuous film. This gave the initial and final volumes at constant pressure. Under these conditions the concentrations of the gases about to explode remained constant. The flame velocity was found to be constant and proportional to the initial concentrations of the reactants. For example, with carbon monoxide, this can be expressed by

$$S = k\,[CO]^2\,[O_2]$$

in which S is the speed of the flame, and k is a proportionality factor dependent on the vapor pressure of the water present in the gases.

MECHANISM OF COMBUSTION AND THE EFFECT OF KNOCK-INDUCING AND KNOCK-SUPPRESSING COMPOUNDS

The work of Callendar, King and Sims[59] led to the formulation of the nuclear theory of the self-ignition of motor fuels. Briefly, this theory states that the detonation of liquid fuels, at high compression ratios, is due to the presence of nuclear drops or residues of low ignition points and probably to the presence of heavy paraffins since these have the lowest ignition temperatures of any of the constituents of gasolines. The antidetonating properties of lead tetraethyl and nickel or iron carbonyl, and the pronounced effect which results from the presence of relatively small quantities, was attributed to the reducing action of the metals, formed by decomposition at high temperatures, which became concentrated in and delayed the action of the nuclear residues. Other substances which exhibited antidetonating properties were aromatic hydrocarbons, aromatic amines, and alcohols.

Further work on the slow combustion of fuels appeared to confirm this theory.[60] The temperature of initial combustion of a number of organic liquids was determined by passing a mixture of the vapor and air through a glass tube, the temperature of which could be gradually increased. It was observed that nuclei in the form of a dew or fog always preceded or else accompanied the initial stage of oxidation. The products of the reaction included water, carbon dioxide, aldehydes or acids, and traces of "active oxygen." Detonation and the presence of active oxygen became more marked when the fuel was injected into the tube as a fine spray, which phenomena indicated the formation of organic peroxides in the nuclear drops. The small amount of peroxide was not sufficient in itself to cause the detonation, but acted as a primer which effects the simultaneous ignition of the drops. The addition of antidetonants such as lead tetraethyl and others, completely altered the course of the reaction. Antidetonants inhibited the formation of active oxygen among the products of combustion, and thus raised the spontaneous ignition temperature of the mixture.

[60] Callendar, *Engineering*, 1927, **123**, 147, 182, 210; *Brit. Chem. Abs.* **B**, 1927, 272; *Chem. Abs.*, 1927, **21**, 1697.

In investigating the reactions taking place during the combustion of fuels, Mardles[61] employed two experimental methods. In the first, a mixture of air and fuel was passed through a heated tube and the products of the reaction were identified. These products were active oxygen, probably present as organic peroxides, and aldehydes and acids, formed by the decomposition of such peroxides. The addition of substances such as benzene, aniline or lead tetraethyl to the fuel-air mixture effected a marked decrease in the amount of active oxygen produced. In the presence of fuels, both aniline and benzene were oxidized at temperatures much lower than are required for their oxidation alone. This oxidation was shown to be due to peroxides and not to hydrogen peroxide formed by the hydrolysis of the peroxides. Similar results were obtained also by the second method, in which the reactants were placed in a bulb and the rate of reaction was followed by the change in pressure as the temperature was slowly raised. This experimental work confirmed the views of Callendar.

The results of Berl and Werner[62] on the ignition of mixtures of ethylene or methane with insufficient air for complete combustion but under just sufficient pressure for reaction to take place led them to conclude that combustion results in the preferential oxidation of the hydrogen. On increasing the pressure, however, the proportion of carbon dioxide and especially of carbon monoxide formed increases rapidly, For example, of the oxygen present in a 40 per cent ethylene-air mixture, 83 per cent appeared as water, 3 per cent as carbon dioxide, and 14 per cent as carbon monoxide after ignition under 40 atmospheres pressure. Under 92 atmospheres pressure, 50 per cent of the oxygen appeared as water, 10 per cent as carbon dioxide, and 40 per cent as carbon monoxide after ignition.

The ignition temperatures of mixtures of the inflammable vapors of motor fuels and air, at pressures varying from 1 atmosphere to 20 atmospheres, and the influence of knock-suppressing compounds on these temperatures was investigated by Berl, Heise and Winnacker.[63] In the case of mixtures of air and hydrocarbons such as n-pentane, n-hexane, and cyclohexane, an increase in pressure had only a very slight effect in depressing the ignition temperature. With a mixture of ether vapor and air, the effect of pressure was somewhat greater. With mixtures of air and benzene or alcohol vapor, ignition did not occur at 800° C. under the pressures investigated. Cyclohexene at 60° C. and under 20 atmospheres pressure was polymerized by the oxygen in the air. In general, those substances which were the most easily oxidized also caused knocking the most readily. The addition of knock-suppressors, such as lead tetraethyl or iron carbonyl, raised the ignition temperature to approximately the same extent. The compression strength was found to increase according to the series: hexane, cyclohexane, cyclohexene, benzene.

Experiments by Butkov[64] also confirmed the view that those hydrocarbons which have a pronounced tendency to knock are readily oxidized. The heavy ends of gasoline, which have a high knock value are comparatively easily oxidized. Butkov suggested that two types of oxidation were involved: an explosive reaction resulting in the formation of water, carbon monoxide and dioxide and a non-explosive reaction which yields asphalt-like materials and acids. The second type is characteristic of heavy hydrocarbons and takes place at relatively low temperatures.

Oxidation of hydrocarbons in the presence of an insufficient quantity of oxygen for combustion was also investigated by Berl, Heise and Winnacker,[65] as well as the effect of knock suppressors such as lead tetraethyl and iron carbonyl. The antiknock metallic compounds proved to be powerful inhibitors for the conveyance of oxygen, their action being attributed to decomposition into finely divided metals.[66] A similar but less pronounced effect was obtained with finely divided lead and iron in a luminous arc. The finely divided metals arrest oxidation of the hydrocarbon molecules by interrupting the chain reactions or by forming compounds with the peroxides which result. Hydrocarbons which were rich in hydrogen were decomposed into hydrogen and an unsaturated hydrocarbon, both of which were then oxidized to form water, hydrogen peroxide, and organic peroxides. The finely divided metals inhibited this latter peroxide formation before the succeeding intramolecular oxidation could take place.

Egerton,[67] as well as Weerman,[68] showed that antidetonating substances raise the ignition temperature of gasoline in air. Weerman observed that the metallic vapors which were most effective in increasing the ignition temperature fell in the following order: thallium, potassium, lead, iron, nickel, manganese, bismuth, selenium, tellurium, sodium, cadmium, calcium, and antimony. The ineffective elements were aluminum, magnesium, mercury, iodine, phosphorus, gold, and zinc. The effect of the following metals was doubtful: tin, cerium, titanium, zirconium, thorium, tantalum, tungsten, chromium, cobalt and uranium. Weerman stated that, in general, a state of equilibrium exists between certain products of the antiknock at the temperature at which they operate.[69] For example, with potassium there is an equilibrium between the oxides, K_2O_3 and K_2O_4, in favor of the higher oxide at 400° C. Any reduction to the lower state is followed by a regeneration to the higher state by the next suitable impact with an oxygen molecule. Peroxide formation with the production of centers of high energy content is regarded as the initial stage in the combustion of a hydrocarbon molecule, and the antiknock substances inhibit oxidation of the fuels prior to ignition.[70]

Berl and Winnacker suggested that with decrease in symmetry of a combustible molecule, as a result of its combination with oxygen, it becomes more readily oxidized. Thus, the oxidation of hexane, a symmetrical molecule, is preceded by an induction period[71] during which small quantities of oxygenated products, aldehydes and acids, are formed. These unsymmetrical oxygenated products add oxygen more readily than the symmetrical hydrocarbon molecules, and they therefore act as autoxidizers towards the hydrocarbon molecules.

This theory appeared to be substantiated by the results obtained on the oxidation of benzaldehyde.[72] The rate of autoxidation of liquid benzaldehyde was measured at ordinary temperature, the reaction being followed by the direct measurement of the rate of absorption of oxygen. In the experiments, the oxidation of benzaldehyde proceeded at a rapidly increasing rate after the expiration of a period of induction. On adding benzoic acid to the benzaldehyde, a longer period of induction was observed as well as a decrease in the maximum reaction velocity which was attained. Benzoyl peroxide, on the other hand, shortened the induction period and increased the maximum reaction velocity. Benzene, hexane, acetone, cyclohexane, ether, cyclohexene, ethyl alcohol, benzyl alcohol, and lead tetraethyl retarded the reaction, the effects increasing in that order, either by preventing the formation of peroxides or by reacting with them. Sols resulting from the dispersion of lead, tin or iron in benzaldehyde also diminished the capacity for oxidation.

Taylor,[73] who also observed a decreased rate of oxidation of benzaldehyde in the presence of lead tetraethyl, suggested that not only the lead atoms but also the free radicals function as oxidation centers. These free radicals, ethyl in the particular instance, are very active in the presence of hydrocarbon-oxygen mixtures. Free radicals possibly act as oxidation centers, producing homogeneous combustion which would be supplementary to the inhibitory action of the metal alkyl on the oxidation of the aldehydes produced by the partial oxidation of the hydrocarbons. The action of free radicals may also account for the inhibitory action of antiknocks of the non-metallic type, such as aniline.[74]

Graetz[75] concluded that any thermal dissociation reaction is preceded by the autoxidation of the gasoline, which occurs mainly in the liquid phase and at an optimum temperature of 120° to 160° C. The most readily autoxidizable hydrocarbons are those of the ethylene series (C_2H_4 and homologues), and these may yield either unstable and detonating compounds or stable compounds. The presence of a large proportion of ethylene hydrocarbons in gasolines effects a more regular autoxidation of the paraffin hydrocarbons and leads to more stable or easily hydrolyzed products. The antiknock properties of aromatic compounds can be attributed to the stability of the peroxides which they form. This stability, however, renders them less appropriate as catalysts for the oxidation of paraffin hydrocarbons. They can combine directly with unsaturated compounds and thus act as reagents rather than as catalysts. Graetz stated that they must be present in large quantities (50 per cent or more) in order to produce beneficial effects. Ketones and aldehydes, particularly cyclohexanone and menthone, behave like the ethylene hydrocarbons. The two chief factors which destroy peroxides are water which hydrolyzes them and high temperatures which bring about their decomposition.

Layng and Youker[76] investigated the action of accelerators and inhibitors upon the oxidation of hydrocarbons in both the liquid and the gas phase. The hydrocarbons together with oxygen were introduced into a bulb which was kept at a constant temperature and the reactions were followed by measuring the change in pressure. The data indicated that aniline, diphenylamine, potassium ethoxide and lead tetraethyl were all inhibitors of gas phase oxidation, but sodium and potassium ethoxides and lead tetraethyl were accelerators of liquid-phase oxidation. For a compound, therefore, to act as an antiknock they assert that it must be an inhibitor of gas-phase oxidation and an accelerator of liquid-phase oxidation. Compounds which fail to approach lead tetraethyl but which have some effect as antiknocks seem to exert an action in only one of the phases present in the gas engines at the temperatures employed during the test.

The changes taking place during the oxidation of gasoline-air mixtures previous to ignition, both in the absence and in the presence of knock-suppressors, have been studied by Zaikowsky, Holroyd and Sokolov.[77] The untreated mixtures underwent greater oxidation, though there was no corresponding increase of the compression pressure. This indicated that oxidation was not a homogeneous reaction. The addition of lead tetraethyl, or other antiknock compounds, reduced the rate of oxidation in the gas phase for a short time, and the metallic oxides which were deposited were effective antioxidizing agents. Lead oxide was a positive surface catalyst for carbon. The effectiveness of antiknock compounds was attributed to their temporary elimination of oxygen molecules which are activated sufficiently to react directly with hydrocarbons.

The combustion process taking place in gasoline-air mixture was followed by determining the oxygen concentration in the gases withdrawn from different parts of the combustion chamber at various intervals during the combustion of the charge.[78] The results indicated that there was a definite combustion zone which passed through the charge of gasoline and air at a definite velocity. This conclusion was based upon the fact that longer intervals elapsed between the instant of ignition and the start of decreasing oxygen concentration as the distance increased between the point of ignition and the point in the chamber at which the gas was removed. During these intervals, the oxygen concentration in the sample remained fairly constant.

The combustion zone traveled faster through the middle portion of the combustion chamber than along the side walls. This phenomenon was probably a result of the cooling effect of the walls. It was also thought that the flame front, which is convex in the direction of travel, proceeded outward from the point of ignition through all portions of the charge.[79] The speed of the combustion zone, through both the middle portion and along the side walls, was increased by increasing the speed of the engine. This increased speed of combustion was attributed to, at least in part, increased turbulence of the charge. With gasoline, the knocking appeared to be associated with the combustion of the last portion of the fuel. The data seemed to indicate that there was a more rapid speed of the combustion wave through the last quarter of the combustion space in detonating explosions than in non-detonating explosions.

It has been pointed out by Grebel[80] that calculations based on the assumption that combustion goes to carbon dioxide and water are incorrect. The gas mixture in the cylinder is not homogeneous, and its composition does not correspond to a chemical equilibrium. Combustion takes place in stages with the production of aldehydes,[81] acids, carbon monoxide, and other substances. Combustion is catalyzed by the presence of appropriate quantities of some of the products, such as carbon dioxide or water vapor. More efficient operation will result when fuel and air are thoroughly mixed in optimum proportions together with a small quantity of the exhaust gases, as catalyzers.

From a consideration of the analyses of exhaust gases from automobile engines obtained by a number of investigators, Lovell and Boyd,[82] contrary to the views of Grebel, concluded that the components of such gases are in a state of equilibrium which may be represented by

$$CO_2 + H_2 \rightleftharpoons CO + H_2O$$

The equilibrium value, represented by $K = \frac{[CO]\,[H_2O]}{[CO_2]\,[H_2]}$, lies within very narrow limits (from 3.0 to 4.0) and corresponds to an equilibrium reaction at temperatures of 1350° to 1550° C. They also concluded that over 95 per cent of the hydrocarbon was burned to carbon dioxide and carbon monoxide under various conditions during which the engines ran smoothly. The amounts of hydrogen burned to water and carbon burned to carbon dioxide seemed to confirm the hydroxylation theory of combustion of hydrocarbons, and disprove the idea that the maxima of power curves for gasoline engines occurred when 85 per cent of the theoretical air was used because of a preferential burning of hydrogen.

GASEOUS IONIZATION AND KNOCKING

One of the explanations offered for the effects of knock-inducing or knock-suppressing compounds is based on the ionization of gases. It is known that burning gases are conductors of electricity, and therefore are ionized. Part of the energy from the reactions of the molecules in the flame were thought to be used in liberating electrons which then precede the flame front and ionize the combustible mixture just ahead. The higher the temperature and pressure of the reacting gases, the greater would be the velocities of the liberated electrons, and consequently the faster the propagation of the flame, thus causing a larger portion of the charge to detonate. The liberated electrons are absorbed by the lead atoms, hence the effect of the lead tetraethyl on detonation. The negatively charged lead atoms attracted positively charged atoms and discharged them. In this manner one atom of lead would prevent a large number of molecules from being sufficiently activated to bring about detonation. A knock-inducing compound would act in the opposite manner.

Clark, Brugmann and Thee[83] tested this theory by measuring the ionization of air, air-benzene, air-benzene-butyl nitrite (knock-inducer), and air-benzene-lead tetraethyl (knock-suppressor) mixtures. The ionization was affected with monochromatic molybdenum Kα x-rays of constant intensity, and the ionization currents were measured by a very sensitive quadrant electrometer and a gold-leaf electroscope.

The presence of butyl nitrite in an air-benzene mixture slightly increased the total ionization, these results being in accord with the theory. The presence of lead tetraethyl, however, gave a still larger total ionization, which was not according to theory. The presence of butyl nitrite in the benzene-air mixture decreased the rate of recombination, again in accord with the theory, but the presence of lead tetraethyl decreased the rate of recombination to a larger extent. This latter effect again was contradictory to the theory. The experimental evidence, therefore, did not adequately substantiate the theory of gaseous ionization and detonation.

The influence of an antiknock compound on the rate of slow oxidation of methane under the ionizing action of radon was investigated by Lind and Bardwell.[84] The antiknock compound used was diethyl selenium, because of its greater volatility than lead tetraethyl. The results indicated some acceleration but no retarding influence of this compound on the rate of the reaction. These investigators therefore concluded that ionization did not play a primary rôle in the explosive reaction or in the flame propagation.

[84] *Ind. Eng. Chem.*, 1927, 19, 231.

By means of a delicate electrometer, Gill[85] attempted to measure ionization in fuel vapors during slow combustion in air. No detectable ionization occurred when the vapors of hexane or carbon disulphide were undergoing slow phosphorescent combustion in air at temperatures up to 400° C. Similar results were obtained when substances such as lead tetraethyl or iron carbonyl, which inhibit phosphorescence, were present. With hydrogen-air mixtures appreciable ionization occurred only immediately before self-ignition at relatively high temperatures. The ignition temperature was lowered by the presence of nitrogen peroxide. This cannot be accounted for by ionization effects, as no ionization was detected in the reaction between hydrogen and nitrogen in the absence of air.

ANTIKNOCKS OR KNOCK-SUPPRESSING COMPOUNDS

In the preceding pages various substances have been mentioned which can be used as antidetonants or knock-suppressors. These include ethyl and benzyl alcohols, potassium ethoxide, aromatic compounds (benzene, toluene, and aniline), and organo-metallic compounds (lead tetraethyl and iron carbonyl). Numerous other substances have been suggested and the following examples are given merely to illustrate their wide variety.

Egerton recommended the vapors of thallium or thallium compounds,[86] such as thallium ethyl, ethoxide or oleate. The heavy metal derivatives of β-diketones, such as those of iron, nickel, cobalt, and, as well as the aluminum, zinc, and other metallic compounds of acetylacetone or benzoylacetone or their homologues have been proposed by Coffey.[87] Mercury cyanide has also been suggested.[88] The butyl esters of hydroxynaphthenic acids as well as the mercury compounds of naphthenic acids or their esters have been mentioned.[89] The alkali oleates, naphthenates and sulphonates are said to be antidetonants.[90] The cracking of hydrocarbons in the presence of ammonia, or of nitrogenous organic compounds, in order to produce gasolines containing cyclic nitrogen compounds which are nondetonating was suggested by Brown and Sullivan.[91] Mixtures of various antiknock substances can be used, as for example, a mixture containing aniline, acetone and anhydrous alcohol.[92] The antiknock properties of aromatic amines may be increased by the addition of a substance having a high critical temperature and a high spontaneous inflammation temperature.[93] Such a mixture may consist of aniline and hydrocarbons obtained from coal tar and having a boiling range of 170° to 250° C. "Targol," a mixture of terpenes which have been oxidized with oxygen, has been used.[94] Oxidized kerosene has been proposed as a fuel of much less knocking tendency than straight kerosene for use in kerosene engines.[95] "Brittolizing" of motor fuels is a process which is said to consist in binding ether into any straight-run distillate with the aid of a catalyst to improve its combustion.[96]

Grote[97] showed that those compounds containing tetravalent lead were the best antidetonants, whereas those containing bivalent lead, with few exceptions, possessed little or no antidetonating properties. He states that as a rule the most powerful antiknock materials yield finely divided particles of the metallic constituent on heating, but compounds which undergo complete oxidation on heating are inefficient.

Straight-chain paraffin hydrocarbons show a regular and rapid decrease in antiknock quality as the number of carbon atoms in the chain increases. When the number of carbon atoms in the chain remains constant the antidetonating quality is improved as methyl groups in the form of side-chains are introduced. For a given number of carbon atoms in the molecule the antiknock quality is improved as centralization of the molecule is increased.[98]

Oxidation products, such as peroxides, acids, aldehydes or ketones, formed during the storage of cracked gasoline (see chapter 40), decrease the antiknock value of the fuel.[99] Accelerated oxidation of the fuel also has the same effect. The degree to which these changes take place varies with different gasolines. Oxidation of gasoline can be prevented by the use of chemical oxidation inhibitors, such as aniline, dimethylaniline, quinol, urea and anthracene. The antiknock value of stored gasolines can be increased by treating them with fuller's earth, caustic soda or borax. It has been stated that the accelerated oxidation test for gum is also applicable as an accelerated test for the depreciation of the antiknock value of a gasoline.[100]

MEASUREMENT OF KNOCK RATING

Although a detailed discussion of the various methods of determining the knock rating, or antidetonating value, of different fuels is outside the scope of this text, nevertheless, certain phases of the testing are briefly considered.

In the bouncing-pin method, which is the basis of most methods of measuring the knock rating, the relative intensities of different detonations are determined by means of a bouncing pin combined with the standard pressure element of the Midgley indicator[101] which is screwed into the combustion chamber of the engine.[102] On detonation, the pin jumps upward, the fluctuations closing an electric circuit. The volume of gas evolved from an electrolytic cell measures the period during which the circuit was closed. Comparison of these volumes determines the relative knocking values of the fuels. Hexane at one time was suggested as a standard fuel.[103] This fuel was matched in knocking tendency with the fuel under investigation by the addition of either isopropyl nitrite (knock-inducer) or diethyl selenium (knock-suppressor). Later, Faragher and Hubner[104] suggested determining the knock rating by comparing the fuel with blends of chemically pure benzene in a standard straight-run gasoline.

[103] For a comparison of the antiknocking qualities of benzene, toluene and xylene, see Midgley and Boyd, *Ind. Eng. Chem.*, 1922, **14**, 589.

Lovell, Campbell and Boyd[105] measured the knock rating of a number of paraffin hydrocarbons in terms of the aniline equivalent. This was defined as the number of centigram-moles of aniline that must be added to a reference fuel to make 1000 cc. of a fuel equivalent in knocking tendency to a molal solution of the hydrocarbon in the reference gasoline, provided the hydrocarbon knocked less than the reference fuel. When the hydrocarbon knocked more than the reference fuel the aniline equivalent was the number of centigram-moles of aniline added to a one-molal solution of the hydrocarbon in the reference gasoline to make a fuel that was equivalent in knocking tendency to the reference gasoline. On this basis n-heptane (hydrocarbon with high knocking tendency) had an aniline equivalent of —14, and 2,2,4-trimethylpentane (hydrocarbon of low knocking tendency) had an aniline equivalent of +17.

From the measurements so obtained it was found that as the length of the chain increased the knocking tendency of the hydrocarbon increased. The knocking tendency decreased as methyl groups were added as side-chains. Substances with the most compact structures were the most resistant to knocking. This is illustrated by the data in Table 155:

TABLE 155.—*Effect of Structure on Resistance to Knocking.*

Hydrocarbon	Aniline Equivalent	Hydrocarbon	Aniline Equivalent
n-Pentane	1	2-Methylbutane	9
n-Hexane	6	2-Methylpentane	4
n-Heptane	—14	2-Methylhexane	0
n-Octane	—21	2,2-Dimethylpentane	6
n-Nonane	—28	2,3-Dimethylpentane	12
n-Heptane	—14	3,3-Dimethylpentane	13
2-Methylhexane	0	2,2,3-Trimethylbutane	19
3-Methylhexane	3		

Still another method of measuring knock rating is that of comparing the knocking tendency of the fuel with various mixtures of an isooctane (2,2,4-trimethylpentane) and n-heptane. The former is a hydrocarbon which has a very slight tendency to knock, but the latter has a great tendency to knock (cf. aniline equivalents given above). The octane number of a fuel, therefore, is the percentage by volume of this isooctane in a mixture of isooctane and n-heptane required to match the knocking tendency of the fuel.[106] The higher the octane number the greater the antiknocking property of the fuel.

These primary standards, isooctane and n-heptane, are rather expensive. Alternate methods, therefore, involve the use of secondary standards such as benzene, lead tetraethyl or aniline in standard fuels, which have been rated against the primary standards.[107]

The possibility of removing from a gasoline the fraction responsible for its greatest tendency to knock was investigated by Fenske.[108] Straight-run Pennsylvania gasoline, which boiled from 43° C. to 204° C., was fractionated into 165 different fractions, of which the density, index of refraction and knock rating were determined. Unexpected periodic relations were found between the properties tested. In general, the fractions which had the lowest densities and refractive indices were found to have the highest knock ratings, and *vice versa.* Since the index of refraction, which is an easily measured constant, increased with decreasing knock rating, it was suggested that this determination be used for the separation and detection of fractions of different values.

[108] *Ind. Eng. Chem.*, 1930, **22**, 913.

The variation in knock rating with the distillation range was studied by Weld.[109] A naphtha, obtained by the liquid phase cracking of a Mid-Continent gas oil, was separated by distillation into the following seven fractions: 0-10%, 10-19.1%, 19.1-28.2%, 28.2-75.1%, 75.1-81.1%, 81.1-93%, and 93-100%. These fractions were combined to form 16 different experimental gasolines, and the knock rating of each was determined. The octane number of the original gasoline (fractions 0-100%) was 55. Discarding 24.9 per cent from the heavy ends (i.e., using fractions 0-75.1%) raised the octane number 6 points, but discarding 28.2 per cent of the lighter ends (i.e., using fractions 28.2-100%) decreased the octane number by about 5 points.

In testing various fuels in Diesel engines Le Mesurier and Stansfield[110] observed that "combustion shocks" depended not only on the initial rate of pressure rise but also upon the period during which the highest rate of pressure was applied. In general, fuels having the longer period between ignition and commencement of pressure[111] produced the greatest combustion knocks. The addition of amyl nitrite (knock-inducer) or acetaldehyde reduced the angle of delay and induced smoothness of running. It also appeared that the heavy fractions of crude oils, which yielded explosion engine fuels of the highest antiknock value, would be the worst from the standpoint of combustion shocks, and *vice versa.*

Chapter 45

Miscellaneous Oxidation Reactions. Denaturants, Insecticides, and Other Products

In a number of the preceding chapters the oxidation of individual hydrocarbons or of petroleum fractions has been considered. The products obtained by such reactions are principally ketones, alcohols, esters, aldehydes and various types of aliphatic and aromatic acids and anhydrides. The effect of autoxidation on certain distillates, particularly gasoline and lubricating or transformer oils has been pointed out. In this chapter are included the production of other compounds, such as alcohols, by oxidation and the utilization of these oxidized bodies in the preparation of many different kinds of materials; e.g., denaturants, insecticides, solvents, synthetic resins and waxes, plastics, detergents and emulsifying agents.

Mild or limited oxidation is sometimes employed in the refining of hydrocarbon distillates, particularly when it is desired to eliminate constituents which are readily polymerized. or resinified. In some instances sulphur compounds, present as impurities, may be preferentially oxidized to sulphur dioxide, or sulphur, and the oxides of carbon and thus be removed. A brief review of such methods is also included.

OXIDATION AS A REFINING PROCESS

For decolorizing and deodorizing naphtha, cracked oils or petroleum, an oxidation process was suggested[1] in which air is passed through a series of tanks containing the oil. The oil in the first tank may contain dissolved heavy-metal salts of fatty, naphthenic or resin acids, which are said to activate the oxygen passing to the subsequent tanks of oil containing copper or lead turnings. After oxidation, the product may be treated with acid and alkali.

Polymerization of the resin-forming constituents of oils is accelerated by treating the hot oil, or its vapors, with very small quantities of oxygen, and the polymerization products are then removed.[2] This polymerization may be further accelerated by the use of a glow discharge, irradiation, or the addition of small amounts of acids or alkalies.

The phenol fractions, boiling up to 230° C., from lignite-tar creosote can be refined by oxidation under pressure.[3] By the same procedure the liquid tar products containing a high percentage of creosote are converted into a solid condensation product which possesses electrical insulating properties.

In refining crude aromatic hydrocarbons such as benzene, toluene and naphthalene, it has been proposed to mix them in the vapor phase with air and pass them over metallic oxide catalysts. Very short periods of contact (0.25 second) are maintained. Substances such as thiophene or carbon disulphide are oxidized to sulphur dioxide, carbon monoxide and dioxide, and water, while only a small proportion of the aromatic hydrocarbon is oxidized.[4]

[2] Tauss, German Patent 475,277, 1923; *Chem. Abs.*, 1929, **23**, 3340.
[3] Karpati, *Chem. Runds. Mitteleuropa u. Balkan*, 1926, **3**, 3; *Chem. Abs.*, 1926, **20**, 3227.

In some refining operations ozonized air is employed. For example, Bruzac[5] treated crude benzol with air having 1 per cent ozone. During treatment the benzol darkens in color and a brown precipitate settles out. After treatment, the benzol is washed with sodium carbonate solution which leaves it yellow and of sweet odor. A colorless product is obtained by distillation. The losses from this process are much less than in the usual sulphuric acid-soda treatment. This method is said to be applicable also to the light fractions from the low-temperature distillation of coal, oil shale[6] or peat. Deodorization and desulphurization are accomplished with a minimum loss, and gum- and resin-forming constituents are removed without destroying antiknock compounds. The viscosity of lubricating oils can also be increased by the procedure.

A similar process consists in subjecting the crude hydrocarbons to ozonized air followed by treatment with 70 per cent sulphuric acid, containing ferric chloride or sulphate, and washing with alkali.[6a]

The removal of easily oxidizable constituents from oil or tar products is said to be accomplished by treatment with ozone in the presence of inorganic adsorbents, e.g., silica gel or iron oxide, mixed with a base such as calcium oxide.[7] Organic acids may be recovered from the adsorbing material by subsequent treatment with steam.

Oxidation is used for refining not only liquid and solid but also gaseous hydrocarbons. For example, gases can be largely freed of their sulphur compounds by heating in the presence of metallic catalysts with sufficient oxygen to oxidize these compounds.[8] One catalyst suggested for this purpose is prepared by igniting coke impregnated with a concentrated solution of nickel nitrate. The sulphur dioxide or trioxide formed during oxidation is removed by ammonia.

Preferential catalytic oxidation is also applicable to the removal of hydrogen sulphide in fuel gas, this substance being converted to water and elemental sulphur.[9]

For the removal of any oxygen present in natural gas, the latter can be mixed with a small quantity of air and passed over porous refractory materials at 800° C. or higher. The gaseous mixture, which then contains carbon monoxide and hydrogen (substances more reactive toward oxygen than saturated hydrocarbons), is mixed with a fresh quantity of natural gas and the resulting mixture is passed over a metallic catalyst (iron or copper) at 400° to 500° C. In this latter step the oxygen present in the natural gas reacts with the carbon monoxide and hydrogen and its removal is thus effected.[10] Any hydrogen sulphide present in the natural gas is also removed in this process.

Clear purified hydrocarbon products are said to be obtained by treatment with oxidizing gases in the presence of small proportions of mineral acids, acid salts or organic acids.[10a]

ALCOHOLS

Methanol and other organic compounds have been prepared synthetically from carbon monoxide, or dioxide, and hydrogen. It is not within the province of this book to discuss such reactions in detail but rather from the standpoint of the use of petroleum hydrocarbons in these operations.

In one process [11] coal-gas, coke-oven gas, natural gas or cracking gas is partially oxidized with a limited quantity of oxygen to convert part or all of the hydrocarbons to carbon monoxide and hydrogen. The sulphur compounds are then removed, after which the carbon monoxide and hydrogen are caused to react, under pressure and at high temperatures, in the presence of a catalyst to yield methanol.

In producing methyl alcohol from methane Patart [12] first made carbon monoxide and hydrogen by passing methane mixed with half its volume of oxygen over coke or other combustible fuel at 800° to 1000° C. The gaseous product, which consists of approximately two volumes of hydrogen and one volume of carbon monoxide, is then converted to methyl alcohol at high temperatures and pressure in the presence of a catalyst (zinc and chromium oxides). The methane which is formed as a by-product of the last reaction is used over again in the process. Webster and Schuler [13] inject a mixture of natural gas, e.g., methane, and steam into a retort at 260° C. and the resulting mixture of carbon monoxide and hydrogen was then passed at 325° to 475° C. through a catalyst chamber. The mixture of alcohol and hydrocarbon vapors was led through a condenser which separated the alcohol and the hydrocarbons were returned to the system.

The direct production of methyl alcohol from methane has been reported.[14] The process is the same as that employed in making formaldehyde (see Chapter 38) except the gases are conducted through the reaction tube at a slower rate. The presence of hydrogen and 20 to 30 per cent of alcohol vapor in the gaseous mixture aids the reaction which appears to be the direct oxidation of methane by carbon dioxide:

$$CH_4 + CO_2 \longrightarrow CH_3OH + CO$$

In the process developed by Futacchi,[15] oxidation is carried out by treating the material either in the liquid phase or dissolved in an inert solvent. The temperatures during oxidation should not exceed 500° C., though the pressure may vary from 1800 to 9600 pounds per square inch. Catalysts such as iron, copper or vanadium may be used. Methyl alcohol and air when heated together at 180° C. and under 3000 lbs. pressure are said to yield about 40 per cent glycol, 5 per cent methyl alcohol, 20 per cent glycerol, and a viscous mixture of various carbohydrates.

Pichler and Reder [15a] observed that the best yields of methanol by oxidation of methane and ethylene are obtained by the use of high pressures and repeated combustion with small amounts of oxygen. With a mixture of methane or ethylene containing 10 per cent of oxygen, 7 per cent of the theoretical yield results, but with a mixture containing only 0.6 per cent of oxygen the methane conversion is 60 per cent. The yield of methanol was decreased by copper, nickel or cobalt oxide catalysts and increased by the presence of water vapor and carbon monoxide. The optimum temperature for methane is 350° C. With ethylene, increasing yields are obtained with rising temperatures. Sand has been suggested as a catalyst in similar reactions.[15b]

Pugh, Tauch and Warren[15c] suggested the production of alcohols by dissolving an oxidizing gas in a hydrocarbon, such as propane, butane, naphtha or gas oil in the liquid state, and passing this mixture through a reaction zone at 200°-600° C. at a pressure of 1000 to 3500 pounds per square inch. Naiman and Leggett[15d] proposed to introduce a gaseous mixture containing free oxygen and saturated aliphatic hydrocarbons over copper gauze or granulated zinc at 165° C. under a pressure of 1500 pounds per square inch. Another process consists in passing a cooled mixture of oxygen and hydrocarbons (from methane up to hexane) into a reaction zone and forcing heated hydrocarbon gases into the zone to raise the temperature.[15e] Metals that form carbides (iron, nickel or cobalt) may be employed as catalysts, as well as copper, borax and siliceous materials. The products consist of a mixture of lower aliphatic alcohols, aldehydes, acids and ketones.

Beller and Luther[15f] prepared high molecular weight alcohols by blowing paraffin wax in the liquid phase with air at 160° C. in the presence of manganese naphthenate (see Chapter 43) and treating the resulting products (after carboxylic acids are removed by sodium hydroxide) with hydrogen at 100° to 300° C. under pressures of 10 to 300 atmospheres, in the presence of nickel or a similar hydrogenation catalyst. The alcohols can be extracted with an aqueous solution of lower alcohols or their esters.

Aliphatic or cycloaliphatic mono- or poly-carboxylic acids above five carbon atoms or their esters may be hydrogenated at 170° to 250° C. under a pressure of 40 to 400 atmospheres in the presence of hydrogenation catalysts to produce alcohols. The catalysts may consist of reduced copper chromate and silica, cobalt, cobalt and potassium oxide, cobalt with 2 per cent of vanadium pentoxide or reduced cobalt carbonate and copper carbonate. Oxidized paraffin wax, ethyl oleate, palmitic and stearic anhydrides and olive oil may be thus treated.[15g]

Alcohols of high molecular weight may also be produced by oxidizing hydrocarbons of boiling point above 180° C. in the liquid phase with air containing 2 per cent or more of formic, acetic or propionic, or weak inorganic acids, until the saponification value reaches 70, in the presence of manganese naphthenate. By blowing paraffin wax at 180° C. for 3 hours with air containing 22 grams of acetic acid per cubic inch, for example, 40 per cent conversion to alcohols is said to be obtained.[15h]

Solid or liquid alcohols of high molecular weight[16] can be prepared by the reduction of more complex oxidized alkyl derivatives with aqueous alcoholic (ethyl) solutions of alkalies. A small portion of the product is frequently dehydrated to ethylenic hydrocarbons or to ethers. Stearic acid ketone (2 moles), aqueous sodium hydroxide (1 mole) and ethyl alcohol (2 moles) when heated together for 6 hours at 200° to 300° C. yield acetic acid and 1,8-pentatricontanol, $C_{35}H_{71}OH$, melting at 93°-94° C. The acids and other partial oxidation products of paraffin wax are converted to alcohols by this treatment.

Ethylene can be directly oxidized to either glycol or chlorhydrin.[17] For the production of the former, the ethylene is fed into a vessel in which is placed water containing some substance which aids in holding the gas in solution. These substances may be solids such as bone black, charcoal, or platinum black, or oily liquids such as turpentine. At the same time a solution of an oxidizing agent such as a permanganate or bleaching powder containing a small quantity of cobalt chloride can be added. The cobalt salt acts as a catalyst, causing the decomposition of the bleaching powder with the evolution of oxygen. If chlorhydrin is desired, bleaching powder alone is used, and a weak acid, such as boric acid, is added to liberate hypochlorous acid.[18] Instead of using bleaching powder, chlorine can be passed into the aqueous solution of ethylene in which is suspended calcium or magnesium carbonate. These carbonates neutralize the hydrochloric acid formed by the reaction between chlorine and water.

The direct electrolytic oxidation of ethylene to glycol can also be effected in solutions of salts of oxygen acids, for example, sulphates or borates. Manganese, chromium or cerium salts may also be added. During oxidation ethylene is led into the cell so as to maintain the gas and liquid in the condition of a foaming mass or emulsion. If sodium chloride is used as the electrolyte, the product first obtained is chlorhydrin. The formation of this compound, however, is accompanied by the accumulation of an equivalent quantity of alkali (from the electrolysis of the sodium chloride) and this alkali saponifies the chlorhydrin to glycol with the re-formation of sodium chloride. During the electrolytic oxidation, rises in temperature are avoided by the use of external cooling.

SOLVENTS AND MOTOR FUELS

It is best to consider solvents and motor fuels simultaneously, as they may both be made by oxidation methods which produce low-boiling hydrocarbons from high-boiling hydrocarbons. The production of motor fuels is probably dependent on the formation of unsaturated hydrocarbons, alcohols and also in some degree, esters, aldehydes, ketones, and ethers. All of these products could be formed by the direct oxidation of the hydrocarbons, or by the reactions of the oxidation products themselves (e.g., esters by the condensation of aldehydes alone, or from the alcohols and acids), and such substances are said to increase the antiknock value of the motor fuel. The solvent properties of the products are dependent on the presence of alcohols, esters, aldehydes and ketones.[18a]

In obtaining other products from the Penniman[19] process (Chapter 36), the distillate is separated into two layers, an upper layer of oil-soluble products, and a lower aqueous layer which contains water-soluble substances. The upper layer, consisting of acids, aldehydes, alcohols, unsaturated hydrocarbons and other substances, is given a light alkali treat, followed by washing with water. It is then treated with a small proportion of acid and distilled. The fraction distilling up to 204° C. (400° F.) can be used as a motor fuel, and the residue recycled. The water layer, which consists of aldehydes, ketones, alcohols and acetals, when distilled yields a fraction boiling between 45° and 85° C., which, after a mild alkali treat, can be used as a solvent in the extraction of fats, for nitrocellulose, and for gums and varnishes. It may be added also to fuels for internal combustion engines.

The lower-boiling fractions of the condensate obtained in the vapor-phase catalytic oxidation of high-boiling hydrocarbons have been suggested as solvents. The acids present in the oxidation product may be esterified by heating with alcohols and the resulting esters can be separated by distillation.[20] The fractions which boil between 100° and 250° C. have been proposed as solvents for nitrocellulose or varnish gums in the preparation of lacquers. If aldehydes and ketones only are desired they can be obtained by extraction of the oxidation product with solutions of sodium bisulphite. Instead of distilling the oxidation products they may be extracted with an immiscible solvent, e.g., 50 per cent alcohol, and the solvent subsequently separated by distillation.

For producing motor fuels and other products, Ellis[21] allowed a petroleum distillate such as kerosene to run slowly into a reaction chamber containing a catalyst supported on pumice and kept at a temperature of 430° to 450° C. while air is forced into the reaction chamber. The exit gases are then condensed. This condensate is a gasoline substitute. Acids and aldehydes can be removed from it by scrubbing with water. This process may also be modified by first passing the kerosene through a cracking tube kept at 540° to 590° C., then through a trap to remove easily condensible substances and subsequently through a reaction chamber which contains a catalyst. Moist air is passed into the reaction chamber at the same time. A gasoline substitute, together with acids, is again obtained. Catalysts such as copper, chromium or vanadium oxides or duplex catalysts such as iron vanadate or silver chromate can be used.

In a method for producing motor fuel, the vapors of the heavier hydrocarbons together with air are passed through screens containing catalysts such as the oxides of molybdenum, vanadium, or uranium.[22] The lighter fractions of the oxidation product, boiling up to 200° C., are separated by distillation and used as motor fuels. The heavier fractions are recycled. Any free acids in the products are eliminated by distillation over sodium hydroxide. In place of air, steam may be used, and the hydrocarbon vapor and steam are passed over metallic catalysts at a temperature of about 450° C. The metal is oxidized by the steam to give hydrogen and the metallic oxide.

Heavy petroleum hydrocarbons, such as heavy lubricating oils or wax distillates, are first mixed with light petroleum and the mixture is vaporized with steam.[23] This mixture of vapors can then be passed through a series of catalytic screens without clogging. The high molecular weight hydrocarbons are preferentially oxidized. The best results are obtained when only a portion of the required air is put into the vaporizing chamber, and the remainder added after the mixture has passed the first screen.

Strache and Porges[24] passed the vapors of the hydrocarbons mixed with steam over a catalyst such as iron or lead oxide or manganese dioxide at 600° C. This process, however, is not a continuous one since the metallic oxide, which is the actual oxidizing agent, must be regenerated from time to time.

Reid[25] produced low molecular weight hydrocarbons, which boil within the gasoline range, by the oxidation of petroleum distillates at 300° to 500° C. under 300 pounds per square inch pressure. The air, which is the oxidizing agent, is disseminated throughout the liquid in an extreme degree of subdivision, comparable to molecular dispersion. In this way the rate of oxidation is very greatly increased. This subdivision of the air can be obtained with a very rapidly rotating stirrer (for example, a Witt stirrer). The gasoline vapors are continuously withdrawn and condensed during the process of oxidation. By lowering the temperature of oxidation it is possible to obtain partially oxidized products such as aldehydes.

Beall[25a] prepared a motor fuel composed of a partially oxidized liquid hydrocarbon mixture. Natural gas and an oxygen-containing gas are compressed and heated separately. The two gases (without previous mixing) are passed under pressure through a reaction zone over a platinum catalyst, under such conditions of time and temperature that a liquid, partially oxidized mixture results.

The deposition of carbon during the cracking of high molecular hydrocarbons is said to be largely avoided by a method developed by the I. G. Farbenindustrie A.-G.[26] A liquid hydrocarbon is heated by rods or wire of metals, graphite, or silicon carbide. These rods are placed in the liquid and heated electrically to the desired temperature while they are exposed to a blast of air, hydrogen, steam or ammonia. If the cracking temperature is maintained at 500° C. the product is principally an oil boiling between 80° and 300° C. and the gases are mainly olefins. At higher temperatures (700° to 1000° C.) the product is an oil of lower boiling range together with a gas that is principally methane.

Low-boiling hydrocarbons can also be obtained by distillation of heavy hydrocarbons in the presence of oxidizing agents such as potassium permanganate or dichromate, or manganese dioxide.[27] This process is applicable to such materials as resins, pitch, waxes, tars and asphalts. The reaction may be assisted by ionizing the vapors by means of high-frequency discharges.

Howard[28] produced motor fuels of high antiknock value by passing a mixture of the higher-boiling fractions of gasoline and air (in the proportion of 4 mols. of oxygen to 1 mol. of the hydrocarbon) through tubes heated to 230° to 370° C. The condensed products are steam-distilled to remove gummy substances, and can then be blended with other gasolines. In a procedure which has been developed by Hopkins,[29] the vapors obtained by the distillation of high-boiling fractions, such as kerosene, are mixed with air and passed through a heating zone kept below the cracking temperature (385° to 470° C) (725° to 875° F.). The gaseous mixture, after passing through a rectifying column, is washed with sodium hydroxide solution and distilled. This process seems to be principally dehydrogenation, as the acid adsorption value of product indicates a high percentage of unsaturated hydrocarbons.

Stryker[29a] suggested adding about 0.2 to 1 per cent of a completely soluble oxidized paraffin wax to gasoline or kerosene, the oxidized wax serving as a lubricant in the cylinders of internal-combustion engines.

Watkins [29b] prepared a gas for heating purposes by passing heated air through a conduit under superatmospheric pressure, the heat from the air being used to partially vaporize liquid hydrocarbons, which were then mixed with the air.

EMULSIFYING AGENTS

Emulsifying agents can be prepared from the oxidation products of petroleum, particularly from paraffin wax. As shown in Chapter 43, the oxidation of these solid hydrocarbons leads to the production of wax acids of high molecular weight together with saponifiable material, most probably esters. These products can then be treated with alkalies, either before or after the removal of the acids, and the resulting soaps can be used for making emulsions of many different types. This is apparently the basis for most of the processes, which differ only in the manner in which the various steps are carried out.

For example, the oxidation products of solid paraffin are treated with a quantity of alkali hydroxide just sufficient to saponify the saponifiable constituents.[30] Hydrocarbons, or other liquids which are insoluble in water and which may contain sulphur or other dissolved substances, can be added before or after saponification. The product so formed can be used either as an emulsifying agent for drilling oil and other similar oils, or directly as a lubricating oil.

Partially oxidized wax, or mixtures of petroleum and other waxes (also partially oxidized), has also been proposed as an ingredient for paper sizes by Ellis.[31] For low grades of paper, where color is not important, the blown or oxidized wax can be mixed with various petroleum distillates. For high-grade paper a white oil such as "Nujol" or "Marcol" is employed. The sizing is made by dispersing the oil and oxidized wax mixture in an aqueous medium with emulsifying agents such as soap or silicate of soda. Other sizing agents, such as rosin, can also be used along with the blown wax.

The oxidation products of paraffin wax have been mentioned as stabilizers for asphalt emulsions.[32] The wax is oxidized by passing a rapid stream of oxygen through it at 150° to 160° C., in the presence of metallic soaps as catalyzers. The oxidation product is then dissolved to the extent of 0.1 to 0.3 per cent in petroleum asphalt (m.p. 40° C.) and the mixture is poured into an equal volume of dilute alkali solution (0.5 per cent), agitated well, and heated to 90° to 100° C.

In another process [33] the wax is oxidized until the acidic contents amount to about 30 per cent by weight. The oxidation is carried out at 160° C., under pressure, and in the presence of catalysts such as manganese oleate. The oxidized material is then washed and pressed to remove the highly acidic substances. The resulting products are subsequently neutralized with alkali and emulsified with water. An emulsion is obtained which has been suggested for use as a textile dressing, and also for the "proofing" of permeable materials such as strawboard, asbestos, brick, stone, or concrete. The addition of rosin or other size to the oxidized product before neutralization yields an emulsion which can be used in sizing paper.

Beller and Pfaff[83a] prepared an emulsifying agent by treating high molecular weight hydrocarbons, or a partially oxidized mixture containing about 70 per cent or more of unchanged hydrocarbons, with sodium carbonate and ammonium stearate.

Hydroxyalkyl ethers of aliphatic polyhydric alcohols containing more than 2 carbon atoms may be etherified or esterified with aliphatic compounds containing more than 5 carbon atoms, of which at least 2 hydroxyls are left free, to obtain wetting, cleansing and dispersing agents. Such compounds are sorbitol hexa-(2-hydroxyethyl) ether with lauric acid, linoleic acid, coconut oil acids, or acids containing from 8 to 11 carbon atoms from oxidized paraffin wax.[83b]

PAINT VEHICLES AND DRIERS

In one process, paint vehicles are made by hydrogenation followed by oxidation of a mineral oil. This product is then mixed with drying, semi-drying or non-drying oils. Only mild oxidation need be applied. For example, the mineral oil is heated in contact with manganous oxide at 85° to 90° C. (185° to 194° F.) for about two hours.[84] Tung oil may be added to the final blend.

Driers are obtained by treating the crude or saponifiable oxidation products of paraffin or montan wax with the oxides or salts of the alkaline earths or metals such as aluminum, zinc, manganese or lead to form products which are insoluble or only slightly soluble in water.[85] These products may be used alone or mixed with salts of high molecular weight acids of natural origin, e.g., resinates, linoleates, or stearates.

Mixtures of aluminum resinates obtained from petroleum distillates and low-boiling petroleum fractions have been proposed as substitutes for linseed oil.[86] The aluminum compounds are prepared in the following manner: The sodium soaps obtained from the alkali used in washing acid-treated lubricating oils are dissolved in a light hydrocarbon, dilute sulphuric acid is added to neutrality, followed by the addition of a dilute solution of aluminum sulphate. The solution of aluminum resinate so obtained is separated, the solvent is removed, and the residue is then ready to mix with a low-boiling hydrocarbon.

Metallic salts of acids of oxidized mineral oils dissolved in low-boiling petroleum fractions, aromatic hydrocarbons or terpenes have been suggested as varnishes by Petrov, Danilovich, and Rabinovich.[86a]

Compositions which may be used as weather-proof coatings for stone-work have been made by mixing drying oils with higher aliphatic alcohols, the latter having been prepared by the oxidation of paraffin hydrocarbons or by catalytic reduction of the acids of paraffin hydrocarbons.[86b] Any acids present in such oxidation products may be converted into aluminum or zinc salts and added in this form. Varnish products with a high luster have been prepared by heating the alcohol obtained from oxidized paraffin wax with turpentine and ozokerite, or with nigrosin to produce a shoe polish.[36c] Fatty acids of oxidized paraffins, montan or carnauba wax mixed with turpentine or similar substances and then emulsified with water by means of soaps or sulphonic acids have been proposed as polishing materials.[36d]

[86b] I. G. Farbenindustrie A.-G., British Patent 375,002, 1931; *Brit. Chem. Abs.* B, 1932, 807.

Weber[36e] prepared a coating composition by dissolving nitrocellulose in a water-soluble, acetylated oxygenated petroleum derivative boiling between 66° and 85° C., with an acetylated distillate from the volatile water-soluble petroleum oxidation products boiling between 77° and 95° C., and adding this mixture to a solution containing rosin-phthalic glyceride resin. Cellulose acetate or other cellulose esters or ethers and other synthetic resins, such as benzoic phthalic glyceride, salicylic phthalic glyceride, or natural resins may be used similarly.

Lubricants and Greases

Penniman[37] obtained machine lubricants by adding to a hydrocarbon of low viscosity, (1) a "polar body," such as oleic acid, or the higher alcohols and ketones obtained by oxidizing petroleum with air, (2) a protective material, e.g., a mixture of castor oil and oleic acid, and (3) an antioxidant, lead tetraethyl and phenyl disulphide being examples.

James[38] oxidized petroleum distillates to obtain a large percentage of aldehydes and alcohols and condensed these to form acetals which may be used as lubricants. Condensation is also accompanied by some polymerization of the aldehydes, which is said to result in the formation of lubricating bodies. Alternatively, the petroleum may be oxidized to give a large quantity of aldehyde acids. This product can be mixed with one containing a larger quantity of alcohols to obtain liquid mineral waxes or esters, which also are proposed as lubricants.

Dengler[38a] manufactured lubricants by oxidizing, with air at 205° to 270° C., the residues of paraffin or semi-paraffin crudes having flash points of 190° to 245° C.

The addition of small proportions (0.25 to 2.0 per cent) of oxidized paraffin wax to lubricating oils appears to enhance the lubricating power of the oils. This applies to lubricating oils for machinery cutting tools and molds,[39] lubricants for internal-combustion engines,[40] and lubricants for transmission systems of automobiles.[41] The unsaponifiable matter may be removed from the oxidized wax before using.

Greases were produced by James[42] by careful neutralization of the acids in partially oxidized petroleum with alkalies such as lime or sodium hydroxide, carbonate, or bicarbonate. Upon neutralization, the soaps formed cause an emulsification of the whole product. The grease thus obtained, either before or after blending with other oils or greases, can be brought to the desired consistency by careful evaporation of the water.

WAXES AND RESINS

As mentioned in Chapter 43, the oxidation of paraffin wax progresses through the formation of esters which are further oxidized to acids. This oxidation can be made to yield substances for the preparation of artificial waxes. Waxes produced by this method are held to be substitutes for carnauba, beeswax, and other similar substances.

Before oxidation the paraffin may be mixed with resins, and oxidation of the mixture serves as a purification step. For example, Schliemann[43] produced artificial waxes by oxidizing a mixture of paraffin and American resins or French colophony at 90° C. with air. During this operation an insoluble resin separates and the mass assumes a peculiar sweet odor. After separation of the insoluble portion the mass is cooked with steam. It can then be mixed with smaller quantities of high-melting paraffins and coloring matter. The finished paraffin-resin mixture is a plastic mass which can be kneaded without sticking and retains this property after long storage. It can be used in many technical applications as a substitute for wax or rosin.

A number of processes have been developed for the manufacture of such materials as shoe polishes, creams, and floor polishes, and substitutes for beeswax. In the production of a substitute for beeswax,[44] paraffin wax is oxidized at 150° C. with air and the oxidation product is then separated into a solid and a semi-solid portion by pressing or by extraction with organic solvents. Synthetic wax thus obtained from a paraffin wax melting at 52° C. had the following characteristics: acid value, 21; saponification value, 75.6; iodine value, 4.7.

Artificial waxes are also produced by bleaching montan wax with oxygen, or by oxidizing mixtures of paraffin wax, castor oil, and resins[45] for a short time in the presence of oxidizing catalysts. Any free acids formed can afterwards be esterified with glycol.

For the making of light colored wax-like substances which can be used as shoe or floor polishes, heated mixtures of oils and lignite wax, or other similar mixtures of vegetable or animal fats and waxes or resins are oxidized with air in the presence of contact materials such as clay, glass, aluminum rings or balls.[46]

Waxes which have similar uses are obtained by the oxidation of montan wax with a mixture of chromic and hydrochloric or phosphoric acids.[47] Too vigorous oxidation and carbonization must be prevented. The products are white or light yellow in color. The oxidized wax is then partly esterified with glycol and partly neutralized with lime. The material can be further improved by the addition of glycol esters to reduce its salt content to not more than 15 to 20 per cent.

Acetic acid may also be substituted for hydrochloric or phosphoric acid in the oxidation of montan wax.[48] The product thus obtained can be used as a substitute for beeswax, or it can be mixed with oxidation products of paraffin hydrocarbons to give wax-like materials.

The synthesis of waxes from fatty acids, or from the wax acids resulting from the oxidation of paraffin wax, has been accomplished by Grün, Ulbrich, and Krczil.[49] The acids were converted to ketones, from which the secondary alcohols, olefins and esters found in natural waxes could be made. The mixed wax esters were much easier to prepare than the individual esters and had more useful properties. Stearic acid, for example, when heated in an iron vessel for 4 hours at 300° C. gave a 91 per cent yield of ketone. The ketone was reduced by heating with a mixture of ethyl alcohol and sodium hydroxide solution, and the secondary alcohol obtained was easily esterified with acid chlorides. After neutralization of the excess acid, the ester and salts were separated by the Hönig and Spitz method[50] with petroleum ether and 50 per cent alcohol. To accomplish further separation of the unesterified wax alcohol from the reaction product it was extracted with hot alcohol in which the esters are insoluble. High yields of waxes were obtained in this way.

Szidon[51] produced a white paraffin wax melting at 45° C. by the oxidation of spindle oil in the presence of copper oxide at 180° C. under pressure.

Hard resins which are said to be of value in the manufacture of varnishes are made by oxidizing the resinous substances removed from cracked petroleum distillates by adsorbing agents.[52] The oxidation is effected with air at slightly elevated temperatures and in the presence of polymerizing agents such as the salts of heavy metals. Resins may also be obtained by heating cracked petroleum distillates with phenolic substances, e.g., wood- or coal-tar distillates. These distillates are heated to a temperature of about 150° C. while oxidizing gases (ozone, air, or an oxide of chlorine) are passed into the mixture until the desired consistency is obtained.[53]

Ramage[54] produced an oxidized resin by treating rosin dissolved in liquid hydrocarbons with air or ozonized air at 93° C. (200° F.). The oxidized product possesses lower iodine and saponification values than the original product, though the acid value is higher, and the metallic salts of the oxidized product are much less soluble than those of the original substance. The oxidized product can be used in the manufacture of paints and varnishes, and as a filler for plastic molding.

Products containing resinous oxygen-containing substances, paraffin compounds, oily liquids, alcohols and aqueous solutions of organic acids have been obtained by passing mixtures of oxides of carbon and hydrogen over iron catalysts containing small proportions of alkalies and alkaline earths at about 200° C., under atmospheric, slightly reduced, or increased pressures.[54a]

PLASTICS AND RELATED SUBSTANCES

Products which can be used in the manufacture of linoleum, lacquers, or rubber compounds may be obtained in the following manner: The liquid acids insoluble in petroleum ether, which are obtained on the oxidation of paraffin wax, are esterified at 150° C. or above with alcohols containing at least two hydroxyl groups, such as glycol or glycerol. The alcohols may be mixed with organic unsaturated acids or hydroxy-acids, such as linoleic acid, or with their glycerides. Before or during the heating process the liquid acid portion is heated with siccatives, e.g., lead oxide, or with sulphur or sulphur compounds.[55] The same class of substances can also be obtained by using the unsaturated fatty acids made by the dehydration of the oxidation products of paraffin wax in place of the acids just mentioned.[56]

Milvitzkii and Maksorov[56a] produced synthetic resins by heating at 180° to 220° C. a mixture of glycerol and phthalic anhydride with carboxylic acids, obtained from the oxidation of paraffin hydrocarbons. Petrov[56b] suggested the formation of resins by condensing acids obtained in the oxidation of petroleum distillates with aldehydes in the presence of amines.

It has been stated that plastic materials are produced by the reaction of alginic acid with hydrocarbons (paraffin wax), followed by the addition of an alkali, sodium hydroxide or ammonia.[57] Finely divided metals may be added to the product.

When liquid petroleum, for example, fuel oil, is oxidized at 130° to 160° C. under 150 to 350 pounds per square inch pressure in the presence of catalysts the reaction mixture eventually separates into three layers.[58] The upper and lower layers contain principally unchanged hydrocarbons, petroleum-soluble materials, and an aqueous solution of acids, respectively. The middle layer, principally hydroxy-acids insoluble in petroleum, is separated and distilled at low pressures (10 to 20 mm. of mercury) to yield artificial asphalt. The temperature of distillation varies from 140° to 275° C.; the higher the temperature, the harder and more brittle are the products obtained. The less brittle products, however, have high dielectric properties.

Hard-blown products of mixed petroleum residues or other asphaltic bitumens, with softening points of about 50° C. and penetrations between 8 and 16 at 50° C. (A.S.T.M.), are advantageous ingredients for rubber. Such materials can be prepared by blowing a mixture of 60 and 40 per cent, respectively, of residues from Illinois and California petroleums.[59] From 5 to 25 per cent of this oxidized material can be added to rubber before vulcanization.

Oxidation of petroleum distillates, of 43° to 48° Bé., in the liquid phase can be effected at 130° to 140° C. under 150 to 350 pounds per square inch pressure, so as to avoid as much as possible the production of hydroxy-acids. The acids thus obtained, after separation from aldehydes and ketones, can be used as plasticizers for coating compositions of nitrocellulose, for artificial rubber, or can be esterified to give substitutes for castor oil.[60]

SUBMERGED COMBUSTION

In the cracking of asphalts, cracking pitches or still residues, Ellis[61] used submerged combustion.[62] The process may be operated at atmospheric or increased (20 atmospheres or more) pressure. Under pressures above atmospheric, submerged combustion is more intensified and more positive. The burner is supplied with air and fuel (gaseous, liquid or solid) at such a rate as to maintain a temperature of about 425° C. (800° F.). The volatile products formed are recovered by passing them through a heat exchanger, to preheat the oil fed to the still, then through a condenser and scrubber, and subsequently through an absorber.

Submerged combustion is particularly applicable to the distillation of tar or tar oils, and to the cracking of petroleum. In some instances, the steam produced can be utilized for the generation of power.

Nitric acid and oxides of nitrogen are obtained in the combustion of oil or other fuel and air in a flame submerged in water, and in the presence of catalysts such as vanadium, nickel, chromium, iron, or other metals which form more than one oxide.[63] Calcium hydroxide or carbonate is added to the water to neutralize the acid and prevent corrosion of the apparatus. The salts thus formed can be recovered. The steam produced in the process may be employed for generating power.

Baum and Herrmann[64] obtained acetylene by means of a hydrogen-oxygen flame in petroleum. A carbon monoxide-hydrogen-oxygen flame in petroleum produced ethane and acetylene. Acetylene may also be produced on burning oxygen or a gas containing oxygen in an atmosphere of hydrocarbon gas or submerged in a liquid hydrocarbon.[65] The yield is affected by the ratio of hydrocarbon to oxygen and also by the shape of the vessel. The yield is greater when the oxygen is supplied through a jet with small diameter than with a large diameter and by supplying the gas through several jets in one vessel than through the same number of jets each in a separate vessel.

SULPHONATED AND CHLORINATED OXIDIZED HYDROCARBONS

Sulphonated[66] and chlorinated[67] oxidized hydrocarbons have found a variety of uses. They have been suggested as emulsifying, wetting, and flotation agents, and as insecticides.

The vapor phase oxidation of a Pennsylvania gas oil distillate gave alcohols, aldehydes, ketones, saturated and unsaturated acids and unchanged hydrocarbons.[68] This mixture, after being sulphonated, washed, and neutralized with sodium hydroxide yielded a composition having 40 per cent oxygen and 1.5 per cent sulphur. It was a clear stable, maroon-colored liquid which easily emulsified with water. A 1 per cent solution was toxic to aphids, leaf hoppers and red mites. As an activator for poisons such as nicotine sulphate it was much more effective than the soaps usually employed.

[66] The action of sulphonating agents on hydrocarbons and the production of various other sulphonated derivatives is discussed more completely in Chapter 46.

[67] See also Chapter 30.

Sulphonated products of partially oxidized petroleum hydrocarbons, either as free acids or as alkali salts, can be used as cleansing or emulsifying agents, in the manufacture of lubricants, with flotation oils, or in tanning.[69]

Oxidation products of solid or liquid paraffin or naphthene hydrocarbons, tars, or waxes may be sulphonated with sulphur trioxide[69a] or with oleum or chlorosulphonic acid[69b] to produce emulsifying and wetting agents. These sulphonated products may be improved as textile assistants by addition of electrolytes, such as salts of sodium, potassium, magnesium, ammonium, barium, aluminum or zinc, or water-soluble salts of acids stronger than carbonic.[69c]

Chlorination or sulphonation of the unsaturated hydrocarbons, resulting from the dehydration of oxidized paraffin or waxes, gives substances which form water-soluble salts with bases such as ammonia, pyridine, amines, sodium hydroxide, or sodium carbonate, which are useful as wetting, emulsifying or cleansing agents, and in the preparation of insecticides and disinfectants.[70] The unsaturated liquid hydrocarbons are obtained by first oxidizing liquid or solid paraffin or naphthene hydrocarbons in the presence of barium cinnamate, uranyl tungstate, or manganese naphthenate. The product, which contains a mixture of alcohols, hydroxy-acids, esters, lactones, and other substances, is then heated to 180° C. in the presence of catalysts with the result that water or carbon dioxide is split off and the unsaturated compounds are formed.[71] The use of boric acid or vanadium pentoxide is said to increase the yield of alcohols. Any free acids which still remain in the crude product can be removed in a number of different ways.

A mixture consisting mainly of aliphatic alcohols of 12 to 20 carbon atoms and acids of 11 to 24 carbon atoms, obtained by extracting partially oxidized paraffin hydrocarbons with methyl alcohol, may be reacted with one-third of its weight of 98 per cent sulphuric acid at 35° C. for 2 hours, and the excess sulphuric acid removed by washing with sodium sulphate solution to produce sulphonated products. The resulting material may be mixed with 3 to 4 times its weight of spindle oil and 2 to 3 per cent of ammonia to form a stable emulsion with water, which may be used as a wetting, cleansing and emulsifying agent.[71a] Products for similar purposes may be obtained by sulphonation of oxidized products of mineral oil, ceresin, or tar fractions.[71b]

The sulphonation of hydroxy acids obtained by oxidation of crude montan wax, or amides, anhydrides or esters of montan wax acids, or alcohols or amines corresponding to these alcohols, to produce wetting, cleansing and emulsifying agents has also been suggested.[71c]

Sulphonic acids, which can be used in the hydrolysis of fats, as emulsifying agents, or in the textile industry, are made by sulphonating white oil or liquid paraffin which has been previously oxidized at 140° to 180° C. by a current of air.[72]

Chatrov,[72a] by using different proportions of reagents and temperatures, obtained four different sulphonated derivatives from crude hydroxy acids of oxidized paraffin hydrocarbons. The products were soluble only in sodium hydroxide, and partly in sodium carbonate and carbon disulphide and emulsified with water. The most highly sulphonated acid showed wetting properties, but was not satisfactory as a soap although it could be substituted for sodium ricinoleate in naphthol or lizarol baths for printing with alizarin red or rose.

MISCELLANEOUS PRODUCTS

A medicinal product is obtained when hydrocarbon oils, such as kerosene, are atomized and partially burned with a limited supply of air, and the vapors condensed.[73] The product is described as a liquid of low irritability and high absorbability for medicinal purposes in the treatment of catarrhal diseases.

For preserving wood, Petrov, Danilovich and Rabinovich[73a] suggested forcing oxygen under pressure through the material impregnated with warm hydrocarbon oil, the oxidation taking place in the pores of the wood. An oil-soluble catalyst such as a metallic salt of a fatty acid may be employed.

Compositions which may be used as insecticides or fumigants may be prepared by oxidizing the sulphur dioxide extract of kerosene distillates and emulsifying the resulting products with water.[73b]

A wood preservative[74] which contains aldehydes and aldehyde-acids is prepared by the partial oxidation of petroleum hydrocarbons by passing the oil vapors and air over catalysts at 200° to 500° C. The oxides of molybdenum are used as catalysts, and steam may also be added to the gaseous mixture. The insoluble calcium salts of these acids can be used for waterproofing fabrics or paper making. Soluble soaps are employed for the emulsification of disinfectants or in mixtures for spraying trees.[75] A water emulsion of petroleum oils with the acids from such oils (particularly from the oxidation of naphthenic hydrocarbons) is suggested as a herbicide.[76]

Mineral frothing agents, which may be employed in the concentration of ores, are obtained by the partial oxidation of various petroleum fractions in the liquid phase.[77] Catalysts need not be used during the oxidation step.

Unsaturated acids of high molecular weight, such as are produced by the dehydration of the acids obtained in the oxidation of paraffin wax, when mixed with an alkaline agent, e.g., a solution of ammonia, yields a composition which finds application for the oiling of fibrous materials like wool.[78]

In the manufacture of stove lacquers the residues from the distillation of oxidized paraffin waxes are polymerized by heating with chlorine and sulphur and then dispersed or dissolved in various organic solvents.[79]

Bituminous materials (free of volatile oils) oxidized in the presence of alkalies and emulsified with water furnish a product which can be mixed with cement and used for producing a cold glaze.[80] Before the addition of the oxidized bituminous substance, the cement may be mixed with pigments to obtain glazes of various colors.

The pitch-like residues from the distillation of coal-tar or of petroleum can be air-blown in the presence of manganese dioxide to yield products for impregnating roofing paper.[81] The addition of formaldehyde to the blown residue before cooling is said to aid deodorization and to increase the durability of the product.

Organic acids, suggested as synthetic tanning agents, are obtained by the oxidation of fossil vegetable materials in the presence of nitric acid.[82] Thus, brown-coal residues, e.g., those extracted with benzene, are heated to 90° C. in a covered vessel in a current of air, while fuming nitric acid is allowed to percolate through the mass. When samples of the material show no increase in solubility in water, oxidation is stopped and the nitrous gases removed by a current of air. The product is a mixture of acids, which contain no more nitrogen than the original substance. Ozokerite gives a water-insoluble acid mixture, the sodium salts of which possess soap-like properties.

The oxidation product from paraffin wax, after it has been freed of resins or asphalts, or the acid compounds after being separated from the other oxidation products, or the zinc salts of these products, may be added to synthetic or natural rubber before vulcanization.[83] Or the oxidized products mixed with an accelerator, such as mercaptobenzothiazole, may be employed similarly.[83a]

Oxidized petroleum oils, pine tar, or stearic acid have been added to rubber, before incorporation of reenforcing ingredients and vulcanizing agents, to obtain rubber compositions of increased resistance to abrasion.[83b]

Linseed, or other similar unsaturated oils, can be oxidized by mixing with molten paraffin wax, cooling, powdering the mixture and exposing it to air at ordinary temperatures.[83c] When dispersed in this manner the linseed oil is rapidly oxidized. The wax is subsequently melted and separated from the solid oxidation

product. The linseed oil can also be dispersed on sodium chloride, oxidized at 100° C., and the salt removed later by washing with water.

Materials such as sawdust, wood, moss, paper pulp and rags are oxidized by heating in an alkaline solution to which is added a heavy hydrocarbon, for example, paraffin, which appears to act as a catalyst.[83d] Air may be used as the oxidizing agent, at a temperature of about 200° C. Salts of oxalic and other organic acids are the principal products of this oxidation.

BACTERIAL OXIDATION OF CRUDE OILS

In a study of the bacterial oxidation of crude oils, Tauson[84] found that *Penicillium* develops on paraffins melting at 45° to 56° C., and utilizes about 80 per cent of the hydrocarbon, *B.fluorescens liquifaciens, B.pyocyaneus, B.stutzeri* and other bacteria utilize paraffins as well as kerosene, and microorganisms obtained from the Baku region (bacteria as well as the mold *Aspergillus flavus*) can utilize both hard and soft paraffin as well as white vaseline. The paraffins are oxidized to carbon dioxide and water, there being no evidence of the production of fatty acids. Hydrocarbons of the olefin group are apparently easily oxidized, and the oxidation of terpenes also seems very probable. Conditions necessary for oxidation of the paraffins are: (1) The presence of an aqueous solution of mineral salts, including a nitrate or ammonium salts. In the case of the latter, calcium carbonate must be present to neutralize the acid set free by the liberation of ammonia. (2) The reaction of the solution must be as nearly neutral as possible, and (3) there must be a free access of oxygen. Other bacteria oxidize aromatic substances. For example, benzene, toluene, and xylene are oxidized by *B.benzoli*, naphthalene by *B.naphthalinicus liquifaciens, B.naphthalinicus*, and *B.naphthalinicus nonliquifaciens*, and phenanthrene by *B.phenanthrenicus*. Since the soil in oil-bearing regions is rich in a great variety of microörganisms which utilize hydrocarbons and display considerable specificity, and also because the conditions for this growth are very frequently found, it was concluded by Tauson that bacterial action plays a very important rôle in those changes of the crude oil which take place before it comes from underground.

Chapter 46

Action of Sulphonating Agents on Petroleum Hydrocarbons. Sulphonic Acids, Detergents, and Other Products

The action of sulphonating agents such as concentrated or fuming sulphuric acid on petroleum hydrocarbons is of considerable interest in view of the large-scale application of sulphuric acid in the refining of petroleum distillates. The various classes of hydrocarbons behave in markedly different ways toward this reagent. In general, when combination occurs, two main reactions may be distinguished, namely, *sulphation* and *sulphonation*. The former, which is exemplified by the interaction of unsaturated hydrocarbons with sulphuric acid, yields a sulphuric acid ester in which a carbon atom is linked through an oxygen atom to a sulphur atom, i.e., in compounds of the type $R—O—SO_3H$. These sulphuric acid esters are distinguished by their ready hydrolysis to alcohols (see Chapters 13, 14 and 16). On the other hand, the true sulphonated products contain a carbon atom directly linked to a sulphur atom which is itself part of a sulphonic, or $—SO_3H$, group. This carbon-sulphur linkage is much more stable than the carbon-oxygen linkage and even alkylsulphonic acids of the type $R^1R^2R^3—C—SO_3H$ are extremely resistant to hydrolytic influences.[1]

The action of sulphuric acid on hydrocarbons not only forms sulphates or sulphonates, however, but also induces polymerization and oxidation reactions (which have been discussed in Chapters 26 and 37). The unsaturated hydrocarbons are polymerized in the presence of this acid, particularly with high concentrations of acid. With very concentrated or fuming sulphuric acid, oxidation of the hydrocarbon molecule often results, in which the sulphuric acid or sulphur trioxide is itself reduced to sulphur dioxide. Many of the stable paraffin and cycloparaffin hydrocarbons are oxidized as well as sulphonated on treatment with warm fuming sulphuric acid or sulphur trioxide.

As already indicated in Chapter 13, the unsaturated hydrocarbons of the olefin series generally undergo sulphation, with the production of esters, when subjected to the action of sulphuric acid. However, polymerization is often the main result of treatment of olefins with this acid, particularly if the acid is very concentrated. Even more pronounced is the action of sulphur trioxide on olefin hydrocarbons, which induces both polymerization and oxidation. The reaction of olefins with sulphuric acid to form derivatives of carbyl sulphate [2] is discussed in this chapter.

---

[1] These differences are pointed out also by Hart, *Ind. Eng. Chem., Anal. Ed.*, 1932, **4**, 411. *Cf.* Stadlinger, *Chem. Umschau*, 1932, **39**, 217; *Chem. Abs.*, 1933, **27**, 3840; Lindner, Russe and Beyer, *Fettchem. Umschau*, 1933, **40**, 93; *Chem. Abs.*, 1933, **27**, 3838. Kalinor and Schmidt (*Chimie et industrie*, 1933, **29**, 1278; *Brit. Chem. Abs.* **B**, 1933, 718) made a further distinction: those sulphonic acids having a sulphonic acid group in the middle of the chain are called "internal" whereas those having one at the end are called "external." The numerous proposals for the treatment of different stocks with sulphuric acid of various strengths appear in many cases to use the term "sulphonated" rather loosely. Generally, however, the word has the significance of its usual meaning, namely, that involving direct linkage of sulphur to carbon. Luther, however, stated that under the term "sulphonated" as used by him in U. S. Patent 1,908,376 he included the products which have been acted upon by sulphonating agent so that either sulphuric esters or sulphonic acids or mixtures of both may be obtained, depending on the character of the sulphonating treatment. Perhaps, from the standpoint of this chapter, the term "sulpho compounds" as used by a number of investigators could be applied conveniently in a generic sense. Gray, for instance, stated ("The Mineral Industry," 1901, 579): "In the treatment of oils with sulphuric acid, considerable action takes place and the reaction is a very complex one. The acid removes the asphaltic matter and attacks and combines with many hydrocarbons forming 'sulpho' compounds." At the risk of some confusion, the author has been impelled to adopt the terms reported to have been used by the investigator or investigators in each case.

The most readily sulphonated hydrocarbons are those of the aromatic series. The aromatic sulphonic acids are in most cases prepared by warming the aromatic hydrocarbon with concentrated sulphuric acid. The conversion of benzene into its monosulphonic acid is a typical reaction, and proceeds as follows:

$$C_6H_6 + H_2SO_4 \longrightarrow C_6H_5SO_3H + H_2O$$

The aromatic sulphonic acids derived from benzene and naphthalene and their immediate homologues and derivatives find extensive application in the manufacture of dyestuffs. An extended discussion of the sulphonation of aromatic hydrocarbons, however, is outside the scope of this book. The relatively greater ease of sulphonation of the typically aromatic hydrocarbons as a class should, nevertheless, be noted and a few instances will be cited in which aromatic hydrocarbons present in petroleum appear to have been sulphonated.

Comparatively little work has been carried out on the sulphonation of saturated hydrocarbons of the paraffin and cycloparaffin series, but the indications are that most of these hydrocarbons, despite their apparently great resistance to chemical action, can be sulphonated by fuming sulphuric acid, oxidation also occurring in the presence of this reagent. Certain types of saturated hydrocarbons, notably those containing a tertiary carbon atom, i.e., the grouping  $\begin{matrix}\equiv C & \\ \equiv C & -CH \\ \equiv C & \end{matrix}$, appear to be much more readily sulphonated (and also nitrated) than their straight-chain isomers.

Since immense quantities of petroleum hydrocarbons are refined with sulphuric acid, during which process considerable formation of sulphonic acids takes place, this action of sulphuric acid on hydrocarbons is of importance. These sulphonic acids derived from mineral oils have attracted a high measure of technical interest. The acid refining of gasoline distillates is usually accomplished under conditions which preclude attack of all but the most reactive constituents, and are such that probably no saturated aliphatic hydrocarbons are sulphonated. However, the conditions are somewhat more severe in the acid refining of certain lubricating distillates, and even treatment with fuming sulphuric acid is resorted to in the manufacture of petrolatum. Undoubtedly, under the latter conditions, considerable sulphonation and oxidation of the more reactive saturated (paraffin and cycloparaffin) hydrocarbons can, and does, take place. Our knowledge of the sulphonation of the saturated hydrocarbons is largely limited to that of hydrocarbons of comparatively low molecular weight. Only inferences can be drawn from these data concerning the reactions which occur in the acid refining of higher petroleum fractions. It appears that the saturated hydrocarbons present in the higher distillates of many petroleums are much more reactive toward chemical reagents, sulphuric acid included, than the simpler saturated compounds and that the almost

---

[2] Carbyl sulphate,  $\begin{matrix} CH_2-SO_2 \\ | \\ CH_2-O-SO_2 \end{matrix}$ O, is the anhydride of ethionic acid,  $\begin{matrix} CH_2-SO_3H \\ | \\ CH_2-O-SO_3H \end{matrix}$

unknown class of polynuclear cycloparaffins may embrace more highly reactive hydrocarbons than has hitherto been suspected.

Although the sulphonation of saturated hydrocarbons is primarily of interest in connection with the acid refining of petroleum distillates, another aspect of the question should not be overlooked. Since the saturated aliphatic and saturated cyclic sulphonic acids can be made the starting point of a number of syntheses (for example, the conversion into alcohols by hydrolysis or lower carboxylic acids by alkali fusion), it may be possible to utilize the sulphonation process as a method of transforming the more readily sulphonated paraffins and cycloparaffins into derivatives with desirable properties. It is unfortunate that our knowledge of the sulphonation of even the simpler paraffins and cycloparaffin hydrocarbons is so exceedingly meager.

Sulphonation of Paraffin Hydrocarbons

Most of the simpler paraffin hydrocarbons appear to be unattacked in the cold by concentrated sulphuric acid (up to 100 per cent H_2SO_4). However, McKee[3] stated that saturated hydrocarbons of ordinary Pennsylvania kerosene fraction which boiled at about 200° C. could be sulphonated to disulphonic acids by ordinary concentrated sulphuric acid with vigorous stirring (900 revolutions per minute). Brooks and Humphrey[4] were unable to verify this; both pure n-heptane and diisopropyl were unaffected by shaking with 95 per cent sulphuric acid (specific gravity 1.84) at 25° C. for 48 hours.

Paraffin hydrocarbons are absorbed in cold fuming sulphuric acid. For example, Orndorff and Young[5] found that propane was absorbed to the extent of 50 per cent in 50 days. Worstall[6] observed that ethane was absorbed more rapidly than methane by fuming sulphuric acid. The absorption of methane, ethane, propane, butane, isobutane, pentane, hexane, isopropylethane, heptane, ethylisoamyl, and octane in fuming sulphuric acid of various concentrations has also been determined.[7] Mabery[8] noted that various fractions of Pennsylvania petroleum were dissolved by fuming sulphuric acid. Other results on the absorption of constituents of gasolines and petroleum distillates in sulphuric acid of several concentrations were given by Ormandy and Craven[9] and Carpenter.[10]

Fuming sulphuric acid reacts with some paraffin hydrocarbons to yield sulphonic acids. An investigation of the action of fuming sulphuric acid on n-hexane, n-heptane and n-octane was carried out by Worstall.[11] He found that although these hydrocarbons were unaffected by cold fuming acid, rapid sulphonation occurred when the acid was added to the boiling hydrocarbons. The products consisted of monosulphonic acids together with smaller proportions of disulphonic acids. Better yields of the latter were obtained by passing sulphur trioxide into the boiling hydrocarbons. The hexane-monosulphonic acid, the yield of which was about 30 to 40 per cent of the theoretical, was a light brown liquid, very soluble in alcohol and water but insoluble in ether. Considerable oxidation of the hydrocarbons took place in the sulphonation. The disulphonic acids produced by the action of sulphur trioxide on the boiling hydrocarbons were dark syrupy liquids. In addition to the disulphonic acids, brown brittle solids, insoluble in water and all organic solvents, were isolated. These solid products Worstall considered were probably oxysulphones.

Burkhardt and Lapworth[12] observed that sulphur trioxide attacked ligroin and crude hexane completely in the cold, considerable sulphur dioxide being evolved. This led to an investigation by Burkhardt[13] of the action of fuming sulphuric acid on n-hexane and cyclohexane. By vigorously stirring n-hexane with fuming sulphuric acid (35 to 65 per cent free SO_3) at 0° to 10° C., almost all the sulphur trioxide was consumed in the resulting reaction, and approximately 1 molecule of sulphur dioxide was formed for each molecule of hydrocarbon attacked. Isolation of individual substances from the complex mixture of barium salts, obtained by neutralization of the acid layer with barium carbonate, was not effected. The general nature of the products was determined from the analytical data of the mixed barium salts (and the derived sulphonyl chlorides). Partial separation of the mixed salts was made by fractional precipitation from their concentrated aqueous solutions with alcohol. The mixed barium salts from n-hexane were partly unsaturated and contained sulphuric acid ester groups, probably as salts of sulphato-sulphonic acids formed by the action of fuming acid on the unsaturated compounds produced by initial oxidation. After hydrolysis of these substances, the products contained 2 molecules of disulphonic acids to 1 molecule of monosulphonic acid. About 5 per cent of the hexane chains were unsaturated and 30 per cent contained a hydroxyl group. It is evident, therefore, that fuming sulphuric acid both oxidizes and sulphonates hexane. Burkhardt believed that the oxidation probably leads to the formation of an unsaturated hydrocarbon which is immediately sulphonated by the acid to a sulphuric ester. Hydrolysis of these sulphato-sulphonic acids then yields sulphonated compounds containing either an unsaturated linkage or a hydroxyl group.

According to Brooks and Humphrey,[14] hydrocarbons containing a tertiary hydrogen group, such as diisopropyl, are much more readily sulphonated and oxidized than straight-chain members. They regard it very possible that the large losses experienced in the refining of mineral lubricating oils by concentrated sulphuric acid may be partly attributed to sulphonation and oxidation of such branched-chain hydrocarbons. It is interesting to note at this point that in 1875 Vohl[15] found as much as 3.1 per cent of sulphuric acid (probably as esters) in American cracked kerosene.

The sulphonation of various higher-boiling distillates with fuming sulphuric acid is discussed in the section on the production of mineral oil sulphonic acids. Very little is known of the reaction or constitution of the products formed. Gill and Meusel,[16] as early as 1868, observed that fuming sulphuric acid had no effect on a paraffin which melted at 60° C. and contained 85.5 per cent carbon and 14.9 per cent hydrogen. However, Istrati and Michailescu[17] noticed that paraffin waxes of high melting points, when cautiously heated with sulphuric acid, reacted without the formation of coke. No sulphonic acids were obtained but they did observe the evolution of carbon dioxide and sulphur dioxide which resulted from partial

decomposition by oxidation. From this behavior they concluded that the various paraffins contain a large number of branched-chain isomers.[18]

The action of *chlorosulphonic acid* [$SO_2(OH)Cl$] on the paraffins often produces sulphonated products, hydrogen chloride being eliminated during the process.[19] Aschan [20] found that diisopropyl reacted with chlorosulphonic acid at room temperature with the evolution of hydrogen chloride, and abundant heat production. The reaction was regarded by Aschan to be of a complicated character for, besides sulphonated products, a considerable amount of unsaturated oily material was formed. Isopentane also reacted with chlorosulphonic acid in a similar way. The relative ease with which many branched-chain hydrocarbons are sulphonated by this reagent has been used by Young,[21] and later by Shepard, Henne and Midgley [22] to obtain straight-chain paraffins free from the more reactive branched-chain members and naphthenes.

SULPHONATION OF CYCLOPARAFFINS

The naphthenes react with fuming sulphuric acid, resulting both in sulphonation and oxidation.[23] Concentrated sulphuric acid, however, has no effect in the cold, except on the lower members of the series.[24] With an excess of sulphuric acid, at ordinary temperatures or more readily at 40° C., some cycloparaffins yield aromatic mono- and di-sulphonic acids, resins, and products volatile with steam.[25]

Of the cycloparaffins, the cyclopropane derivatives appear to be most readily attacked. Treatment of cyclopropane or its homologues with even moderately concentrated sulphuric acid usually results in rupture of the ring and the formation either of sulphuric esters of a straight-chain alcohol or of polymerized straight-chain olefins. Thus, cyclopropane itself is absorbed by concentrated sulphuric acid to the extent of 480 cc. of cyclopropane per gram of acid at 18° C.[26] Dilution of the acid solution followed by distillation affords propyl alcohol.[27] Absorption of methylcylcopropane in concentrated sulphuric acid results in the formation of a mixture of high-boiling polymers (evidently derived from the corresponding butene) and, if the solution is diluted, secondary butanol is formed on distillation.[28] 1,1-Dimethylcyclopropane also dissolves in dilute sulphuric acid (2 volumes of acid and 1 volume of water).[29]

Cyclohexane itself gives no indication of being attacked by concentrated sulphuric acid but treatment with fuming sulphuric acid results in oxidation and sulphonation. Burkhardt[80] treated cyclohexane and methylcyclohexane with fuming sulphuric acid (35 to 65 per cent free SO_3) at 0° to 10° C. and observed the formation of sulphur dioxide to the extent of about 1 molecule per molecule of hydrocarbon attacked. As in the case of n-hexane, the products consisted of sulphato-sulphonic acids (probably derived from unsaturated hydrocarbons), which on hydrolysis yielded both mono- and di-sulphonic acids, often containing an ethylene linkage or a hydroxyl group. Small amounts of benzenesulphonic acids were also noted by Burkhardt in the sulphonation of cyclohexane.

---

[18] See their previous work (*Bull. soc. sci. Bucharest*, 1897, **6**, 61; *Chem. Zentr.*, 1897, 1, 1222) on an ozokerite (m.p. 97-98° C.) which also gave no sulphonic acids on heating with concentrated sulphuric acid.

[19] The sulphonation of the more reactive paraffins by chlorosulphonic acid apparently proceeds according to the typical equation $C_6H_{14} + ClSO_3H \rightarrow C_6H_{13}SO_3H + HCl$. On the other hand, chlorosulphonic acid reacts with *aromatic hydrocarbons* and their derivatives with the formation of *sulphonyl chlorides*. Thus benzene and chlorosulphonic acid at 150°-160° C. yield benzene-1,3-disulphonyl chloride according to the equation $C_6H_6 + 2ClSO_3H \rightarrow C_6H_4(SO_2Cl)_2 + 2H_2O$ (Pollak, Heimberg-Krauss, Katscher and Lustig, *Monatsh.*, 1930, **55**, 358; *Chem. Abs.*, 1930, **24**, 4004).

A similar result was obtained by Menschutkin and Wolf.[81] They observed that 1 gram of cyclohexane reacted with 27 grams of 25 per cent fuming sulphuric acid at 25° C. From the dark brown aqueous extract of the reaction product they isolated 70 per cent of barium salts of aromatic sulphonic acids. The action with anhydrous sulphuric acid was entirely comparable to that of fuming acid. This reaction indicates dehydrogenation of the naphthene to an aromatic compound.

Methylcyclohexane is not attacked at room temperature by concentrated sulphuric acid but fuming acid oxidizes it, and yields little or no sulphonic acids, according to Markownikow.[82] Burkhardt observed that methylcyclohexane was attacked by fuming sulphuric acid (35 to 65 per cent free SO) somewhat more rapidly and more extensively than cyclohexane, with the liberation of about ½ molecule of sulphur dioxide from each molecule of hydrocarbon. The products obtained were similar to those from cyclohexane.

Octanaphthenes react with fuming sulphuric acid, particularly on heating, to give both sulphonation and oxidation products. Markownikow and Spady,[83] for example, obtained 4 grams of barium sulphonate (from which m-xylene could be separated by distillation with steam) by the action of fuming sulphuric acid on 5 grams of 1,3-dimethylcyclohexane after its complete solution at 50° to 60° C. The conversion of 1,2,4-trimethylcyclohexane into pseudocumenesulphonic acid under similar conditions was described by Konowalow.[84]

1,4-Dimethyl-2-ethylcyclopentane dissolved in fuming sulphuric acid (containing 10 per cent sulphur trioxide), with darkening, according to Zelinsky.[85] Little heat is liberated and no sulphur dioxide was evolved, a behavior unlike that exhibited by derivatives of cyclohexane.

The action of chlorosulphonic acid on the cycloparaffins has also been studied. Aschan[86] found that by treating cyclohexane at 60° C. with chlorosulphonic acid, both hydrogen chloride and sulphur dioxide were evolved. The products consisted of unsaturated compounds which resinified on standing but no sulphonic acids were isolated. Methylcyclohexane reacted similarly but at room temperature.

In summarizing the action of sulphonating agents on cycloparaffins it can be said that, in general: (1) The lower cycloparaffin homologues, on treatment with concentrated sulphuric acid, dissolve readily, at the same time these cycloparaffins undergo rearrangement, for the solutions on hydrolysis yield aliphatic alcohols. (2) The higher cycloparaffins are not attacked by concentrated sulphuric acid at ordinary temperatures but are dehydrogenated by fuming acid. The cyclohexane derivatives thus yield aromatic sulphonic acids.

PROPERTIES OF MONOSULPHONIC ACIDS DERIVED FROM PARAFFINS

The aliphatic sulphonic acids are strongly acidic, stable compounds which are usually obtained in the form of viscous, very hygroscopic liquids. They exhibit the usual properties of sulphonic acids and are readily converted into sulphonyl chlorides and sulphonamides. The carbon-sulphur linkage in these compounds is not broken by the usual hydrolyzing agents but by heating with aqueous alkali at 310° to 375° C., hydrolysis takes place with the formation of an alcohol and sodium sulphite, according to the equation $RCH_2SO_3Na + NaOH \rightarrow RCH_2OH + Na_2SO_3$. This main reaction is also accompanied by decomposition of the resulting alcohol according to the equation $RCH_2OH + NaOH \rightarrow RCOONa + 2H_2$. Wagner and Reid[37] examined this reaction for the sodium salts of a number of normal and secondary saturated aliphatic sulphonic acids. They obtained the results in Table 156 for the percentage decomposition of these salts when heated (in the form of approximately molar solutions) with a 3.7N NaOH solution at 345° C. for 3 hours.

TABLE 156.—*Decomposition of Sodium Salts of Saturated Aliphatic Sulphonic Acids.*

Sulphonic Acid	Decomposed Per Cent	Sulphonic Acid	Decomposed Per Cent
Methyl	1.5	Amyl	13.3
Ethyl	62.7	sec-Amyl	64.2
Propyl	20.2	Hexyl	11.7
Isopropyl	88.6	sec-Hexyl	54.9
Butyl	17.3	Benzene	5.0
sec-Butyl	75.2		

It will be seen that although methylsulphonic acid is by far the most stable, the stability of both the normal and secondary series of acids increases with increasing number of carbon atoms from C_2 to C_6. The secondary acids are less resistant to this hydrolysis than the corresponding normal acids.

A series of sulphonic acids was prepared by Noller and Gordon[38] by oxidation of lead mercaptides with nitric acid. The melting points of the anhydrous sulphonic acids, their monohydrates, and their benzylaniline salts[39] were as follows:

TABLE 156a.—*Melting Points of Sulphonic Acids and Derivatives.*

Sulphonic Acid	Anhydrous Acid ° C.	Monohydrate ° C.	Benzylaniline Salt ° C.
Nonyl	—	—	90.5–91.0
Decyl	—	—	84.0–84.5
Undecyl	49	40–41	84.6–84.7
Lauryl	52	43–45	—
Tridecyl	58	48–49	87.5–88.0
Myristyl	65.5	55–56	82.5–82.7

SULPHONIC ACIDS PRODUCED FROM HIGHER PETROLEUM DISTILLATES DURING REFINING

Concentrated sulphuric acid is the most important reagent for the refining of various petroleum distillates. Although there is an increasing tendency to displace this method in favor of refining processes which depend upon the use of adsorbent materials, Kalichevsky and Stagner,[40] expressed the opinion that, because of its cheapness and its almost universal applicability, it will continue to maintain this leading position for many years in the future. The precise action of the sulphuric acid in the refining process depends largely upon the character of the distillate, the time of treatment, and the amount and concentration of the acid. The refining action of the sulphuric acid involves both chemical reaction and physical solution. When highly unsaturated compounds are present, sulphation and polymerization reactions undoubtedly occur, but under certain circumstances sulphonation of the aromatic constituents also takes place.[41] However, the removal of sulphur compounds, asphaltic materials and naphthenic acids by sulphuric acid appears in most cases to involve purely physical phenomena rather than chemical combination.[42]

---

[37] *J.A.C.S.*, 1931, 53, 3407; *Brit. Chem. Abs.* A, 1931, 1268.

[38] *J.A.C.S.*, 1933, 50, 1090.

[39] The salts of benzylmorphine with alkylsulphonic acids of low molecular weight are also easily crystallizable and soluble (Chem. Fabrik vorm. Sandoz, French Patent 709,787, 1930; *Chem. Abs.*, 1932, 26, 1066; *cf.* also Stoll and Burckhardt, U. S. Patent 1,892,019, Dec. 27, 1932; *Chem. Abs.*, 1933, 27, 1894).

The formation of sulphonated products is, as might be expected, at a maximum in the drastic refining of heavier fractions of petroleum for the production of white oils and medicinal paraffins. Even under the less stringent conditions employed in the production of ordinary high-grade lubricants, a certain amount of sulphonation occurs nevertheless. According to Weir, Houghton, and Majewski,[43] there is reason to believe that the following are the changes which take place during the acid refining of solar reduced oil with concentrated acid: (1) the formation of indicator-like substances; (2) the flocculation and adsorption of (colloidally?) dissolved bitumens; (3) solution of other color substances containing chromophoric groups; and (4) some sulphonation and oxidation.

Dunstan and Thole[44] and others showed that most lubricating oils contain 20 to 40 per cent of reactive hydrocarbons which are partially removed from the oil by agitation with sulphuric acid. The resulting acid tars, or sludges, tend to become solid. The fact that these reactive hydrocarbons (which can be concentrated by solution in liquid sulphur dioxide) cannot be hydrogenated by known means to yield fully saturated substances and that their iodine values are exceedingly ill-defined, leads to the presumption that they are not unsaturated hydrocarbons of the types known to us at present but are probably polynuclear naphthenes with unstable groupings or "bridged" structures. As previously noted, Brooks and Humphrey[45] considered it very possible that the extensive oxidation and sulphonation which occur in the acid refining of some heavier petroleum distillates is a result of the attack of certain of the more reactive saturated hydrocarbons, such as paraffins and cycloparaffins with reactive groupings (i.e., a tertiary carbon atom). Because the more reactive constituents of lubricating oil fractions, which are removed or destroyed by drastic acid refining, often possess desirable lubricant properties, the modern tendency is to avoid unnecessarily drastic treatment so as to minimize the elimination of these desirable constituents. Sulphuric acid refining tends to remove the valuable olefins from gasoline also.[46]

The production of sulphonated and oxidized products becomes very pronounced during the manufacture of very highly refined oils of the type of medicinal paraffin (petrolatum liquidum). For the production of such oils, oleum or fuming sulphuric acid is usually employed, the amount of such acid used depending upon the degree of refining desired. According to Holmes,[47] for example, white petrolatum is produced by treating a suitable petroleum distillate with fuming sulphuric acid at an elevated temperature, usually up to 170° C. In the manufacture of technical or medicinal white oils, treatment of lubricating oil stocks with 5 to 10 per cent of oleum has been recommended.[48] Under such stringent conditions, considerable sulphonation and oxidation of the more reactive types of saturated hydrocarbons is to be anticipated.

PRODUCTION AND RECOVERY OF MINERAL OIL SULPHONIC ACIDS AND OTHER PRODUCTS

Sulphuric acid refining of petroleum distillates gives sludges which usually contain, in addition to free acids, polymerized bodies, asphaltic materials, and oxidized substances, together with various sulphonated products. In the disposal of this acid sludge, which has long been a problem to the refiner, the acid is usually separated by the addition of water and reconcentrated for further treatment of distillates. The residual material is largely used as a fuel.[49]

The chemical and physical nature of the sludge, as is quite evident, is dependent upon the character of the original distillate and the refining treatment. Methods for the recovery of sulphonic acids vary with the character of the sludge and with the type of product desired. The sulphonic acids can be separated from acid sludge usually by some selective action such as that of solvents or adsorbents or they can be salted out in the form of their alkali or alkaline earth salts. It becomes extremely difficult and hazardous to generalize concerning these procedures. The most that can be said about some of them is that with a particular sludge, the products removed in the described way can be used for certain definite purposes. Obviously, much of the detail of the individual operations must be omitted here.

As early as 1863, Millochan[50] recovered an oil which could be used in paints as a substitute for linseed and other oils. He mixed 40 per cent of water with acid sludge and allowed it to settle into two layers. The oily layer was then washed with a solution of sodium or potassium hydroxide.

A dyestuff was made by Frasch[51] from crude oil or acid sludge by the action of sulphuric acid. This product was soluble in water, alcohols and acetone and dyed silk or wool a yellow color. Its calcium and alkali salts were soluble in water and could be used for a similar purpose. Forward and Davidson[52] proposed to treat crude petroleum, petroleum tar, or heavy hydrocarbon oil with sulphuric acid in such a way that when heated to 425° C. (800° F.) for 4 to 8 hours, asphalt was produced.

Sulphoparaffins were obtained by Kaufmann[53] by heating acid sludge with a solution of sulphur in petroleum ether at 200° to 250° C. with stirring.

The production of Russian mineral oil, a clear white pharmaceutical oil, required considerable refining with sulphuric acid or anhydride of high concentrations. In these treatments large quantities of sulphonic acids were produced.[54] Great interest was manifested in the recovery and utilization of such sulphonated petroleum derivatives at an early date in Russia, where the industry was concentrated. To extract sulphonic acids from petroleum oils, which have been treated with sulphuric acid or anhydride, Petroff[55] used such solvents as aqueous solutions of methyl and ethyl alcohol or acetone. The sulphonic acids could be recovered from the acid sludge by extraction of the hydrocarbons with gasoline, carbon disulphide, or similar water-immiscible solvents.[56] The sulphonated products were called "kontakt."[57]

In another method for the preparation of sulphonic acids, Petroff[58] first diluted acid sludge with an equal part of water and heated the mixture in an autoclave for 3 to 4 hours at 20 atmospheres.[59] The oily layer was then distilled and the fractions were sulphonated. In related processes for the recovery of sulphonated materials from acid sludge, temperatures of 75° to 120° C.[60] and 160° to 180° C.[61] are used.

Oil-soluble sulphonic acids can be isolated by treating the sulphonated oil with an aqueous solution of acetic acid or one of its water-soluble esters.[62]

For the recovery of sulphonic acids of high molecular weight Petroff[63] has also suggested adsorbing them from solution on porous cellulose or wood flour, which is subsequently dried. From this the sulphonic acids can be extracted with benzene, alcohol, or other solvents.[64]

Sodium salts of organic sulphonic acids, which result on boiling the crude sulphonic acids with sodium chloride solution, can be purified, according to Twitchell,[65] by salting out the simultaneously formed sodium sulphate and extracting the free unsulphonated mineral oils with organic solvents. Petroff[66] treated the aqueous solution of sulphonic acids in alkali with gasoline, to remove the hydrocarbons, and salted out the dissolved sulphonates with sodium chloride.

salts was proposed by Divine.[67] He allowed the acid sludge to stand with water for 8 to 12 hours. The lower layer, which consists of an aqueous solution of the sulphonic acids and sulphuric acid, is separated, neutralized with calcium hydroxide and the precipitated calcium sulphate is filtered off. The calcium sulphonates are precipitated from the filtrate by the addition of about 20 per cent of sodium or calcium chloride. The calcium sulphonate is a water-soluble, light yellow plastic material with a distinct aromatic odor. The use of this and similar products as detergents, fat-splitting reagents and for other purposes is discussed in a succeeding section of this chapter.

The recovery of sulphonic acids with calcium hydroxide has also been described by Pilat and Sereda.[68] By boiling the calcium sulphate precipitate with sodium carbonate, the insoluble calcium sulphonates are converted into their soluble sodium salts, which can be salted out of solution.

Divine [69] recommended the recovery of sulphonic acids by boiling the sludge with a solution of aluminum sulphate. The precipitate which forms is washed with water and from it the sulphonic acids are liberated with sulphuric acid. Similar methods have also been described by Taveau [70] for the separation of sulphonic acids during the treatment of petroleum acid sludge to obtain asphalts, and by Fischer and Reddish.[71] The latter investigators decomposed the aluminum sulphonates with sodium hydroxide, using phenolphthalein as indicator.

Sulphonic acids can be recovered from acid oil, which remains after tar has been removed from acid sludge, in the following manner: The acid oil is treated with alkaline solutions and alcohol. Sodium chloride, which is then added to the alkaline liquid, causes a separation into two layers, one of which contains about 30 per cent sodium sulphonate and 30 per cent mineral oil, together with salt and free alkali. Methyl alcohol, ethyl alcohol, acetone or other solvent miscible with water is added to the lower layer. The mineral oils thus precipitated are subsequently removed and the solvent evaporated. From the residue, the sulphonic acids are precipitated by the addition of inorganic acids.[72] These crude sulphonic acids can be purified by washing at about 60° C. with 40 to 50 per cent sulphuric acid.[73] However, the resulting sulphonic acids still contain about 5 per cent sulphuric acid, which can be removed by the addition of alcohol and neutralization with solid sodium carbonate.[74] The precipitated sodium sulphate is filtered or allowed to settle out and the solution is evaporated.

The following method was suggested by Happach.[75] The acid tar is dissolved or emulsified in water or an alkaline solution and subjected to fractional precipitation by the addition of sodium chloride or calcium chloride. Sufficient salt is added to precipitate the sulphones and neutral hydrocarbons but not the sulphonic acids. After separating the precipitated material, the bulk of the sulphonic acids is thrown down by the further addition of salt. The salts of the sulphonic acids thus obtained may be purified by solution in water and further fractional precipitation or by treatment with a solvent. The latter method of purification consists in extracting the sulphonic acids with water and treating the aqueous solution of sulphonic acids with a small proportion of methanol, ethanol, or acetone. Petroleum hydrocarbons separate and form an upper layer while sulphonic acids remain in solution.

Sulphonates can be removed from sulphonated petroleum oil by washing the oil with isopropyl alcohol, according to Robinson.[76] A similar method of recovering oil-soluble sulphonic acids produced in the manufacture of white petrolatum has been described by Cobb and Holmes.[77] For improving the color of the salts of oil-soluble sulphonates, Buc [78] heated them to above 150° C. in the presence of 3 per cent sodium hydroxide solution and purified them further with isopropyl alcohol. During evaporation of the isopropyl alcohol, from 1 to 10 per cent of a sodium salt of a weak organic acid, such as sodium resinate, can be added to prevent darkening.[79]

The treatment of the heavier fractions of petroleum for the production of highly refined products, yields not only the ordinary oil-soluble sulphonic acids known as "mahogany" acids [80] but also under certain conditions, acids which are insoluble in oil but readily soluble in water, chloroform, alcohols, and benzene and sparingly soluble in carbon tetrachloride, carbon disulphide, xylene, naphtha and ether. To these latter acids the term "green" acids has been applied. The sludge from a mineral oil, for example, a lubricating stock from a Mid-Continent crude petroleum, which has been sulphonated by successive additions of fuming sulphuric acid, is subjected to the following treatments, by Humphreys, Rogers and Bransky,[81] for separation of the green acids: The sludge is first diluted with a medium heavy hydrocarbon oil. The mahogany acids remain in the resulting oil layer which is separated. The residual sludge is boiled with water, the diluted sulphuric acid settling at the bottom. The supernatant layer is neutralized with sodium carbonate and the remaining oil is extracted with naphtha. The oil-free sodium sulphonates (green acid salts) are then purified by washing with sulphuric acid or by extraction with alcohol.

Cushman and Doell,[82] to obtain mineral oil sulphonated soaps, subjected the oil resulting from a preliminary treatment with sulphuric acid to the further action of sulphuric acid of 97 per cent concentration. From this second sludge the sulphonated products are separated from the free sulphuric acid and are neutralized. The oil-soluble coloring substances which remain in the soap are extracted with benzene. Petroleum oils can be sulphonated by emulsification with concentrated sulphuric acid, according to Terry and Craig.[83] When water is added to this emulsion, stratification occurs and the free acids separate in the aqueous solution. Myers [84] used sulphuric acid containing 25 to 35 per cent free sulphur trioxide at 50° to 60° C. to obtain maximum yields of oil-soluble sulphonates from the refining of medicinal oils.

[80] As the extent of this Chapter bears evidence, the literature describes many processes for sulphonating mineral oils for the purpose of obtaining sulphonates, nevertheless the commercial preparation of sulphonated mineral oils is largely confined to the recovery of these sulphonates as by-products from the manufacture of white medicinal and technical mineral oils. In the various white oil processes, the mineral oil is treated with fuming sulphuric acid and the mixture is allowed to separate into two layers. The upper oil layer contains most of the oil-soluble sulphonic acids and the lower sludge layer contains all of the water-soluble sulphonic acids together with minor proportions of the oil-soluble sulphonic acids. The upper oil layer is washed with aqueous ethyl or isopropyl alcohol, which solvents remove the sulphonic oil-soluble (mahogany) acids, or the upper oil layer is neutralized with an alkali and the sulphonic acids are extracted with alcohols as the alkaline salts (mahogany salts). The water-soluble sulphonic acids (green acids) are recovered from the sludge by extraction with water and other solvents. The relatively small proportion of oil-soluble sulphonates present may be removed from the sludge by extraction with hydrocarbons.

[82] U. S. Patent 1,718,335, June 25, 1929, assigned to Standard Oil Co. of California; *Chem. Abs.*, 1929, **23**, 4059.

Various solvents have been proposed for the separation of sulphonated products from acid sludges and other residues. The use of alcohols has already been mentioned. Bennett, Murphy and Story [85] suggested a mixture of alcohol and benzene. Holmes [86] refined petrolatum-yielding material by treatment with fuming sulphuric acid at 170° C., the purified petrolatum being removed by dissolving it in naphtha or benzene.

Residues from the cracking of heavy oils, treated with concentrated sulphuric acid free from sulphur trioxide, yield sulphonic acids which Bestuzhev and Sakhanov [87] extracted with a solvent.

The unsulphonated oils may be separated from the sulphonated oils in acid sludges by distillation *in vacuo* with superheated steam.[88] Before distillation the acid tars can be neutralized with alkali.[89] The residue is then treated with a solution of alkali in an organic solvent, particularly alcohol. Unsulphonated constituents, which may still be present, separate and the solution can be clarified, evaporated and acidified to obtain the sulphonic acids.

The progressive sulphonation of waste oils (which remain after the refining of mineral oil distillates with liquid sulphur dioxide) using sulphuric acid of increasing concentration is described by Kirch.[90] The reaction can be carried out in the presence of carriers such as organic or inorganic acids, anhydrides or chlorides.[91] Baddiley and Chapman [92] also sulphonated mineral oil fractions, for example, Borneo petroleum refined with liquid sulphur dioxide or those from oil-cracking processes, which have an initial boiling point above 200° C.

Petroff and Shestakoff [93] observed that crude petroleum distillates, which were no longer susceptible to sulphonation, could be sulphonated if first subjected to dehydrogenation. The crude material was blown with air at 140° to 150° C. until about 5 per cent of acid bodies were formed. The oxidized oil was then treated with an equal part of concentrated sulphuric acid (specific gravity 1.82) at 60° to 70° C., about 35 per cent of sulphonic acid derivatives being obtained. Higburg and Reilly [94] vaporized and superheated distillates containing a sub-

stantial amount of sulphonatable residue to convert a large part of the unsulphonatable constituents into sulphonatable products and gases.

Purification and deodorization of petroleum oils and naphtha by treatment with a sulphonating agent in the presence of about 5 to 15 per cent of stearic, oleic or other fatty acids of high molecular weight, has also been proposed by Petroff.[95]

Fischer and Reddish[96] purified neutralized mahogany acids, containing oil, by drying and mixing them with an aqueous solvent, for example, 75 per cent alcohol, saturated with sodium carbonate or other water-soluble salts. The sulphonates were concentrated thus in the upper layer and were recovered by decantation and evaporation of the solvent. A relatively homogeneous suspension of the sulphonates and entrained oil can be formed in an aqueous medium.[97] The separation of oil and sulphonates can be effected from this by centrifuging. Extraction of oil-soluble sulphonates with alcohol from lubricating oil stocks which have been treated with 5 to 10 per cent by weight of oleum for the preparation of medicinal white oils has been used by Reddish and Myers.[98] The alcoholic extract of the sulphonic acids was neutralized and evaporated and yielded pure sulphonic acids free from alcohol and water.

The constituents of high-boiling mineral oils which are insoluble in liquid sulphur dioxide have been sulphonated at normal temperature by Limburg[99] to obtain water-soluble sulphonic acids, the calcium salts of which are soluble in water and calcium chloride solution. Sulphonic acids, the calcium salts of which are insoluble in water, can be treated further with concentrated or fuming sulphuric acid to obtain sulphonic acids which yield soluble calcium salts.[100]

The purification of these sulphonic acids can be accomplished in a number of ways. Thus, the sulphonic acids can be purified by the addition of a volatile electrolyte, for example, ammonia or hydrogen chloride, to an aqueous solution of the crude acids.[101] Alternatively, to the aqueous solution can be added tar oil sufficient in quantity to separate with all the sulphonic acids.[102] The residual aqueous solution is withdrawn and the tar oil is distilled from the purified products. To remove oil-soluble sulphonated products formed in refining, alcoholic alkali has also been used. Accordingly, the sulphonated residue is made neutral or feebly alkaline and is then treated with dilute alcohol.[103] Eichwald[104] purified sulphonic acids by dissolving them in amyl alcohol or an alcohol practically insoluble in water and washed this solution with water. Ammonia or volatile organic bases such as propylamine, aniline, or cyclohexylamine, which do not form water-insoluble compounds with the impurities, have also been proposed for the precipitation of the sulphonic acid salts from aqueous solutions.[105]

A wide variety of hydrocarbon materials have been sulphonated by the I. G. Farbenindustrie A.-G. to produce wetting, cleansing and dispersing agents. Only a few of these will be mentioned. Chlorosulphonic acid has been recommended for the sulphonation of solar, yellow, gas, paraffin and other mineral oils and hydrocarbons obtainable from brown-coal or shale-tar.[106] Sulphonation of the oils together with aromatic or hydroaromatic hydrocarbons was proposed by Marx, Broderson and Bittner.[107] Oxidation products of paraffin waxes can also be sulphonated with oleum or chlorosulphonic acid to give emulsifying and wetting agents.[108] Fats or oils which contain more than 8 carbon atoms, especially mineral lubricating fractions, may be sulphonated at —12° to —15° C. with sulphur trioxide, oleum, or chlorosulphonic acid dissolved in liquid sulphur dioxide.[109] Products of the destructive oxidation of non-aromatic hydrocarbons or further products obtained from these by catalytic reduction, dehydration or decarboxylation can be treated with sulphur trioxide at 20° to 40° C. to obtain wetting agents.[110] Wetting agents have also been prepared by sulphonation of olefins.[111]

A large number of halogen-substituted sulphonic acids have been described which are made, in general, by treating aliphatic, aromatic, or hydroaromatic compounds with sulphuric acid and halogen derivatives of acids, such as chlorosulphonic acid.[112] These materials can be used as protective agents for wool, silk, rayon, cotton, linen and similar fibers in washing, fulling, carbonizing, scouring, steeping, bleaching and dyeing.

Oils resembling Turkey-red oils have been prepared by treating naphthenic acids or their esters with reducing agents followed by sulphonation,[113] for example, with chlorosulphonic acid at 40° C. Arylamino-derivatives which have been prepared by condensing naphthenic acids with aromatic amines have also been sulphonated.[114] The sulphonic acid group in this reaction enters the aromatic ring. Mineral oil sulphonates can also be condensed with isopropyl or butyl alcohols, according to Baddiley and Chapman,[115] to yield emulsifying agents for dyes. The reaction is conveniently conducted at a temperature of 65° C. or lower and chlorosulphonic acid may be employed as the sulphonating agent.[116]

Sulphonic acids (kontakt) which are satisfactory detergents have been obtained by Likhusin and Deĭ-Karkhanova[117] by treating kerosene distillates with gaseous sulphur trioxide. They found that the yield of acids was increased by the presence of higher-boiling fractions, best results being obtained with distillates with a boiling range up to 350° C.

Gilsonite distillates have been sulphonated to give products whose alkali salts exhibit detergent properties. These sulphonated hydrocarbons have been proposed also as catalysts for the hydrolysis of glycerides. Forrest, Hayden and Douthett[118] purified a gilsonite fraction with sulphuric acid and then treated it with fuming sulphuric acid. The product was a semi-drying viscous oily product, which when added to linseed oil promotes homogeneous drying.

PROPERTIES OF SULPHONIC ACIDS DERIVED FROM PETROLEUM

The sulphonic acids produced in the acid refining of the higher petroleum distillates are complex mixtures. They all undoubtedly contain at least one sulphonic acid group ($—SO_3H$) attached to a carbon atom but the structure of the hydrocarbon radical associated with this group in any particular class of sulphonic acids is not known. A number of rather sharply differentiated types of sulphonic acids of high molecular weight have been described. Sulphonated products derived from aromatic hydrocarbons, cycloparaffins, and polynuclear cycloparaffins can be formed from high-boiling oils. A considerable variation in properties and composition, however, is to be expected of petroleum sulphonic acids from various sources. It is even possible that some of the more reactive high molecular weight paraffins may undergo sulphonation with sufficient ease to yield sulphonic acids under the conditions employed in practice in the manufacture of white oils. It is probable that, in some cases at any rate, sulphonation is also accompanied by oxidation, so that the acids obtained contain either unsaturated linkages or hydroxyl groups or both.[119]

The mineral oil sulphonic acids (evidently formed by the action of oleum on petrolatum) investigated by Schestakoff and Rabinovitsch[120] were found to have the general formula $C_nH_{2n-12}SO_3$ and the average formula $C_{20}H_{27}SO_3H$. Two fractions which corresponded to $C_{17}H_{21}SO_3H$ and $C_{19}H_{25}SO_3H$ were separated. Their reactions revealed characteristics of aromatic compounds.

Von Pilat and Davidson,[121] from a careful examination of some sulphonic acids produced in acid refining, found them to correspond approximately to the formula $C_{24}H_{33}SO_3H$. These naphthenesulphonic acids, as they were called, did not lose their sulphonic acid group even on prolonged boiling with alcoholic alkali, and their barium salts possessed the rather exceptional property of being soluble in ether, from which they were precipitated by the addition of alcohol. The sodium salts exhibited high permanent foaming properties in aqueous solution which were retained even in fairly acid solutions.

Later, von Pilat and Davidson[122] investigated the technical naphthenesulphonic acids which separated during the alkali treatment of petroleum subsequent to acid refining. They obtained products which consisted of a thick, almost black liquid, containing 19 per cent of water and 6 to 8 per cent of ash. The crude material was soluble in water and possessed an acid value of about 25. Impurities in these acids were removed by extracting a slightly alkaline solution of them with limited amounts of ether. The residue was freed from the sodium salt solution, washed and dried at reduced pressure over phosphorus pentoxide when it formed a dark, gummy, hygroscopic mass. The molecular weight of this material was 400 to 401 by the boiling-point method, and 410 by titration, indicating that the acids were monobasic. They noticed that two series of salts could be derived from these acids, which they designated as α- and β-compounds, the latter being distinguished by their solubility in ether. The relationship of these compounds to one another has not yet been clearly defined.

The sulphonic acids formed in the refining of mineral oil were later distinguished by the solubility of their calcium salts. According to von Pilat, Sereda, and Szankowski,[123] three classes can be distinguished, characterized as follows:

α-Sulphonic Acids; found mainly in the acid sludge, but also partly in the oil-layer; calcium salts are insoluble in water and ether.

β-Sulphonic Acids; present principally in the oil phase but also occur in the acid sludge when oleum is used; calcium salts insoluble in water but soluble in ether.

γ-Sulphonic Acids; appear to remain in acid sludge only; calcium salts soluble in water but insoluble in ether.

The content of γ-acids depends on the source of the oil but their nature appears to be invariant, i.e., γ-acids from petroleum of different geographical origins are similar if not identical. From a variety of oils, two acids $C_9H_9SO_3H$ and $C_{19}H_{20}SO_3H$ were isolated as calcium salts. These were converted to sodium salts, methyl esters, sulphonyl chlorides and sulphonamides. Reduction of the sulphonyl chlorides gave substances similar to sulphinic acids or thiols, according to the conditions. Alkali fusions of the acids at 200° to 210° C. yielded phenolic compounds which formed red dyes with diazobenzene-p-sulphonic acid but gave no well-defined benzoyl derivatives. With acetyl chloride a substance $C_8H_8OOCCH_3$ was obtained from the phenolic compounds in one instance.

The oil-soluble sulphonic acids, for example, the technical mahogany acids exhibit a relatively high solubility in mineral oils and water. The mahogany acids are soluble in ether, chloroform and insoluble in amyl alcohol. Other sulphonic acids are the water-soluble green acids formed by exhaustive sulphonation of lubricant fractions. These green acids, described by Humphreys, Rogers and Bransky,[124] are readily soluble in either hot or cold water, difficultly soluble in oil, readily soluble in chloroform, aliphatic alcohols, and benzene, and somewhat sparingly soluble in carbon tetrachloride, carbon disulphide, xylene, naphtha, and ether. The combining weights of the green acids from lubricating oil sludge are approximately 360 and the acids, when anhydrous, are practically solid at ordinary temperature. They are strongly acid and may be titrated with methyl orange as an indicator.

Some of the sulphonic acids produced in the acid refining of heavier petroleum fractions exhibit colloidal characteristics. Although soluble in water to a considerable extent, these acids are usually readily displaced from their aqueous solutions by salts and mineral acids.[125]

Petroff[126] stated that the low molecular weight (350) oil-containing naphthenesulphonic acids are soluble in water in the presence of alkalies, acid and neutral salts to yield strongly foaming solutions, and the higher molecular weight (about 450) oil-containing acids, which possess colloidal characteristics, are soluble in water in the presence of ammonia, sodium carbonate, and sulphuric acid. When free from oil, the high molecular weight acids are soluble in water in the presence of most electrolytes.

The petroleum sulphonic acids form a large number of metallic salts some of which have attained considerable technical importance. According to Dobrjanski and Anurov, salts of the first group metals, except copper, are soluble in water while the beryllium, zinc, cadmium, and mercury salts are appreciably soluble in hot water.

USE OF MINERAL OIL SULPHONATES AS DETERGENTS

The mineral oil sulphonic acids were early proposed as fat-hydrolyzing agents and their salts as detergents, wetting and emulsifying agents. New applications for these materials have continually been found so that they now have a wide range of utility. Some of their uses will be discussed in the sections which follow.

Much interest has been centered about the detergent properties of these substances, probably because of the potentially large outlet for them in this field. Common fatty acid soaps cannot be used for all washing purposes (for example, in hard water). In attempting to find new and better washing materials a wide variety of products has been proposed.[127] Many of these have appeared on the market. A brief list of some of these newer detergents with their approximate composition and trade-mark names may serve to emphasize how great is the interest in these materials in fields other than that of petroleum.[128]

I. Soaps containing fat-dissolving chlorinated hydrocarbons embrace Lanadin, Hydraphthal, Terpuril, Cycloran, Sovental, and Prestabitol.

II. Alkylnaphthalenesulphonic acids include Nekal and Neomerpin.

III. Sodium salts of higher sulphated alcohols[129] are Avirol[130] and Gardinol. The word *hymolal,* derived from "high molecular alcohol," has been proposed[130a] to designate the C_{12} to C_{18} alcohols obtained by the reduction of fatty acids or esters or from other sources. The wetting and cleansing agents, such as those mentioned, which are principally alkali alkyl sulphates, can thus be called *hymolal salts.*

IV. A mineral oil sulphonic acid has been called Kontakt (noted earlier in this chapter).

V. Products derived from pyridine and other compounds include Tetracarnite.

VI. Salts of ester-like condensation products of ethionic acid and fatty acids are known under the general name of Igepons.[131]

[131] Hueter, *Chem. Umschau Fette, Öle, Wachse Harze,* 1932, 39, 25; *Chem. Abs*, 1932, 26, 2611. Some of these are described in the section on sulphonation of olefins.

Petroff[131a] stated that the oil-free naphthenesulphonic acids and their neutral salts are superior in detergent properties to ordinary soaps and the oil-containing sulphonic acids (and neutral salts) are equal to soaps. The presence of free sulphuric acid, he reported, is without influence on the detergent power of the sulphonates. Petroff found that an increase in the molecular weight of the sulphonic acid resulted in a lowering of the detergent power and the solubility in water. Thus, for example, three acids of molecular weights 350, 400, and 450, respectively, had detergent powers in the ratio of 5:3:2.

The low molecular weight naphtha sulphonic acids were considered by Schaeffer[132] to be equal to soap flakes in the scouring of cotton goods. Attention has been drawn to the excellent emulsifying power of the alkali salts of naphthenesulphonic acids which renders them valuable as detergents and Schaeffer described a method of analysis of such substances in mixtures which contain mineral oils.

Because of the wide variety of products, considerable effort has been made to have some standard procedure for their evaluation. Methods for the testing and comparison of detergents have been described by Zhukov and Schestakoff,[133] Schaeffer,[134] Pantyukhov[135] and by the Reichsausschuss für Lieferbedingungen.[136] Provisional procedures for the standardization of detergents have been advanced by the Detergent Committee of the American Oil Chemists' Society.[137]

The alkali salts of most mineral oil sulphonic acids which have been described in the preceding section have been proposed as detergents. In the following section a few specific methods for the production of detergent compositions are mentioned.

A neutral detergent composition was made by Petroff[138] by treating an aqueous alcoholic solution of the sulphonic acids produced in refining mineral oils with a solution of alkali or ammonia. The solvent is distilled from the non-oily alkali-sulphonic acid compounds thus obtained. A washing composition was made by incorporating the polymerization products of drying or semi-drying oils and fats with the sulphonation products of petroleum naphtha or mineral oils.[139]

A detergent consisting of an alkali sulphonate extracted by water from acid sludge was used by Divine.[140] Reddish[141] proposed an oil-soluble sulphonate combined with a stable water-soluble amine such as triethanolamine. A mixture of oil-soluble and oil-insoluble mineral oil sulphonates, recovered from the oil and sludge layers, respectively, in refining petroleum fractions having a naphthenic base can be used as a detergent in acid, alkaline or hard water.[142] A liquid consisting of 99 per cent water and 1 per cent mineral oil sulphonates has been recommended as a wetting agent.[143] Carver,[144] for removing mineral oils from various surfaces, used a detergent comprising 25 per cent alkali metal mineral oil sulphonate, 25 per cent coconut oil soap and 50 per cent water. Wetting agents have been produced by treating bark-tanned leather waste with aqueous solutions of sulphonic acids or their salts to form plastic masses.[145]

[131a] *Masloboino-Zhirovoe Delo,* 1929, (1), 34; *Chem. Abs.,* 1930, 24, 4415. Statements concerning relative detergency are oftentimes misleading as testing methods and wash goods vary, giving rise to conflicting results. A strict comparison demands resort to tests of a standardized character to be made under uniform conditions. Since such information is lacking in most cases the author has to rely on data furnished by the investigator. Götte (*Kolloid-Ztg.,* 1933, 64, 327, 331; *Brit. Chem. Abs.* B, 1933, 973) observed that maximum detergency in an alkaline solution of the sodium salts of alkylsulphonic acids ranging from C_{12} to C_{18} is dependent on chain length. Maximum detergency is displaced in the direction of increasing chain length by rise of temperature and by increase in water hardness. Götte reported that, in alkaline solutions, the sulphonates which he examined had several times the detergent power of soaps but that the difference is less marked in neutral and acid solutions. Foaming is most evident at concentrations at which molecular aggregates form and does not bear any simple relation to detergency.

Becker and Müller[146] suggested for use as wetting, emulsifying or foaming agents, water-soluble sulphonated polymerization products of the lower hydrocarbons (prepared by the action of strong condensing agents such as sulphuric acid or zinc chloride on alcohols with more than 3 carbon atoms or on cracking gases). The properties can be improved by pretreating the polymerization products with lower aliphatic acid anhydrides or chlorides or by carrying out the sulphonation in the presence of these compounds. Products with similar properties can also be prepared from α-naphthalenesulphonic acid and butylene,[147] and from the treatment of butyl alcohol with solvent naphtha (or tetrahydronaphthalene) and sulphonated fatty acids (or naphthenic acids).[148]

Alcohols, hydroxy acids, or other products of high molecular weight obtained by the oxidation of paraffin wax,[149] or by halogenation of wax and subsequent treatment with alkali give, on sulphonation, esters which form the basis of other compositions having detergent properties.[150] The detergent power of these sulphonated products is improved by the addition of sodium bisulphate, silicate, phosphate or other sodium, potassium, magnesium, or amine water-soluble salts of acids stronger than carbonic.

The salts of sulphonated derivatives of the partial oxidation products of petroleum hydrocarbons have been proposed by James[151] as cleansing agents.

Chatrov[152] sulphonated the hydroxy acids obtained from the oxidation of paraffin wax. The products dissolved only in sodium hydroxide solution and partly in sodium carbonate and carbon disulphide and emulsified with water. The most highly sulphonated acid was a good wetting agent, but was not a satisfactory substitute for soap.

MINERAL OIL SULPHONIC ACIDS AS FAT-HYDROLYZING AGENTS

About 1900 Twitchell [153] observed that benzenestearosulphonic and other similar acids [154] had the property of splitting fats (when heated with them) into glycerol and fatty acids. Sulphonic acids of this class became known as Twitchell reagents.

Divine [155] noted that the sulphonic acids which he recovered from petroleum acid sludge [156] had similar properties and could be used for treating low-grade fats and oils in the manufacture of fatty acids and glycerol.[157] A product obtained by boiling petroleum acid sludge with aluminum sulphate (method of separating out the sulphonic acids [158]) was also proposed for this purpose by Divine.[159]

Petroff [160] also used sulphonated mineral oil products for the splitting of fats. The fatty acids obtained were said to be decolorized by exposure to a current of air.[161] Charcoal was suggested as a decolorizing substance.[162] For decomposing the emulsions formed in saponifying fats with Twitchell and other reagents, Petroff [163] recommended the addition of a small proportion of calcium sulphate and sulphuric acid.[164] Petroff and Schestakoff [165] also prepared sulpho-aromatic fatty acids for fat-splitting.

SULPHONATED MINERAL OILS IN EMULSIONS

The mineral oil sulphonic acids act as stabilizers of certain types of emulsions but on other dispersions they exert a coagulating effect.[165a] Budriewicz [166] states that in mineral oil refining the sulphonic acids form troublesome emulsions on contact with water. To break these, the sulphonic acids are usually extracted with dilute alcohol. In such a solvent the acids apparently form normal solutions, as do ordinary soaps, but in water they are in a colloidal condition.[167] Sulphonic acids from white oils find particular use as emulsifying agents.[168]

Petroff [169] used mineral oil sulphonic acids for emulsifying oils, paraffin, waxes, resins, and fats. For example, the substance to be dispersed is mixed with a small amount of the sulphonic acid and a volatile solvent, such as benzene. Petroff's "kontakt" has been used for emulsifying hydrocarbon oils prior to oxidation with chromic acid to produce aldehydes.[170]

[169] U. S. Patent 1,230,599, June 19, 1917; *Chem. Abs.*, 1917, **11**, 2284; *cf.* Twitchell Process Co., French Patent 722,752, 1931; *Chem. Abs.*, 1932, **26**, 4195.

Limburg[171] also used mineral oil sulphonic acids (such as those described in this chapter[172]) to produce stable emulsions. As an illustration, Panuco asphalt was heated to about 95° C. and a 5 per cent aqueous solution of the sodium salt of the sulphonic acid was added with stirring, giving a dispersion.

Sulphonated mineral oils of high molecular weight were proposed by Levin[173] as dispersing agents for rubber. Smith[174] and Douthett[175] made emulsions of asphalt and tars with alkali salts of petroleum sulphonic acids. Coggeshall[176] recovered oil from oil sands by circulating an aqueous liquid comprising a highly dispersed colloidal mixture including a hydrocarbon sulphonate through the sands.

In the treatment of petroleum distillates with acids and alkalies, Petroff[177] prevented the formation of emulsions which carry off untreated hydrocarbons by washing the distillate with alcohol or acetone after the acid treatment. For breaking emulsions of petroleum and water, Rogers[178] proposed sodium and Fischer and Reddish suggested the use of sodium[179] or aluminum[180] salts of mineral oil sulphonates and pitch. Reddish[181] proposed the use of mineral oil sulphonates together with triethanolamine or other alkylolamines. Similar treatments of emulsions to effect their resolution have been described by Fischer and Reddish,[182] Heckel and Reddish,[183] Peirce and Reddish,[184] Myers,[185] Peirce and Myers,[186] de Groote and Monson,[187] and Mirzoyan, Romashenke and Fyurst.[188]

The sulphonic acids recovered from acid sludge by Taveau[189] have been recommended by Kennedy[190] for washing petroleum oils in refining operations to prevent emulsification. Burgess[191] also used sulphonic acids from acid sludge to break emulsions. In refining cracked gasoline stocks, Lachman[192] brought the vaporized hydrocarbon oil into contact with aqueous solutions of zinc,[193] copper, cadmium, mercury, iron, chromium, manganese, aluminum, nickel or cobalt salts of sulphonic acids and condensed the vapor.

The reaction products from the sulphonation of mineral oils, which form colloidal suspensions with water, have been proposed by Moser[194] to bring about the separation of petroleum emulsions. Acid resins formed in the refining of light mineral oil fractions with sulphuric acid have also been suggested for the refining of heavy mineral oil fractions with sulphuric acid.[195] Canfield[196] suggested a mixture of a hydrocarbon-substituted derivative of a polycyclic sulphoaromatic compound, isopropylnaphthalenesulphonic acid,[197] for example, chlorobenzene, water, and a phenol, for treatment of wet petroleum oils. Derivatives of aromatic hydrocarbons have also been used for breaking petroleum emulsions.[198]

Mineral oil sulphonic acids have been suggested by Staegemann[199] for use as precipitants for proteins in acid solutions, such as from sewage and raw sugar juices.

SULPHONATED MINERAL OILS IN INSECTICIDES

A number of sulphonated mineral oil compounds have been used in sprays for killing insects. These will have brief mention here.

An insecticide containing a sulphonated petroleum and an alkylated sulphonated petroleum, particularly a sulphonated petroleum condensed with isopropyl alcohol has been suggested by Baddiley and Chapman.[200]

A basis for an insect spray has been obtained by treatment of a petroleum tar acid fraction boiling between 50° and 200° C. with sodium hydroxide and sodium plumbite.[201]

An insect-repellent mixture made by Grant[202] consists of a nicotine compound, a petroleum sulphonic acid, petroleum white oil and soap and water as an emulsifying agent. A sulphonated mineral oil treated with citric or other hydroxy-acid or a polyhydric alcohol, such as glycerol, in the presence of copper sulphate and an alkali is the basis of another insecticide.[203] Sullivan and Adams[204] used a composition of the following typical formula as a contact or stomach poison for insects or as a fungicide: liquid glue 5, water 33.5, copper resinate 8, lead arsenate 9, sodium mineral oil sulphonate 1.5, and white oil 43 per cent.

An emulsion comprising straw oil, sodium mineral oil sulphonates, soap and alcohol has been proposed by Lambert [205] as an insecticide. Bottrell [206] suggested the use of sulphonethylmethane together with glue, water, alcohol, oil of peppermint or sodium benzoate as a rodent-repellent or insecticide.

Sulphonated oxidation products of petroleum act as insecticide activators, according to Inman.[207] Nicotine sulphate, not fully effective alone, is usually employed in the proportion of 1 part to 800 with soap as a spreader. If, instead of soap, a sulphonated oxidized petroleum [208] is added, the concentration of nicotine can be reduced.[209]

The penetration and toxicities of petroleum sprays was determined by Young.[210] Apple and potato leaves partly soaked with oils of less than 6 per cent sulphonatable residue lived for 30 to 80 days. Oils of greater than 13 per cent sulphonatable residue killed the leaves in 7 to 14 days and were toxic if applied in 4 to 8 per cent emulsions. The effect of petroleum oils on the respiration of leaves has also been examined.[211]

Woodworth [212] discussed the efficiency of petroleum oils as insecticides. Smith [213] made a study of the oil-depositing qualities of oil-spray mixtures. The determination of unsulphonated residue in petroleum spray oils has been described by Graham.[214]

MINERAL OIL SULPHONIC ACIDS FOR TEXTILE TREATMENTS

Numerous substances are finding application in the various treatments to which textiles are subjected in their manufacture.[215] Such compounds are usually designated as "*textile reagents*" ("textile assistants" in translations from the German) and may be used in textile treatment in the following way:

1. As a wetting, penetrating, or cleansing agent, for example, for removing natural or artificial impurities from animal or vegetable fibers. Thus, it may be employed in aqueous solution for degumming silk or for removing sizes from textiles of various kinds, or to wash out oils added during various spinning operations.
2. For lubricating or protecting fibers during weaving, spinning, or knitting. In this way it functions as a softening agent. The compound may be used in aqueous solution or as an emulsifying agent for oils.
3. For dispersing or solubilizing dyes or coloring matters in the dyeing of textiles. The compound may simultaneously act as a penetrating agent in the process.

The natural impurities contained in vegetable and animal fibers have been eliminated by heating the fibers in an aqueous solution of mahogany sulphonates.[216]

Silk[217] has been degummed and artificial silk fibers have been prepared for further textile processing in this manner.[218]

Textile oils which can be used for the protection of artificial silk threads and fibers during weaving and knitting have been prepared by mixing mahogany sulphonates and mineral oils extracted with oleum.[219] A textile oil consisting of a low-viscosity mineral oil, an alkali metal soap of a sulphonated mineral oil, oleic acid, and an antioxidant such as beta-naphthol, has been suggested by Sullivan.[220]

Products which are wetting and protective agents for textiles and leather have been obtained by Keller and Gofferjé[221] by the action of fuming sulphuric acid or other sulphonating agent on the material which results from the reaction of an alkali on a polyhalo-derivative of higher paraffin hydrocarbons, for example, a dichloro-derivative of hard paraffin.

MISCELLANEOUS USES OF MINERAL OIL SULPHONIC ACIDS

Mahogany sulphonates have been used to make dyes soluble,[222] for example, in the dyeing of cellulose acetate silk.[223] Oil-soluble dyes have been made from basic dyes such as Victoria green, Bismarck brown, and Malachite green, by treatment with an aqueous solution of an oil-soluble sulphonated petroleum.[224] The absorption of dyes by mineral oil emulsions, according to Vellinger and Hemmer,[225] is a function of the concentration of the coloring material and the p_{H} of the aqueous solution.

Heckel[226] employed mahogany sulphonates for the dispersion of pigments in inks made with an oily medium.

Mineral oil sulphonic acids have been suggested as inhibitors in sulphuric acid pickling baths by Fischer and Stegemeyer.[227] Similar inhibiting agents for pickling baths have been suggested by Chapman[228] and Voorhees.[229] A metal cleaning and pickling composition suggested by Corson and Lawrence[230] consists of a dilute non-oxidizing acid and a small amount of a sulphonated mineral oil similar to ichthyol.

Organic solvents in which are dispersed sulphonated mineral oils and water have been proposed as dry cleaning fluids.[231] Such mixtures remove water-soluble stains as well as those soluble in the organic solvent.

Some attention has been paid in the past to the possibility of using acid sludge as a basis for the manufacture of varnishes and drying oils.[232] Zaloziecki [233] described the production of varnishes from acid sludge. Tarry matter is boiled with an equal volume of water, and neutralized with basic oxides, carbonates, or organic bases. The resulting reddish-brown mass is either dehydrated and dissolved in a cold mixture of strong alcohol and benzene, oil of turpentine or tar-oil, or dissolved directly in an equal volume of 50 per cent alcohol and benzene to give lacquers.

According to Buc, certain of the heavy metal salts of oil-soluble petroleum sulphonic acids may be used as driers, either alone or in combination with other driers. The oil-soluble sulphonic acids (particularly those from lubricating distillates) are first converted into their sodium salts, which are extracted subsequently with a solvent (e.g., 35 to 65 per cent aqueous ethyl alcohol) and freed from oil by treatment with 10 to 20 per cent of gasoline. The sodium sulphonates are then converted into their lead,[234] cobalt,[235] or manganese [236] salts and freed from insoluble material by solution in an organic solvent (e.g., a mixture of benzene and 75 per cent ethanol or isopropanol), the purified salts being used as driers. The calcium salt of an oil-soluble sulphonic acid has been used in varnishes, for example, one consisting of 50 to 90 per cent of a drying oil (linseed or tung oil), 5 to 25 per cent of resins and 5 to 25 per cent of calcium sulphonates.[237] The above mixture may be reduced to the desired consistency by the addition of sufficient thinner, such as turpentine. Metallic salts of oil-soluble sulphonic acids likewise have been used by others in paints.[238]

Rial [239] used neutralized sludge from the refining of asphalt-base crude oils for a color coat for cemented surfaces. Water-insoluble residues of acid sludges have been used as waterproofing ingredients in concretes, mortars, and in gypsum and Sorel cement compositions.[240]

Bolgár [241] obtained a rubber-like material for impregnating jute and similar fibers by boiling linseed or other drying oil at 180° to 200° C. with the residual sludge from acid mineral oil refining.

According to Johnson,[242] a lubricant adapted for use in the die-drawing of metals consists of the sodium salt of green sulphonic acid (water-soluble) obtained from lubricating oil sludge, tallow, and water, the materials being heated to 82° C. to effect a homogeneous mixture.

The preparation of similar lubricants for like purposes is described by

[242] U. S. Patent 1,795,491, Mar. 10, 1931; assigned to Standard Oil Development Co.; *Brit. Chem. Abs.* **B**, 1931, 1039.

Adams,[243] Arveson,[244] and Sharp.[245] Bransky[246] prepared a rust-preventative which comprised a mixture of montan or carnauba wax and an oil-soluble sulphonic acid (20 to 60 per cent), brought to required consistency by the addition of a hydrocarbon oil.

Becker[247] proposed as a lubricant a mixture of a petroleum lubricating oil, an alkali soap of a fatty acid such as sodium oleate and an oil-soluble alkali metal mineral oil sulphonate. The latter facilitates feeding of the lubricant by a wick. A similar mixture can be used for lubricating artificial silk fibers during spinning.[248]

For wood preservation, Hampton and Farrington[249] used a composition consisting of 85 per cent fuel oil and the product resulting from the neutralization of an acid sulphur oil of a petroleum distillate from pressure cracking.

A fine-cutting and fine-finishing grinding compound which contains alkali sulphonates admixed with coarse particles of soft abrasive and fine particles of hard abrasive has been proposed by McClaughry,[250] A typical mixture for such a purpose is 15 per cent mineral oil sulphonates, 15 per cent oil, 30 per cent petroleum, 30 per cent of silicon carbide (150 to 220-mesh), and 10 per cent of emery (80 to 100-mesh).

Moeller[251] obtained a tanning composition by heating mineral oil acid sludge with a quantity of hydrocarbon (naphthalene or anthracene) corresponding to the excess sulphuric acid present, in the presence of formaldehyde, until the mixture was completely soluble in water. The latter was subsequently treated with an excess of alkali. Nastukov[252] condensed crude oil or solvent naphtha with sulphuric acid and formaldehyde. This product is then neutralized, washed, oxidized with dilute nitric acid and dissolved in dilute alkali to give a tanning material.

Considerable interest has been exhibited in the use of mineral oil sulphonic acids for making plastic compositions.[253] One of the many ways which have been proposed is given by Petroff.[254] He condensed phenol and formaldehyde under reduced pressure in the presence of coal-tar or mineral oils; and emulsifying agents, such as high molecular weight sulphonic acids. A dielectric material has been prepared by Nastukov[255] from the condensation of 4 volumes of petroleum oil containing both saturated and unsaturated hydrocarbons first with at least 2 volumes of concentrated sulphuric acid and then with 1 volume of formaldehyde solution. A transparent and flexible product has been made by Heckel[256] from a mixture of gelatin, petrolatum, mahogany sulphonates and butyl cellosolve or other clarifier.

Sulphonation of Olefins

The sulphonation reactions which have been reviewed previously in this chapter include those of the paraffins and cycloparaffins. Somewhat different products are obtained on the sulphonation of the olefins or sulphur-containing shale oils.

Some of the ways in which sulphuric acid can react with olefins have already been discussed in previous chapters. Faraday and Hennel,[257] as early as 1827, observed that ethylene was absorbed in sulphuric acid to form ethylsulphuric acid, which could be hydrolyzed to either ether or ethyl alcohol. Production of alcohols by such reactions is summarized in Chapters 13, 14 and 15. This absorption in sulphuric acid is also a convenient but not accurate method for the determination of the olefin content of gases and distillates (see Chapter 49). Higher olefins are polymerized by the action of sulphuric acid,[258] but ethylene is said to polymerize only when the acid contains a small proportion of such materials as copper and mercury sulphates.[259] These polymerization reactions are mentioned in Chapter 26. Of course, sulphuric acid also causes some oxidation of unsaturated hydrocarbons, this being evidenced by the sulphur dioxide odor on heating, but these reactions have received little attention.[260] Attention now is primarily directed to those reactions of ethylene which lead to the formation of carbyl sulphate  and its derivatives.

In 1837 Regnault[261] observed that, when ethylene and anhydrous sulphur trioxide were passed through a U-tube, a compound collected on the sides of the tube in radiated crystals[262] which melted at about 80° C. The compound was called carbyl sulphate. On dissolving in water, heat is evolved and ethionic acid, $HO_3S.C_2H_4.OSO_3H$ and some isethionic acid, $HO.C_2H_4.SO_3H$, are formed.

When a benzine fraction (boiling between 55° and 65° C.) was distilled in the presence of sulphuric acid and the distillate allowed to stand for 15 days, Boettger[263] noted the separation of fibrous crystals. The composition of these crystals corresponded to $C_5H_{10}SO_3$. They were insoluble in water or alcohol, but soluble in benzine.

According to Daimler and Platz,[264] ethionic acid and carbyl sulphate, or their homologues, may be produced by the action of sulphur trioxide or chlorosulphonic acid on aliphatic or hydroaromatic alcohols and olefins in the presence of liquid sulphur dioxide.[265] On hydrolysis, isethionic acid or its homologues is formed. Salts of ester-like condensation products of ethionic and fatty acids

[265] Merley and Spring (U. S. Patent 1,904,160, April 18, 1933; assigned to Doherty Research Co.; *Chem. Abs.*, 1933, **27**, 3224) prepared carbyl sulphate by reaction of ethylene and sulphur dioxide, and subsequently converted it to acetic acid.

(for example, Igepon) have received much attention as wetting and cleansing agents, especially in textile treatment. Reaction of hydroxyethanesulphonic acid with oleic acid chloride (oleyl chloride) at 80° to 100° C., yields ester-ethanesulphonic acids of the formula $HO_3S.C_2H_4.O.OC.R$, in which R represents an aliphatic hydrocarbon radical having more than 3 carbon atoms. According to Daimler and Platz,[266] these compounds have soap-like wetting and emulsifying properties. Halogenated ethanesulphonic acids can likewise be treated with salts of the higher fatty acids to give similar compounds. Ethionic acid or its anhydride (carbyl sulphate) can be used instead of hydroxyethanesulphonic acid—the fatty acids, their esters or chlorides, entering the molecule instead of sulphuric acid splitting out of the ethionic acid. If sulphuric acid is split out of the ethionic acid in some cases it may have a sulphonating action on the fatty acid but the properties of the resulting product are said to be unchanged.

Wetting agents can also be prepared by condensing butyl alcohol with hydroxyethane-sulphonic acid, beeswax with carbyl sulphate, or Japan wax with ethionic acid.[267]

The detergent properties of the sodium salts of the products resulting from the reaction of the chloride of oleic acid with ethionic acid are improved by the addition of sodium phosphate, zinc sulphate or magnesium sulphate. With such mixtures can be incorporated sodium bisulphite or other salts which have a bleaching action.[268]

1-Propanol-3-sulphonic acid has been prepared by Müller[269] by the action of sulphur trioxide on propyl alcohol.

Hessle[270] obtained synthetic tanning materials by treating mineral oils which contain unsaturated hydrocarbons with oleum (containing 20 to 30 per cent free sulphuric anhydride) at a relatively low temperature. The sulphonated products are said to consist principally of sulphones with relatively small proportions of sulphonic acids.[271]

The conversion of unsaturated aliphatic hydrocarbons containing 10 to 18 molecules or cracked petroleum fractions into wetting agents by the action of sulphuric acid at 0° C. in the presence of a diluent has been proposed. Olefins which have been sulphonated in this manner include tetradecene, octadecene, dodecene, a mixture consisting mainly of cetenes from the distillation of spermacetti, and olefins from the dehydration of oxidation products of naphthenes.[272] The sulphuric esters can be used together with soaps, Turkey-red oils, polynuclear aromatic sulphonic acids, glues, gelatine or mucilage, solvents, bleaching agents, or salts such as sodium chloride, bicarbonate, silicate, carbonate or sulphate. Decylene, and cetylene (hexadecylene) from the distillation of spermacetti, have likewise been sulphonated to give wetting agents by treatment in butyl alcohol solution at —5° C. with concentrated sulphuric acid.[273] The resulting product is washed with saturated sodium sulphate solution to remove the excess acid. The sulphation may be carried out also with chlorosulphonic acid, oleum or mixtures of sulphuric acid with acetic anhydride, acetyl or propionyl chloride, phosphorus chloride or pentoxide, boron trioxide or with sulphur trioxide dissolved in trichloroethylene, ethyl acetate, or ether.[274]

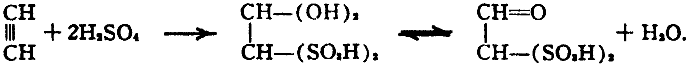
Olefins resulting from the destructive oxidation of paraffin wax and naphthenic hydrocarbons have been sulphonated to give washing and emulsifying agents and especially textile reagents. Beller and Schuette [275] oxidized soft paraffin wax by blowing with air at 160° C. for 6 hours and removing with an alkaline wash the acid constituents which resulted from the oxidation. Unsaponifiable bodies were separated by centrifuging at about 20° C., thereby obtaining a liquid fraction consisting mainly of hydroxylated compounds. This liquid portion was heated at 180° to 220° C. with zinc chloride or concentrated sulphuric acid to bring about dehydration and formation of olefins. The olefin mixture (100 parts) was vigorously stirred at 15° C. with 80 parts of oleum containing 23 per cent of sulphur trioxide. The temperature was then raised to 25° to 30° C. and the reaction mixture stirred for about 5 hours until it was found to be soluble in water. In another case Russian gas oil was oxidized with air at about 160° C. in the presence of a small quantity of manganese naphthenate until the oil had a saponification value of 170. The product was distilled *in vacuo*. The saponifiable constituents were separated from the distillate by saponification with alkalies, and the unsaturated hydrocarbons recovered from the unsaponifiable fraction by distillation. 100 parts of the olefins thus obtained were converted into sulphonic acids by warming them with a mixture of 30 parts of acetic anhydride and 30 parts of sulphuric acid monohydrate at about 35° C. After the reaction mixture has become soluble in water, which is the case after from about 5 to 6 hours, the batch is poured onto ice, then neutralized. The sulphonic acids obtained cannot be saponified by boiling with aqueous mineral acid. Chlorosulphonic acid also has been used by Beller and Schuette to produce sulphonic acids from olefins of similar derivation.

The sodium salts of sulphonated carbazoles of olefins containing more than 2 carbon atoms are said to increase the wetting and emulsifying properties of aqueous solutions.[276]

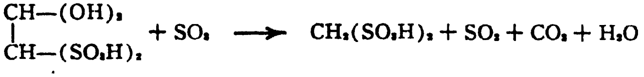
Products of the condensation of isethionic acid with aliphatic acids have been used in the washing and dyeing of wool.[277] Soaps can also be prepared by mixing these condensation products with stearin soaps and glycerol, for example, or with Marseilles soap.[277a]

Acetylene is absorbed by fuming sulphuric acid with evolution of much heat. The first stage of the reaction is:



$$\begin{array}{c}\mathrm{CH}\\ \|\!|\\ \mathrm{CH}\end{array} + 2H_2SO_4 \longrightarrow \begin{array}{l}\mathrm{CH{-}(OH)_2}\\ |\\ \mathrm{CH{-}(SO_3H)_2}\end{array} \rightleftharpoons \begin{array}{l}\mathrm{CH{=}O}\\ |\\ \mathrm{CH{-}(SO_3H)_2}\end{array} + H_2O.$$

Oxidation by sulphur trioxide occurs and methane disulphonic acid [278] (methionic acid) is formed:



$$\begin{array}{l}\mathrm{CH{-}(OH)_2}\\ |\\ \mathrm{CH{-}(SO_3H)_2}\end{array} + SO_3 \longrightarrow CH_2(SO_3H)_2 + SO_2 + CO_2 + H_2O$$

REACTIONS OF CHLOROSULPHONIC ACID WITH OLEFINS

With ethylene, chlorosulphonic acid forms ethylsulphuryl chloride (see Chapter 14), as has been shown by Müller[279] and Baumstark.[280] On prolonged treatment, however, with an excess of chlorosulphonic acid, ethionyl chloride results.[281] If this latter product is warmed, hydrogen chloride is evolved and an oil remains which slowly congeals. When treated with water, this oil yields the anhydride of isethionic acid, $C_2H_4SO_3$, and the anhydride ($C_2H_6SO_5$) of an acid $C_2H_8SO_6$, as well as the acids themselves.[282] The action of chlorosulphonic acid on the higher olefins has been but cursorily investigated. However, Marcusson[283] observed that petroleum asphalts reacted violently with chlorosulphonic acid with the evolution of large quantities of hydrogen chloride. In a chloroform solution the reaction proceeds quietly and addition compounds which contain chlorine and sulphur are formed.

Condensation of olefins with chlorosulphonic acid in the presence of esters or ethers of low molecular weight at temperatures above 100° C. yields true sulphonic acids stable to boiling hydrochloric acid.[284]

SULPHONATION OF AROMATIC HYDROCARBONS

Although the action of sulphonating agents on aromatic hydrocarbons is outside the scope of this book, nevertheless mention should be made of the few instances in which derivatives of aromatic hydrocarbons have been obtained from petroleum. The formation of these aromatic hydrocarbons may be the result of dehydrogenation of naphthenes,[285] as discussed in the section on the sulphonation of cycloparaffins.

By treating various light fractions of a Bustenari petroleum with fuming sulphuric acid (containing 12 per cent sulphur trioxide) at 80° C., Edeleanu and Gané[286] obtained tarry and resinous materials insoluble in water. On distillation with steam the substances yielded about 4.6 per cent of xylene, mesitylene, pseudocumene and hydrocarbons of unknown structure. Hausmann[287] obtained very little phenol on fusing sulphonic acids from a Galician petroleum distillate with sodium or potassium hydroxide.

According to Starke,[288] the naphthenes of a petroleum fraction boiling between 130° to 260° C. give aromatic sulphonic acids when treated with 96 per cent sulphuric acid at 70° to 130° C. Benzene can be recovered from the sludge by distillation with superheated steam.

Popa and Velculescu[289] studied the direct sulphonation of petroleum hydrocarbons in both vapor and liquid phase with 98.8 per cent sulphuric acid. After separation of the sulphonated mixture from the unreacted hydrocarbons, it was subjected to distillation with superheated steam, the mixture being kept at 180°

to 190° C. The aromatic sulphonic acids were thus decomposed and the regenerated hydrocarbons passed over with the steam. Sulphonation in vapor phase required such a high temperature that both naphthenic and paraffin hydrocarbons also reacted with considerable evolution of sulphur dioxide. In the liquid phase, sulphonation was easily conducted at 60° C. The aromatic hydrocarbons recovered contained about 0.5 per cent of other hydrocarbons.

SULPHONATION OF SULPHUR-CONTAINING SHALE OILS

Since the sixteenth century the peasants of the Tyrol have been known to distil the local shale, rich in fossil fish, to obtain a tarry oil which they employed to cure sores and wounds on live stock.[290] In 1890 the name "ichthyol" was given to this oil by Schröter of Hamburg.[291] The oil when treated with sulphuric acid yields ichthyolsulphonic acid which contains about 10 to 15 per cent sulphur, and forms salts with alkali metals or ammonia. The ammonium salt is generally known in commerce as ichthyol and is used for its therapeutic effects in skin diseases. Various other preparations, which include the odorless desichthyol obtained by distilling ichthyol with steam or by treating it with hydrogen peroxide, and the blackish-brown ichthyoform prepared from ichthyolsulphonic acid and formaldehyde are also used for similar purposes.[292] Alderson[293] has given a summary of the deposits and extent of these ichthyol shales and the volume of the industry. Some fractions of the oils have sharp odors and are said to kill flies instantly.[294]

The composition of the ichthyol oil has not been completely determined. Scheibler[295] concluded that the oil contains higher homologues of thiophene (in some cases 50 per cent of the oil) together with hydrocarbons of the benzene series and small proportions of compounds richer in hydrogen. According to Baumann and Schotten,[296] ichthyolsulphonic acid has the formula $C_{28}H_{26}S(SO_3H)_2$.

The sulphonation of shale oil distillates to produce ichthyolsulphonic acids is carried out in a manner similar to that of mineral oil fractions. The purification of the products can be accomplished in a number of ways, the earliest probably being that of precipitating the sulphonic acid from an aqueous solution with salt or with hydrochloric acid.[297]

Helmers[298] recovered the ichthyolsulphonic acids from the mixture by neutralizing them with an alkali and separating with solvents such as alcohol, benzene, and chloroform. The ichthyolsulphonates of the alkaline earths or heavy metals are rendered tasteless by extraction with alcohol[299] or by heating[300] up to about 140° C.

---

[290] Zwingaur (German Patent 216,906, 1907; *Chem. Abs.*, 1910, **4**, 1224) described the distillation of ichthyol shale with steam in vacuum to obtain oils with higher specific gravities and viscosities.

Oxidation of the ichthyolsulphonic acids with agents such as hydrogen peroxide has also been used to render them odorless and tasteless.[301]

The separation of ichthyolsulphonic acids into fractions of various sulphur contents has been effected with aniline, piperazine, or dimethylphenylpyrazolone.[302] As a result of the difference in solubility in water of the double compounds of these sulphonic acids, fractions rich and poor in sulphur can be obtained. The sulphonic acids can be recovered by decomposing the compounds with mineral acids.

Purification of ichthyolsulphonic acids has also been effected by treatment with steam under reduced pressure.[303] For the removal of inorganic salts, dialysis has been proposed.[304]

As a means of purification, double complex compounds of the ichthyolsulphonic acids with albumen[305] and formaldehyde[306] have also been formed. These precipitate from solution and can be used as such in various pharmaceutical preparations, the product with formaldehyde being called ichthyoform, as mentioned previously.

Besides the therapeutic uses for ichthyol-sulphonic acids, they have been suggested by Helmers[307] for bringing phenols and hydrocarbons into solution.

Schaeffer and Faber[308] sulphonated sulphur-containing shale oil distillates with chlorosulphonic acid to obtain disinfectants. The resulting soluble brown mass was called sulphothalassolic acid and its ammonium salt was termed thalassol.

The sulphonic acids prepared by treating the unsaturated hydrocarbons present in middle and higher petroleum fractions, mineral waxes or rosin oils with sulphuric acid have been called tumenolsulphonic acids.[309] These have also been recommended for pharmaceutic purposes. Mineral oil, for example,[310] was heated with fuming sulphuric acid (10 per cent sulphur trioxide) at 80° C. The reaction mixture was dissolved in water and the sulphonic acids and sulphones were precipitated by the addition of salt solution. Sulphonic acid salts were thus formed and the sulphones were removed from them in this precipitate by extraction with ether, naphtha, or similar solvents. The tumenolsulphones were said[311] to have the formula $(C_{41}H_{67}O)_2SO_2$ and the tumenolsulphonic acids, $C_{41}H_{62}O_2SO_3$. These tumenolsulphonic acids have the property of precipitating glue and gelatin from slightly acid solutions with the formation of an elastic rubber-like precipitate which can be drawn into threads.[312]

Another method of making hydrocarbons with high sulphur contents and of therapeutic value is that described by Bengough.[313] Unsaturated hydrocarbons formed on the distillation of sulphonated mineral oils in the presence of lime were treated with 10 to 40 per cent sulphur chloride. This yielded a thick brown oil which contained both chlorine and sulphur. When this oil was boiled with a 10 per cent sodium hydroxide solution, the chlorine was removed and a product containing about 30 per cent sulphur was obtained.

Chapter 47

Chemical Action of Nitric Acid, Nitrosyl Chloride and Various Other Reagents on Saturated Hydrocarbons

Saturated paraffin hydrocarbons are regarded as highly resistant to chemical reagents, and this characteristic has received undue and unjustified emphasis. While the gaseous members of the series are extremely stable and chemically inert, this is by no means true of all paraffins. Some of the branched chain paraffins exhibit a surprising degree of chemical activity, and a number of reactions formerly considered characteristic of aromatic hydrocarbons only are now known to occur with both the paraffins and cycloparaffins—though rarely, be it admitted, with a facility equalling that of unsaturated ring compounds.

Of the cycloparaffins, the cyclopropanes and cyclobutanes are considerably more reactive, as a class, than the cyclopentanes and cyclohexanes. The action of chemical reagents often ruptures three- and four-carbon ring systems with production of straight chain derivatives. Since only the five- and six-carbon ring compounds have been found in any quantities in the lower-boiling fractions of petroleum, these two series will be considered representative of cycloparaffins in the following account. In general, the chemical reactivities of the cyclopentanes and cyclohexanes are similar to those of the paraffins. However, some of their homologues are far from indifferent to various reagents.

The saturated hydrocarbons of the paraffin and cycloparaffin series are sharply differentiated from the unsaturated hydrocarbons (olefins, diolefins, or acetylenes) in that the former yield substitution compounds exclusively with various chemical reagents, while the latter can form direct addition compounds (though both addition and substitution reactions may take place simultaneously with some unsaturated hydrocarbons). This fundamental difference between saturated and unsaturated hydrocarbons is exemplified by the combination of chlorine with methane, representing the saturated hydrocarbons, and with ethylene typical of the unsaturated type. The reactions taking place are illustrated by the following equations:

(1) *Substitution Reactions*

$$CH_4 + Cl_2 \longrightarrow CH_3Cl + HCl$$
$$CH_3Cl + Cl_2 \longrightarrow CH_2Cl_2 + HCl$$

(2) *Addition Reaction*

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2$$

Although the paraffins possess high chemical stability at the temperatures ordinarily employed in the more usual chemical reactions, at higher temperatures their thermodynamic stability is materially reduced. With the exception of the first few (lower) members of the series, the paraffins pyrolyze at elevated temperatures much more readily than other hydrocarbons, and, in this respect, are markedly less stable than the olefin and aromatic hydrocarbons. Saturated hydrocarbons possess no power of polymerization, a property belonging exclusively to unsaturated substances.

The paraffins of low molecular weight are least reactive toward the usual chemical reagents, but the resistance of the homologues of increasing molecular weight to oxidation and other chemical changes, so characteristic of the lower members, is reduced. The branched chain members containing a tertiary carbon atom (i.e., a carbon atom attached directly to three other carbon atoms) exhibit a greater tendency to react chemically, as with nitric or chlorosulphonic acid, than do the straight chain members, but the quaternary paraffins (i.e., paraffins containing a carbon atom linked to four other carbon atoms) are very stable.

In the following account a review is presented of the reactions of the paraffins and cycloparaffins (the latter class being restricted in this discussion to the cyclopentanes and cyclohexanes) with various chemical reagents. Attention is specially directed, as far as possible, to those reactions which appear capable of use in the conversion of these saturated hydrocarbons into chemical products.

NITRATION OF PARAFFIN HYDROCARBONS

Unlike the aromatic and the unsaturated hydrocarbons, the paraffins, in general, are not attacked at ordinary temperatures by concentrated or fuming nitric acid or by mixtures of nitric and sulphuric acids. Francis and Young[1] found the order of reactivity of hydrocarbons with fuming nitric acid to be as follows: (1) aromatic compounds[2] and methyl derivatives of the cycloparaffin hydrocarbons, which react at ordinary temperatures; (2) the tertiary paraffins (characterized by the presence of a branched chain and the $\equiv$CH grouping), which are attacked when heated moderately on a water-bath; (3) the cycloparaffin compounds; and (4) the normal (i.e., straight chain) paraffins. Both of the latter types are slowly attacked on heating on a water-bath. Quaternary hydrocarbons, however, were found by Markownikow[3] to react as slowly as normal paraffins.

The relative yields of oxidation and nitration products obtained in the treatment of hydrocarbons with nitric acid (or with mixtures of nitric and sulphuric acids[4]) depend largely on the following factors: (1) the temperature, (2) the concentration of the nitric acid employed, (3) the pressure,[5] i.e., whether the experiment is carried out in sealed tubes or in open vessels, (4) the duration of heating,[6] and (5) the structure of the particular hydrocarbon under treatment.

It was shown by Konowalow[7] that a very effective method of preparing nitrated products from paraffins consists in heating the paraffin with relatively dilute nitric acid (sp. gr. 1.075) at temperatures over 100° C. Under these conditions, quantities of mono- and di-nitrated products may be obtained from a wide variety of paraffins. Nitro-compounds can also be produced[8] by the action of more concentrated acid at lower temperatures (specific gravity 1.535 at above 0° C., for example) but under these conditions oxidation reactions occur easily. Worstall [9] secured a 60 per cent yield of nitrated products (containing both mono- and di-nitro-compounds) by boiling n-hexane for several days with concentrated nitric acid (specific gravity 1.52 or 1.42), either alone or with concentrated sulphuric acid. An investigation of the influence of acid concentration by Poni and Costachescu [10] revealed that, while isopentane could be nitrated with difficulty by acid of a specific gravity 1.075 to 1.14 at temperatures below 140° C., higher concentrations (specific gravity 1.38 to 1.42) attacked this hydrocarbon readily at 60° C., yielding both nitrated and oxidized products. The best yields of nitro compounds (mono-, di-, and tri-nitro-compounds being produced) were obtained at 60° C. with acid of specific gravity 1.42, using 1.5 moles of acid to 1 mole of hydrocarbon. The action of fuming nitric acid on various isoparaffins at their boiling points was investigated by Francis and Young,[1] who noted the formation of oxidation and nitration products from isohexane, isoheptane, and isooctane. Solid trinitro-compounds were obtained from isohexane and isoheptane.

Of the paraffin hydrocarbons, the tertiary paraffins, containing the characteristic grouping R_3CH, appear to be most easily nitrated, yielding the tertiary nitro-compounds very readily. In the nitration of the paraffin hydrocarbons, the entering nitro-group has the greatest tendency to become attached to a tertiary carbon atom. When no tertiary carbon atom is present the nitro-group tends to attach itself to a secondary rather than primary carbon atom.[11] In general, quaternary paraffins of the type R_4C are nitrated only with difficulty and may often be separated from the other types of paraffins by this characteristic.[12] The orientation of the entering nitro-group appears to depend somewhat upon the strength of nitric acid used.

Direct nitration of paraffins containing less than five carbon atoms in the molecule apparently has not been effected. However, in the purification of a fraction of Caucasian petroleum boiling between 40° and 50° C. by treatment with nitric acid of specific gravity 1.52, Beilstein and Kurbatow [13] recovered a compound, $C_4H_8N_2O_4$. This compound crystallized in glistening needles, melting at 96° C., soluble in alcohol, ether, carbon disulphide and light petroleum, and shown to be identical with a compound prepared by Haitinger [14] from isobutylene and concentrated nitric acid. The constitution of the dinitro-compound is somewhat uncertain; it does not correspond to any of the isomeric dinitrobutanes. Since the 40° to 50° C. fraction is practically free from butanes or other lower hydrocarbons, this nitro-compound must have been formed from products of the decomposition of hydrocarbons of higher molecular weight arising through the action of nitric acid.

Isopentane was found by Francis and Young [15] to yield what was probably a trinitro-derivative by boiling with fuming nitric acid under a reflux apparatus for a prolonged period. Later Poni and Costachescu [10] thoroughly investigated the nitration of this hydrocarbon. With nitric acid of specific gravity 1.075 to

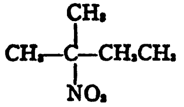
[15] *J.C.S.*, 1898, **73**, 928.

1.14 at temperatures somewhat below 140° C. in sealed tubes, isopentane was slowly nitrated to yield the tertiary nitro-compound, *2-nitro-2-methylbutane,*



$$CH_3-\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}-CH_2CH_3$$

Stronger acid (specific gravity 1.42) at 60° C. yielded products consisting of the above mononitro-compound, *2,3-dinitro-2-methylbutane* (boiling point 105° to 110° C. at 44 mm., and d_0^0 1.1572), *2,3,4-trinitro-2-methylbutane* (a crystalline solid melting at 179° to 184° C.) together with some 1-hydroxyisobutyric acid, oxalic acid and carbon dioxide.

The nitration of *n-hexane* has been the subject of a number of studies. Konowalow[16] reported that though nitric acid of specific gravity 1.155 nitrates n-hexane at 115° to 120° C. in a sealed tube, the yield of the mononitro-compound is low. Better results are procured by using acid of specific gravity 1.075 at 140° C. Under the latter conditions a 60 per cent yield of nitrohexane (boiling point 176° C. at 758 mm. and d_0^0 0.9509) is obtained. This was proved to be the secondary nitro-compound, *2-nitrohexane,* since on reduction with zinc and acetic acid it yielded methyl butyl ketone and β-hexylamine. On the other hand, Worstall[17] found that if n-hexane is boiled for several days in an open vessel with nitric acid of a specific gravity 1.52 to 1.42, either alone or with sulphuric acid, a 60 per cent yield of nitrated products is obtained. These consisted of a primary nitrohexane (*1-nitrohexane*), a light yellow oil (boiling point 180°-183° C., which gave a nitrolic acid on treatment with nitrous acid), together with a *dinitrohexane* (probably also primary). The latter compound is sparingly soluble in aqueous alkalies, though readily so in alcoholic alkalies. It could not be distilled without decomposition. Reduction of this mononitrohexane by Worstall gave a primary amine.

From *isohexane,* Francis and Young obtained a crystalline trinitro-derivative (melting at 85.5°-86.0° C.) by refluxing that hydrocarbon with fuming nitric acid for 6 days. Oxidation products were also produced. A number of crystalline nitration products, apparently derivatives of isohexane, were prepared by Zaloziecki and Frasch[18] by nitration of fractions of Galician petroleum (boiling range, 45° to 65° C.) using a mixture of 1 part of nitric acid (specific gravity 1.404) and 3 parts of concentrated sulphuric acid. The products were fractionally crystallized from alcohol yielding (1) yellow needles, melting point 89.5° C., (2) a substance of melting point 67° C., and (3) two other substances crystallizing in needles and melting at 65° C. and 61° C., respectively. An extensive investigation of the nitration of an isohexane (3-methylpentane) is that of Poni and Costachescu,[19] who used a fraction, boiling at 61.5°-62.5° C., of a Rumanian crude. This fraction was nitrated with nitric acid of specific gravity 1.4 in sealed tubes at 60° C., and the nitrated products were dried and fractionated under a pressure of 35 mm. More than half of the product distilled at 75°-76° C. and this appeared to be the expected tertiary mononitro-derivative, i.e., *3-nitro-3-methylpentane,* boiling point 168°-170° C. at 750 mm., and d_0^0 0.9681. The fraction of highest boiling point (150° to 158° C.) consisted of a dinitro-compound, but was obtained only in a relatively small amount. A quantity of unattacked hydrocarbon was identified as *2-methylpentane.*

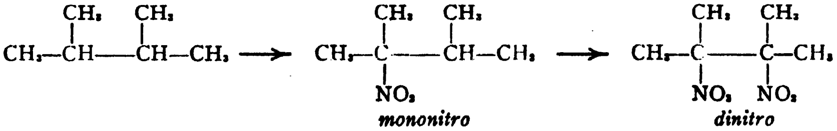
Poni and Costachescu also examined the products of the action of fuming nitric acid (sp. gr. 1.525) on this Rumanian petroleum fraction. Two crystalline trinitro-compounds were identified, one of which proved to be *2,3,3-trinitro-2-methylpentane;* and the other, forming crystals of melting point 85° C., appeared to be *2,2,3-trinitro-3-methylpentane.* These were identical with the trinitro-derivatives isolated by Francis and Young.

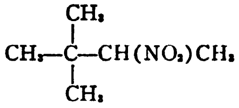
Like most of the di-tertiary paraffins, *diisopropyl* reacts readily with nitric acid at 20° C. It can be nitrated to yield a mononitro-compound, proved by Konowalow [20] to be the tertiary compound, *2-nitro-2,3-dimethylbutane,* a liquid of boiling point 168°-169° C. at 750 mm., and d_0^0 0.9716, together with a di-tertiary nitro-compound, *2,3-dinitro-2,3-dimethylbutane,* melting point 208° C. Konowalow [21] obtained these compounds not only from synthetic diisopropyl but also from fractions, boiling at 55° to 60° C., of American and Baku petroleums. The nitration of diisopropyl accordingly proceeds as follows:



$$\mathrm{CH_3{-}\overset{\displaystyle CH_3}{\overset{|}{C}H}{-}\overset{\displaystyle CH_3}{\overset{|}{C}H}{-}CH_3 \longrightarrow CH_3{-}\underset{\displaystyle NO_2}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}{-}\overset{\displaystyle CH_3}{\overset{|}{C}H}{-}CH_3 \longrightarrow CH_3{-}\underset{\displaystyle NO_2}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}{-}\underset{\displaystyle NO_2}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}{-}CH_3}$$

mononitro *dinitro*

The typical quaternary paraffin, *trimethylethylmethane*, can be nitrated, though with difficulty, to yield a crystalline mono-nitroderivative of melting point 40° and boiling point 167.5°-167.8° C. at 748 mm. This substance has been proved by Markownikow [22] to possess the structure



$$\mathrm{CH_3{-}\underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}{-}CH(NO_2)CH_3}$$

since, on reduction with alkaline stannous chloride, it yields the oxime of pinacoline, while reduction with tin and hydrochloric acid gives the corresponding *β*-amine, a liquid of boiling point 101.5°-102.5° C. *2,2-Dimethylpentane* (trimethylpropylmethane) has also [23] been nitrated to give *2,2-dimethyl-3-nitropentane,* of d_0^0 0.9520, boiling point 89°-90° C. under 40 mm. pressure. It appears to be a general rule with hydrocarbons of this type that nitration takes place in such a way that the nitro-group becomes attached to the carbon atom next to the $(CH_3)_3C$— group.

Beilstein and Kurbatow [24] obtained a nitro-compound by treating a crude American petroleum fraction boiling between 115° and 120° C. with nitric acid. The nitrated fraction boiling between 193° and 197° C. was found to correspond to the formula $C_7H_{15}NO_2$. Konowalow [25] nitrated *n-heptane* by heating it in a sealed tube with dilute nitric acid (of sp. gr. 1.075) at 125° to 130° C. A secondary nitro-derivative, *2-nitroheptane,* a liquid of boiling point 194°-196° C. and d_0^{20} 0.9306, resulted. This secondary nitroheptane appears to be identical with the compound of Beilstein and Kurbatow.

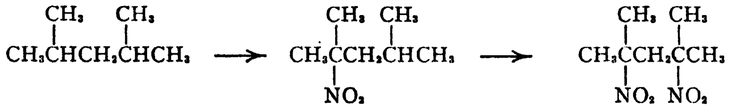
According to Worstall,[26] normal heptane is much more readily nitrated than n-hexane by boiling the hydrocarbon with nitric acid of specific gravity 1.42 to 1.52. The product was said to consist of a primary nitroheptane (boiling at 193° to 196° C.), giving a nitrolic acid with nitrous acid, and readily reducible to a primary amine. A primary dinitroheptane, $CH_3(CH_2)_5CH(NO_2)_2$, was also obtained under these conditions.

A study of the reactions of nitrogen pentoxide with benzene, bromobenzene, toluene, phenol, benzoic acid, m-dinitrobenzene, pyridine, triethylamine and other compounds by Haines and Adkins[27] revealed that heptane was rapidly and quantitatively nitrated at 0° C. The products of the reaction decomposed on distillation at atmospheric pressure but a small amount of unidentified material which boiled at 130° to 180° C. at 25 mm. was obtained.

Of the branched chain heptanes, an *isoheptane* from petroleum was found by Francis and Young[28] to undergo nitration when refluxed with fuming nitric acid for two days. A crystalline trinitro-compound, of melting point 194° C., was isolated from the reaction mixture. Nitration of *2,4-dimethylpentane* by dilute nitric acid (d. 1.11) in sealed tubes leads to the formation of the tertiary mono- and di-nitro-derivatives.[29] The course of the nitration of 2,4-dimethylpentane is, therefore, as follows:



$$CH_3\overset{CH_3}{C}HCH_2\overset{CH_3}{C}HCH_3 \longrightarrow CH_3\underset{NO_2}{\overset{CH_3}{C}}CH_2\overset{CH_3}{C}HCH_3 \longrightarrow CH_3\underset{NO_2}{\overset{CH_3}{C}}CH_2\underset{NO_2}{\overset{CH_3}{C}}CH_3$$

2-nitro-2,4-dimethylpentane, b.p. 181°-182° C./742 mm. *2,4-dinitro-2,4-dimethylpentane,* m.p. 81°-82° C.

Nitration of *triethylmethane* with nitric acid of specific gravity 1.075 at 120° C. yields 57 per cent of a tertiary nitro-compound and 43 per cent of a mixture of primary and secondary nitro-compounds.[30]

The nitration of *n-octane* has been the subject of a number of studies. Konowalow[31] nitrated this hydrocarbon by heating it in a sealed tube at 130° C. with dilute nitric acid of specific gravity 1.075 and obtained a fair yield of the secondary nitro-compound, *2-nitrooctane,* a liquid of boiling point 210°-212° C., and d_0^{20} 0.9201. On the other hand, Worstall[32] reported the formation of primary mono- and di-nitrooctanes by boiling the hydrocarbon with nitric acid (specific gravity 1.42) and sulphuric acid. The use of fuming nitric acid (specific gravity 1.52) resulted in extensive oxidation of the hydrocarbon. The *primary mononitrooctane* was described by Worstall as a liquid boiling at 205° to 210° C., giving the nitrolic acid test and readily reducible to a primary amine.

Francis and Young[33] noted the formation of a liquid nitro-compound on refluxing an *isooctane* fraction from petroleum with fuming nitric acid. Of the branched chain octanes, diisobutyl (*2,5-dimethylhexane*) is readily nitrated at 105° to 110° C. by nitric acid (d. 1.075) to yield[34] a mixture of nitro-compounds consisting mainly of the tertiary mononitro-compound, *2-nitro-2,5-dimethylhexane,* a yellowish liquid of boiling point 200°-202° C. and d_0^0 0.9396. When this nitro-compound is further heated with dilute nitric acid at 120° to 125° C., the tertiary dinitro-compound, *2,5-dinitro-2,5-dimethylhexane*, a crystalline solid of melting point 124°-125° C., is produced. The nitration of this hydrocarbon can be represented thus:

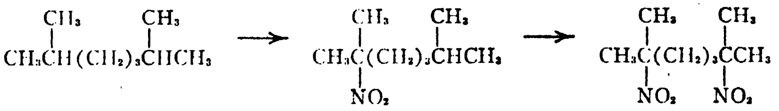
$$CH_3\overset{CH_3}{\overset{|}{C}}HCH_2CH_2\overset{CH_3}{\overset{|}{C}}HCH_3 \longrightarrow CH_3\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}CH_2CH_2\overset{CH_3}{\overset{|}{C}}HCH_3 \longrightarrow CH_3\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}CH_2CH_2\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}CH_3$$

Konowalow[35] has shown that, simultaneously with the formation of tertiary nitro-compounds, there is a slight tendency for nitration to occur in other positions. Under favorable conditions 83 per cent of the mononitro-derivatives of this hydrocarbon consist of the tertiary 2-nitro-compound and 17 per cent of the 1-nitro- and 3-nitro-compounds.

A solid trinitro-compound (melting point 91° C.), derived from diisobutyl, was obtained by Francis and Young[33] by refluxing the hydrocarbon with fuming nitric acid for two days. Markownikow[36] also prepared a solid trinitro-compound, melting point 87°-88° C. (probably identical with the product of Francis and Young) and *4-methyl-3,3,4-trinitropentane* (melting at 95° C.) by the action of nitric acid of specific gravity 1.535.

The nitration of a number of the higher paraffin homologues, including nonane, decane, hendecane and dodecane, by heating with dilute nitric acid has been studied by Worstall.[37] *Nonane* with nitric acid of specific gravity 1.08 gave a 70 per cent yield of mono- and di-nitro-derivatives, and a similar strength acid was used for nitrating *decane*, *hendecane*, and *dodecane*. The nitro-compounds were separated from unaltered hydrocarbons by conversion to their sodium derivatives. These were extracted with water, decomposed by carbon dioxide, and the nitro-compound extracted with ether. Worstall separated the mononitro- from the dinitro-compounds by distillation with steam. Nitrononane was a pale yellow oil, boiling at 215°-218° C. with considerable decomposition. The specific gravities of *nitrononane*, *nitrodecane* and *nitrohendecane* were 0.9227 (17° C.), 0.9105 (15° C.), and 0.9001 (15° C.), respectively.

A number of branched chain higher paraffins have also been nitrated.[38] Thus *2,6-dimethylheptane* is conveniently nitrated at 120° C. with nitric acid of specific gravity 1.075, the chief product being the 2-mononitro-compound. This tertiary nitro-compound is a liquid, boiling point 113°-115° C. at 25 mm., and d_0^0 0.9281. It is readily reduced to the corresponding amine by tin and hydrochloric acid. Further nitration (with acid of specific gravity 1.11) of the mononitro-compound gives the 2,6-dinitro- (or di-tertiary dinitro-) compound, a crystalline solid of melting point 74°-74.5° C. The nitration of this branched chain nonane may be summarized as follows:



$$CH_3\overset{CH_3}{\overset{|}{C}}H(CH_2)_3\overset{CH_3}{\overset{|}{C}}HCH_3 \longrightarrow CH_3\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}(CH_2)_3\overset{CH_3}{\overset{|}{C}}HCH_3 \longrightarrow CH_3\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}(CH_2)_3\underset{NO_2}{\underset{|}{\overset{CH_3}{\overset{|}{C}}}}CH_3$$

The nitration of an analogous hydrocarbon, *2,7-dimethyloctane*, has been studied also by Konowalow. By nitrating with concentrated nitric acid the primary nitro-compound is obtained in an almost pure condition.[39] Nitration by dilute nitric acid (specific gravity 1.075) produces a secondary (3- or 4-nitro) and a tertiary (2-nitro) mononitro-compound, and the tertiary dinitro-compound (i.e., *2,7-dinitro-2,7-dimethyloctane*), a crystalline solid of melting point 101.5°-102° C. Konowalow noticed that the nitration of this hydrocarbon was greatly facilitated by the removal of the nitro-compounds as formed and also by using nitric acid recovered from previous nitrations. Aluminum and bismuth nitrates, when heated in an open vessel with these hydrocarbons, nitrate them mainly to primary and secondary (1- and 3-) mononitro-compounds. In the nitration of *2,7-dimethyloctane* (diisoamyl) by dilute nitric acid in a sealed tube, the tertiary nitro-compound is always formed. Concentrated and fuming nitric acid produce oxidation as well as nitration.

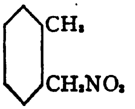
It is interesting to note that the aliphatic side chains in aromatic hydrocarbons may be preferentially nitrated, i.e., without nitration of the aromatic nucleus, by the use of dilute nitric acid. Thus when o-xylene is heated at 110° C. with nitric acid of specific gravity 1.075, nitration of a side chain takes place with the formation of o-tolylnitromethane,[40] a primary nitro-compound readily soluble in alkaline solutions, and possessing the formula



Dilution of the nitrating acid with acetic acid instead of water has the same effect,[41] and, in general, the use of dilute nitric acid and higher temperatures directs the nitration process to the side chains in the benzene homologues. A number of other examples of this phenomenon have been recorded. For example, nitration of durene (*1,2,4,5-tetramethylbenzene*) with benzoyl nitrate leads to nitration of one of the methyl groups.[42] Nitration of *1,2-diphenylpropane*[43] gives the primary nitro-compound of the formula $C_6H_5CH_2CH(C_6H_5)CH_2NO_2$, rather than a nuclear substitution. Similarly, mesitylene gives 1-nitro-1,3,5-trimethylbenzene.[44]

Nitration of Cyclopentane and Cyclohexane Hydrocarbons

Like the paraffins, the five- and six-membered saturated hydrocarbon systems react with nitric acid. Dilute nitric acid at higher temperatures favors the formation of nitro-compounds and more concentrated acid exerts an oxidizing action. Many of the cycloparaffins appear to be nitrated more readily than the corresponding paraffin hydrocarbons. For example, Heusler[45] removed these cyclic hydrocarbons from a crude nonane fraction by dropping the latter into four times its volume of fuming nitric acid. The same method of removing cycloparaffins from paraffin hydrocarbons has been recommended by Ubbelohde,[46] but its general application is doubtful. Of the naphthenes, the cyclopentane homologues seem to be more readily nitrated than the corresponding cyclohexanes. Fuming nitric acid reacts violently with some cycloparaffins at temperatures above 0° C. to form oxidation products.[47] Good yields of dicarboxylic acids may be obtained by the oxidation of cycloparaffins with concentrated nitric acid.

---

[39] This appears to confirm the work of Worstall (*loc. cit.*) on the nitration of the normal paraffins by strong acids in an open vessel.

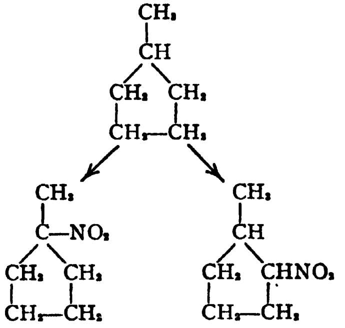
In the nitration of the cycloparaffin hydrocarbons, primary, secondary, and tertiary nitro-compounds are formed, though the latter usually constitute the main product, whenever possible.

The nitration of a *cyclopentane* fraction of Caucasian petroleum, boiling point 50°-51° C., is reported by Markownikow [48] to yield a secondary nitro-compound as well as a large proportion of glutaric acid. No details of the conditions of nitration were supplied by Markownikow but, in all probability, fairly strong nitric acid was employed. The nitrocyclopentane was readily reduced to an amine.

The nitration of *methylcyclopentane* has been investigated. Fuming nitric acid of specific gravity 1.55 acts only slowly on this hydrocarbon if the temperature is kept low, but at temperatures above 0° C. a violent reaction takes place with the production of acetic acid, carbon dioxide, and other oxidation products. Nitrosulphuric acid is without action on this hydrocarbon in the cold.[49] Methylcyclopentane can be nitrated at 115° to 120° C. by nitric acid of specific gravity 1.075 to yield,[50] as the main product, the tertiary nitro-compound, *1-nitro-1-methylcyclopentane*. An isomeric secondary nitro-compound, *2-nitro-1-methylcyclopentane,* is simultaneously formed,[49, 51] and may be separated from the tertiary compound by means of its solubility in aqueous alkali. Both nitro-compounds are readily reduced to the corresponding amines by tin and hydrochloric acid. Succinic and α-methylglutaric acids are also formed during the nitration of the hydrocarbon. The nitration of methylcyclopentane may be summarized as follows:



tertiary nitro-compound, b.p. 92° C. at 40 mm. *secondary nitro-compound,* b.p. 99° C. at 40 mm.

From the products of the action of nitric acid (of sp. gr. 1.38) upon a fraction of Caucasian petroleum, boiling between 95° and 100° C., Beilstein and Kurbatow [52] isolated a compound, $C_6H_{11}NO_2$, boiling at 210° to 215° C. This compound is identical with nitrocyclohexane, later investigated and described by Markownikow.[53]

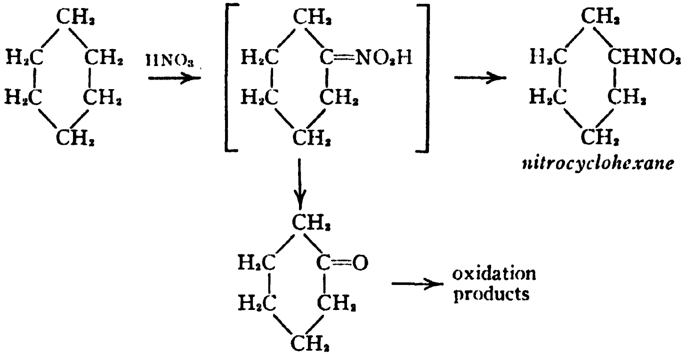
[50] The nitration of methylcyclopentane can also be effected by dilute nitric acid at 100° C. according to Kishner, *J. prt. Chem.*, 1897, **56** (2), 369.

[51] See Nametkin, *J. Russ. Phys.-Chem. Soc.*, 1911, **43**, 1603; *Chem. Soc. Abs.*, 1912, **102** (1), 175.

[52] *Ber.*, 1880, **13**, 1818; *Chem. Soc. Abs.*, 1881, **40**, 159.

Cyclohexane is practically unaffected by the usual nitrating mixture of nitric and sulphuric acids (nitrosulphuric acid) in the cold, while it is oxidized by concentrated nitric acid with the production of adipic acid. The hydrocarbon may be successfully nitrated[54] by Konowalow's method, using dilute nitric acid at temperatures above 100° C. The product is *nitrocyclohexane,* a colorless liquid of boiling point 109.5° C. at 40 mm., and d^0_0 1.0853.[55] According to Nametkin,[56] this nitro-compound is not an intermediate compound in the oxidation of cyclohexane by nitric acid to adipic acid since the latter is formed from cyclohexane more readily than from the nitro-derivatives. Nametkin considers that the intermediate compound in the oxidation reaction is an unstable isonitrocyclohexane which is immediately converted partly into the stable nitrocyclohexane, and partly into an aldehyde (or ketone, according to the nature of the hydrocarbon). The latter product then undergoes further oxidation to the corresponding acid. The application of Nametkin's mechanism to the case of cyclohexane may be represented as follows:



Nametkin[56] has shown that the nitration of cyclohexane can be carried out by using, instead of nitric acid, fused aluminum nitrate, $Al(NO_3)_3.9H_2O$, as the nitrating agent. At temperatures above its melting point, this salt supplies an equilibrium concentration of nitric acid which is maintained constant at any particular temperature as long as any unhydrolyzed nitrate remains in the system. By heating cyclohexane at 115° to 120° C. with about 3 parts by weight of aluminum nitrate a considerably greater yield (i.e., 56 per cent) of mononitrocompound was obtained than when dilute nitric acid was used as the nitrating medium. Cyclohexanone, possibly a nitrocyclohexanone, and a dinitrodicyclohexyl (melting point 216.5°-217° C.) were produced, in addition to mononitrocyclohexane, by this method of nitration.

Methylcyclohexane is vigorously oxidized by fuming nitric acid and acid of lower concentration both nitrates and oxidizes it. The hydrocarbon is scarcely affected by nitrosulphuric acid at 70° C. in sealed tubes or at 80° C. in open vessels.[57] Nitration of this hydrocarbon by acid of specific gravity 1.2, produces three isomeric mononitro-compounds, including a primary, secondary, and a tertiary product, with about a 58 per cent yield. Nametkin[58] found that the yield of nitration products may be increased to 72 per cent by the use of fused aluminum nitrate as a nitrating agent. The constitution and physical constants of the three mononitro-compounds are as follows:

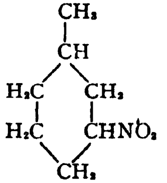
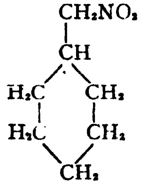
tertiary nitro-compound
(b.p. 109°-110° C.
at 40 mm.)



secondary nitro-compound
(b.p. 119°-120° C.
at 40 mm.)

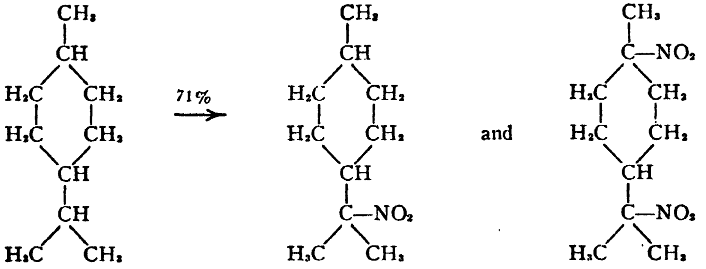


primary nitro-compound
(b.p. 98° C. at 10 mm.)

The tertiary nitro-compound, which may be separated from the isomeric primary and secondary products by the solubility of the two latter in aqueous alkalies, may be readily reduced to an amine by tin and hydrochloric acid.

Little is known of the nitration products of the homologues of cyclohexane. Nitration products boiling between 123° and 126° C. were obtained by Putochin[59] by the action of nitric acid on an isooctanaphthene, C_8H_{16}, of unknown configuration from a fraction of Caucasian petroleum boiling between 122° and 125° C. *1,2,4-Trimethylcyclohexane* can be nitrated by heating with five times its volume of dilute nitric acid (sp. gr. 1.075) in a sealed tube at 120°-130° C. The products consist of a mixture of secondary and tertiary nitro-compounds, readily separated by the usual means.[60] The tertiary nitro-compound, described as a colorless liquid boiling at 128°-130° C. at 40 mm., is reduced by zinc and acetic acid to yield an amine and a ketone.

When *p-menthane* is nitrated by dilute nitric acid (sp. gr. 1.075) at 110° C., a mixture of mononitro-compounds is formed consisting of about 71 per cent of tertiary compound and 29 per cent of primary and secondary products. A tertiary dinitro-compound is also produced.[61] The nitration of p-menthane may be represented as follows:



tertiary mononitro-compound

tertiary dinitro-compound

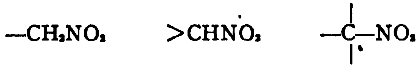
Both the tertiary mono- and di-nitro-derivatives may be readily reduced to the corresponding amines.

The nitration of a *dimethylethylcyclohexane* by dilute nitric acid (sp. gr. 1.075) at 120° to 125° C. was investigated by Markownikow and Rudewitsch.[62] The product is a mixture of tertiary and secondary nitro-compounds, both of which are readily reduced to the corresponding amines by tin and hydrochloric acid. Nitration of this decanaphthene at water-bath temperature by nitric acid of specific gravity 1.41 also resulted in the production of mono- and di-nitro-compounds.

Engler and Halmai[63] nitrated a nonanaphthene fraction boiling at 132° to 137° C. from a cylinder oil from Baku. They obtained a mononitrononanaphthene boiling with decomposition at 220° to 226° C. and having a specific gravity at 18° C. of about 1.02. The configuration of this compound was not determined. They also nitrated a decanaphthene fraction from the same source having a boiling range of 158° to 165° C. The mononitrodecanaphthene, $C_{10}H_{19}NO_2$, formed had a specific gravity of 1.0354 at 18° C. and boiled at 112°-120° C. at 12 mm. This compound was identical with the tertiary nitro-compound obtained earlier by Engler and Routala[64] on nitrating a decanaphthene found in the products of polymerization of amylene with aluminum chloride. Steinkopf and Freund[65] also isolated what appeared to be this same compound on nitrating a fraction (b.p. 165°-172° C.) of turpentine cracked with aluminum chloride.

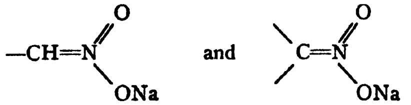
PROPERTIES OF NITRO-COMPOUNDS OF PARAFFIN AND CYCLOPARAFFIN HYDROCARBONS

Three main types of nitro-compounds exist, namely, primary, secondary, and tertiary compounds having the following characteristic groupings:



$-CH_2NO_2$ *primary* $>CHNO_2$ *secondary* $-\overset{|}{\underset{|}{C}}-NO_2$ *tertiary*

The first two are soluble in aqueous (or alcoholic) alkali solutions, in which the tertiary compounds are insoluble. This solubility is associated with the conversion of primary and secondary nitro-compounds into the tautomeric acidic form, the alkali salts of which probably possess the structures,[66]



primary pseudo-acid form and *secondary pseudo-acid form*

From a practical standpoint, the primary and secondary nitro-compounds are readily differentiated by their behavior towards nitrous acid. When a primary nitro-compound is treated with an alkaline solution of sodium nitrite, and the resulting solution just acidified, a nitrolic acid is formed, the alkali salts of which are red in solution. Under similar circumstances secondary nitro-compounds furnish pseudonitroles, which are blue in solution. These reactions are represented as follows:

---

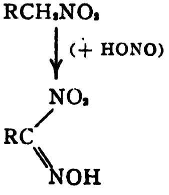
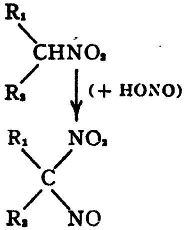
[65] *Ber.*, 1914, 47, 411; *Chem. Soc. Abs.*, 1914, 106 (1), 304.

[66] Nef, *Ann.*, 1892, 270, 331; 1894, 280, 263; *Chem. Soc. Abs.*, 1895, 68 (1), 3. Some of the primary nitro-compounds of the higher paraffins are only slowly soluble in aqueous potassium hydroxide (Worstall, *Amer. Chem. J.*, 1899, 21, 210, 218; *Chem. Soc. Abs.*, 1899, 76 (1), 399).

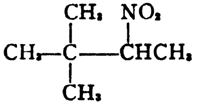


nitrolic acid



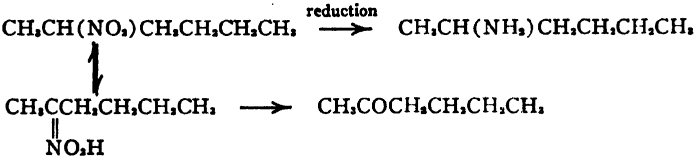
pseudonitrole

The mononitro-compounds of paraffins and cycloparaffins are usually colorless liquids of fairly high boiling point. Some of the dinitro- and a few trinitro-compounds are crystalline solids. While tertiary mono- and di-nitro-compounds are very readily reduced by tin and hydrochloric acid, for example, to the corresponding mono- and di-amines, the primary and secondary nitro-compounds are reduced to the oxime of the corresponding ketone or aldehyde, evidently by reduction of the pseudo-acidic form of the nitro-compound. The relative proportions of the products (i.e., amine or ketone) depend to some extent upon the conditions of reduction. Thus, Markownikow[67] noted that the secondary nitro-compound of trimethylethylmethane, having the formula



$$CH_3-\overset{\displaystyle CH_3}{\underset{\displaystyle CH_3}{C}}-\overset{\displaystyle NO_2}{C}HCH_3$$

is readily reduced to the corresponding secondary amine by tin and hydrochloric acid. Reduction by alkaline stannous chloride, on the other hand, yields an oxime which can be hydrolyzed to a ketone. According to Konowalow,[68] reduction of the secondary nitro-compounds of n-hexane by zinc and acetic acid yields a mixture of β-hexylamine and methyl butyl ketone. These reactions may be represented in the following manner:



The primary nitro-compounds derived from n-hexane and octane, described by Worstall,[69] appear to be quite readily reduced to the corresponding primary amines. On the other hand, the primary nitro-compound of 2,7-dimethyloctane (i.e., 1-nitro-2,7-dimethyloctane) prepared by Konowalow,[70] was reduced by tin and hydrochloric acid to a mixture of the corresponding primary amine and the aldehyde, $CH_3CH(CH_3)CH_2CH_2CH_2CH_2CH(CH_3)CHO$. The secondary nitro-compound of the same hydrocarbon (3- or 4-nitro-2,7-dimethyloctane) is reduced under similar circumstances to the corresponding secondary amine together with a small amount of a ketone, boiling point 190°-192° C.

The tertiary nitro-derivatives of cyclopentane and cyclohexane homologues are also easily reduced to the corresponding amines, though some of the secondary compounds yield only derivatives of the corresponding ketone. Thus, nitrocyclohexane, on reduction with tin and hydrochloric acid, gives cyclohexanone and its condensation products. On the other hand, both the tertiary and secondary nitromethylcyclopentanes are converted largely to the corresponding amines on reduction with tin and hydrochloric acid.[71]

NITRO-COMPOUNDS OF PETROLEUM AND THEIR APPLICATIONS

Frasch[72] produced a brown powdered dyestuff by nitrating crude petroleum, its distillates, or residues. The petroleum is subjected to the action of a mixture of 3 parts of sulphuric and 1 part of nitric acids until all the aromatic hydrocarbons, olefins, naphthenes, and unsaturated hydrocarbons in the oil are taken up in the acid mixture. The acid layer, which contains the aromatic hydrocarbons and tarry substances, is allowed to separate and is withdrawn. This acid mixture is then heated at 60° to 80° C. to effect conversion of the hydrocarbons to nitro- and oxidized products. The free acid is removed by washing with cold water. The soluble nitro-compounds are extracted with water and neutralized with calcium carbonate or oxide, which converts the nitro-compounds into soluble and insoluble calcium salts. The insoluble calcium salts are separated by filtration and may be converted to soluble salts by reaction with sodium, potassium, or ammonium carbonate. The soluble dyestuff thus formed is precipitated from the solution by the addition of hydrochloric acid or sodium chloride. This is a brown resinous material which can be pulverized. It is only slightly soluble in cold water but readily soluble in hot water, acetone, and glycerol. The solution of the soluble calcium salt, obtained in the above procedure, may be treated[73] with hydrochloric acid or sodium chloride to precipitate a soluble yellow or reddish-brown dye which can be applied to silk or wool. Nitro-compounds of "petrocenes", the high-boiling hydrocarbons found in the redistillation of petroleum residues (see Chapter 6), have been described by Zaloziecki and Gans.[74]

Petroleum distillates, boiling between 270° and 380° C. and of specific gravity 0.87 to 0.96, were nitrated by Edeleanu and Filiti[75] with a mixture of concentrated nitric and sulphuric acids. The products were precipitated from the acid by the addition of water. The distillates, before nitration, can be freed from resinous materials by treatment with small quantities of sulphuric acid. These nitro-compounds, they stated, could be used as substitutes for camphor in the manufacture of celluloid and in the preparation of lacquers, varnishes, and brown to black substantive dyes. Freund[76] treated various Borislaw petroleum fractions in this way. He nitrated 1 part of the distillates with 3 parts of a mixture of concentrated nitric and sulphuric acids. Yellow or reddish-brown powders containing from 6.8 to 8.5 per cent of nitrogen were obtained. A brown powder containing 6.80 per cent nitrogen and corresponding to the formula $C_{11}H_{17}NO_2$ was one of these products. Brown substantive dyes could be made by heating these with alkalies.[77] Freund also prepared brown to violet-brown sulphur dyes by heating these nitro-compounds with sulphur and alkalies.

The nitration of high-boiling American and Russian petroleum fractions dissolved in an equal volume of benzine was carried out by Marcusson.[78] By treating such solutions with three volumes of nitric acid (specific gravity 1.52) characteristic yellow dinitro-compounds, containing from 6.5 to 7.5 per cent of nitrogen, were obtained. These were slightly soluble in petroleum ether, partially soluble in alcohol, and dissolved completely in acetone or benzene. Their potassium salts, made by warming the nitro-compounds with alcoholic potassium hydroxide solution and evaporating the alcohol, were dark-brown in color and soluble in water; the original nitro-compounds were insoluble in water.

Although the nitration of aromatic fractions of petroleum is outside the scope of this book, nevertheless the importance of these compounds deserves at least cursory mention. The production of TNT from toluene-containing fractions has already been stressed in Chapter 1. Mizuta[79] prepared mono- and di-nitrotoluenes in good yield from aromatic fractions of Japanese gasolines. The relative yields of secondary and tertiary nitro-derivatives obtained on nitration led Nametkin and Nifontova[80] to believe that paraffin wax contains about 25 to 30 per cent of isoparaffins. From a Grozny and an American paraffin wax they obtained a tertiary nitrate ($C_{24}H_{49}NO_2$) melting at 29° C., a secondary nitrate ($C_{24}H_{49}NO_2$) melting at 45° to 48° C., and an oil consisting of a dinitrate ($C_{24}H_{48}(NO_2)_2$).

Forrest and Meigs[81] obtained resins by treating a distillate from the destructive distillation of asphalt, asphaltic petroleum or materials such as gilsonite with nitric acid of specific gravity 1.42. Because of the great reactivity of the unsaturated bodies formed in the destructive distillation of these carbonaceous materials the addition of nitric acid must be made with caution. Forrest and Meigs recommended that the volume of acid added to the oil at any one time never be more than 1 part to 2500 parts of oil. In carrying out the preparation, the oil is heated to about 93° C. and the temperature during the reaction is maintained below 104° C. The reaction is stopped when 1 part by volume of acid has been added to 2 parts by weight of the oil. Light yellow semi-solids are obtained, the hardness of which depends upon the hydrocarbon fraction used. With a fraction boiling between 204° and 316° C., for example, a resin of medium hardness was formed. A lower-boiling fraction from the decomposition of gilsonite gave a viscous oil similar in properties to nitrated castor oil. These nitro-resins have been suggested as additions to pyroxylin compounds, for example, in the preparation of lacquers, leather dressings, and artificial leather.

Similar resinous products have also been obtained by treating related materials with nitric acid.[82] In this manner Day,[83] for example, used powdered gilsonite, grahamite, and albertite. Tar mixtures also were used by Flexer[84] in making a material resembling asphalt.

Charbonneaux[85] nitrated various hydrocarbon oils, particularly California crude oils, with 5 to 10 per cent of concentrated nitric acid. Several layers were formed on cooling, one of which consisted of a heavy tarry substance insoluble in nitric acid and alcohol, while another was a brown sticky material also insoluble in nitric acid but soluble in alcohol. These substances, which are both nitrated and oxidized products, can be incorporated in liquid fuels. For example, 1 to 3 parts of the resin are added to 100 parts of alcohol and 20 parts of ether.

The preparation of a motor fuel containing amino-compounds and of high anti-detonating properties has been described by Ellis.[86] The distillates obtained by cracking the higher-boiling petroleum fractions under pressure are subjected to the action of concentrated nitric acid and the nitro-compounds thus formed are subsequently reduced by the action of iron and dilute sulphuric acid. Nitration and purification of the distillate may be simultaneously effected by employing a mixture of nitric and sulphuric acids. In addition to acid reduction with metals such as iron, alkaline reduction by zinc or aluminum and a solution of sodium hydroxide is also effective.

The nitration of an *octane fraction of petroleum* to furnish a crude mononitro-compound capable of being used as a solvent for cellulose derivatives and resins, has been described by Hopkins.[87] Fourteen hundred parts of an octane fraction of petroleum, boiling range 125° to 130° C., are mixed with 1000 parts of 94 per cent aluminum nitrate[88] and 600 parts of 68 per cent nitric acid and the mixture heated to 130° to 140° C. in an oil bath. Hydrocarbon, nitric acid, and water distil off and the hydrocarbon is condensed and returned to the mixture. The resulting 950 parts of reaction mixture are steam-distilled, yielding 370 parts of crude mononitro-compound, and 580 parts of unchanged hydrocarbon.

The nitration of non-benzenoid substances, such as petroleum fractions which contain hydrocarbons having from six to twelve carbon atoms, yield materials which can be mixed with alcohols and benzene to form solvents for nitrocellulose.[88a] Nitrated products lower the ignition and flash points of petroleum distillates. The compounds used for this purpose are obtained by the nitration of aromatic hydrocarbons such as benzene or toluene, or by the nitration and distillation of kerosene distillates.[88b]

ACTION OF NITROSYL CHLORIDE AND CHROMYL CHLORIDE ON SATURATED HYDROCARBONS

The photochemical reaction of nitrosyl chloride with n-heptane (from *Pinus jeffreyi*) has been investigated by Lynn and Hilton[89] with the following results: Pure heptane was saturated with nitrosyl chloride and the resultant reddish-brown solution, though unchanged in the dark for weeks, gradually became blue under the influence of sunlight. Simultaneously with the appearance of the blue color, which was probably caused by the production of a nitroso-compound, ammonium chloride was deposited. The blue color quickly disappeared spontaneously and the resulting turbid liquid gradually deposited a yellow oil which sank to the bottom of the container and evolved a yellow gas containing 75 per cent hydrogen chloride and 2.5 per cent nitric oxide. Fifty grams of this oil were steam-distilled, yielding much hydrogen chloride together with 30 grams of an oil having a fragrant odor, and some hydroxylamine. From the boiling points and refractive indices of the fractions obtained by distilling this oil, it was concluded that it contained a mixture of three ketones—methyl amyl ketone, dipropyl ketone, and ethyl butyl ketone, derived from the heptane, with a preponderating proportion of the dipropyl ketone. The production of this latter ketone and its oxime was subsequently substantiated. The following reactions were believed to take place:

---

[84] Austrian Patent 74,127; *Kunststoffe,* 1921, 2, 12; German Patent 332,634, 1918; *J.S.C.I.*, 1921, 40, 349A.

$$\begin{aligned} &C_7H_{16} + NOCl \longrightarrow C_7H_{15}NO \text{ (blue)} + HCl \\ &C_7H_{15}NO \text{ (blue)} \longrightarrow C_7H_{14}{=}NOH \text{ (oil)} \\ &C_7H_{14}{=}NOH + H_2O \longrightarrow C_7H_{14}O + NH_2OH \end{aligned}$$

The reaction therefore proceeds through the intermediate production of a blue nitroso-compound which then isomerizes to the oxime of a ketone. Hydrolysis of this oxime yields the free ketone. Lynn and Hilton found, by experiments with ultraviolet radiation and working at different temperatures, that the formation of the blue nitroso-compound takes place both in sunlight and in ultraviolet light at temperatures up to 80° C. For some reason, however, the less refrangible rays are necessary to effect the conversion of the nitroso-compound into the oxime.

Recent work by Kester, Looker, and Hass[90] on the action of nitrosyl chloride with butane both in the liquid and gaseous phases and under the influence of sunlight, artificial light, heat, and catalysts has demonstrated that at least three types of reactions take place: (1) Chlorination, which is the predominating reaction. Polychlorides prevail over the monochlorides among the products. (2) Oxidation. Notable proportions of fatty acids are formed in this reaction, the principal one being butyric, though propionic and acetic in measurable quantities were also obtained and the presence of formic was indicated. (3) Nitrosation. No oxime of either butyraldehyde or methyl ethyl ketone was isolated and identified but methyl ethyl ketone itself was found in both the upper and lower layers of the reaction product. The amounts of it, however, were at all times small.

The lower layer of the reaction product consisted in the main of strong aqueous hydrochloric acid saturated with ammonium chloride in addition to such water-soluble ingredients as methyl ethyl ketone, fatty acids, and doubtless other unidentified products in small amounts. Ammonium chloride precipitated during the course of the reaction, together with small amounts of hydroxylamine hydrochloride, which was isolated. The upper layer contained unreacted butane, chlorobutanes, methyl ethyl ketone, and fatty acids in addition to small proportions of by-products not identified. The presence of lacrimatory substances was very noticeable. They may have been, and probably were, chlorinated ketones.

The action of *chromyl chloride*, CrO_2Cl_2, on alkylbenzenes has been studied. The reaction, investigated by Etard[91] and by Miller and Rohde,[92] yields oxygenated derivatives. In general, the methylbenzenes produce the corresponding aldehydes, while hydrocarbons with longer side chains usually yield ketones and, in some cases, the corresponding aldehyde. Thus ethylbenzene and chromyl chloride yield acetophenone and an oil which combines with sodium hydrogen sulphite and probably consists of phenylacetaldehyde and benzaldehyde. Similarly p-cymene is oxidized by chromyl chloride to an aldehyde and a ketone, p-tolyl ethyl ketone.

---

[90] Private communication from E. B. Kester.

Little work has been reported on the action of chromyl chloride on non-benzenoid hydrocarbons, but, here again, oxidation to ketones also appear to take place. Etard [93] obtained a chloroketone by the action of this reagent on hexane, and Schulz [94] subjected a number of light Boryslaw petroleum fractions to the action of chromyl chloride and obtained a mixture of ketones, which were not identified.

APPLICATION OF FRIEDEL-CRAFTS REACTIONS TO PARAFFIN AND CYCLOPARAFFIN HYDROCARBONS

One of the most interesting and important developments in the chemistry of the saturated non-benzenoid hydrocarbons is the application of the Friedel-Crafts reaction not only to cycloparaffins, such as cyclopentane and cyclohexane, but also to straight chain paraffins. Formerly such reactions were considered to apply solely to aromatic substances. The investigation of the catalytic effects of metallic halides on the saturated non-benzenoid hydrocarbons is still in the initial stages. The evidence available definitely indicates, however, that changes are effected with non-benzenoid hydrocarbons by these reagents but not nearly as readily as with aromatic compounds. The importance of these reactions lies in the possibility of converting saturated hydrocarbons directly into ketones by reaction with acid chlorides, or with carbon monoxide under pressure, in the presence of aluminum chloride.

The fact that some naphthenes are capable of undergoing certain types of Friedel-Crafts condensations appears to have been noticed as early as 1899 by Zelinski.[95] He reported the production of various ketones by treatment of fractions of Baku gasoline (rich in cycloparaffin hydrocarbons) with acetyl chloride in the presence of aluminum chloride. For example, two isomeric ketones of the formula $C_6H_{11}COCH_3$ (presumably derivatives of cyclohexane and methylcyclopentane, respectively) were obtained in this way from the fraction of Baku gasoline of boiling point 80°-82° C. Similarly, ketones of the formulas $C_7H_{13}COCH_3$ and $C_8H_{15}COCH_3$ were prepared from the fractions boiling at 100°-102° C. and 119°-120° C., respectively. Marcusson and Vielitz [96] proposed a method of removing naphthenes from paraffins by treating the mixture with benzoyl chloride in the presence of anhydrous aluminum chloride. According to Marcusson, the naphthenes were attacked but not the paraffins. In view of later work, however, sharp separation of cycloparaffin and paraffin hydrocarbons is not attained by this procedure.

An example of the reaction of hydrogen atoms not attached to an aromatic nucleus under the influence of Friedel-Crafts condensing agents has been described by von Braun and his associates.[97] When 5-phenyl-1-chloropentane is treated, in light petroleum or carbon disulphide solution, with anhydrous aluminum chloride, elimination of hydrogen chloride takes place and there is a considerable formation of phenylcyclopentane. The reaction may be represented as follows:

---

[93] *Ber.*, 1877, **10**, 236; *Ann. chim. phys.*, 1881, **22** (5), 282; *Chem. Soc. Abs.*, 1881, **40**, 581.

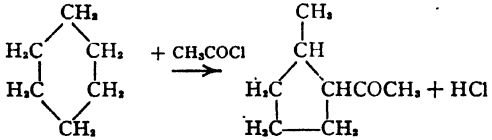
In the same way 5-p-tolyl-1-chloropentane condenses to yield some p-tolylcyclopentane.

Perhaps the most striking work on the preparation of ketones from paraffin and cycloparaffin hydrocarbons by the Friedel-Crafts reaction is that of Hopff,[98] a review of which is to be found in Chapter 18. It is sufficient to state here that both paraffin and cycloparaffin hydrocarbons were condensed with acid chlorides (acetyl chloride) and also with carbon monoxide under high pressure in the presence of anhydrous aluminum chloride to yield ketones and other substances. From *n-pentane* and acetyl chloride, the main product was 2-acetylpentane, while *cyclohexane* yielded a cycloalkyl ketone. In the presence of aluminum chloride, carbon monoxide under high pressure could be made to react with saturated hydrocarbons at temperatures of about 100°C. to give ketones. Although the yields of pure ketones obtained by Hopff in these reactions were rather poor and considerable quantities of other substances were formed, the work of this investigator is of importance to those interested in the chemical transformation of saturated hydrocarbons.

Acetyl chloride reacts slowly with cyclohexane in the presence of aluminum chloride.[99] On standing, the reaction products separate into two layers; the upper consisting of the hydrocarbons, $C_{12}H_{12}$ and $C_{18}H_{22}$, and the lower, on decomposition with water, yielding a ketone of the formula $C_8H_{14}O$. This ketone was not methyl cyclohexyl ketone, but was identified as *1-methyl-2-acetyl-cyclopentane.* In a similar manner butyryl and benzoyl chlorides formed, in addition to hydrocarbons, the corresponding *1-methyl-2-butyryl-* and *1-methyl-2-benzoyl-cyclopentanes,* respectively. In the latter case the lower, or ketone, layer contained a large proportion of benzaldehyde from the reduction of the benzoyl chloride. The above results can be explained on the bases of the following reactions:

(a) Condensation of cyclohexane to higher hydrocarbons ($C_{12}H_{22}$) containing a lower hydrogen content with simultaneous reduction of the acid chloride to aldehyde; and

(b) Direct combination of the acid chloride with cyclohexane, accompanied by the elimination of hydrogen chloride and simultaneous rearrangement of the cyclohexane ring, under the influence of aluminum chloride, to give the 2-derivative of 1-methylcyclopentane.[100] The latter process may be represented as follows:



---

[98] *Ber.,* 1931, **64,** 2739; 1932, **65,** 482. See also, U. S. Patent 1,801,350, April 21, 1931; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.,* 1931, **25,** 3358.

[99] Nenitzescu, Isacescu and Ionescu, *Ann.,* 1931, **491,** 189, 210; *Brit. Chem. Abs.* **A,** 1932, 49. Substantiation of the work of Nenitzescu and Ionescu on the condensation of cyclohexane with acetyl chloride is provided by Unger (*Ber.,* 1932, **65B,** 467) and by Hopff (*Ber.,* 1932, **65B,** 482).

[100] The rearrangement of cyclohexane to methylcyclopentane takes place under the influence of aluminum chloride. See Aschan, *Ann.,* 1902, **324,** 1; *Chem. Soc. Abs.,* 1902, **82** (1), 749.

The yields of ketones reported by Nenitzescu and Ionescu were usually rather small. By agitating 2000 cc. of cyclohexane and 300 grams of acetyl chloride with 600 grams of anhydrous aluminum chloride for 36 hours, a relatively small quantity of 1-methyl-2-acetyl-cyclopentane, of boiling point 167°-168° C. at 759 mm. and d_4^{20} 0.8976, was obtained.

Nenitzescu and Ionescu also investigated the reaction of cyclohexane with chlorocyclohexane and other chloro-compounds. In the presence of anhydrous aluminum chloride a vigorous reaction took place, to yield a reaction product consisting of saturated hydrocarbons (not containing six-membered rings) as well as a sludge of aluminum chloride and unsaturated polymers of cyclohexane. It was believed that the saturated hydrocarbons of the formulas $C_{12}H_{22}$ and $C_{18}H_{32}$ were produced by reactions of the type

$$2C_6H_{12} \longrightarrow C_6H_{11}C_6H_{11} + 2H$$
$$3C_6H_{12} \longrightarrow C_6H_{11}C_6H_{10}C_6H_{11} + 4H\,,$$

the hydrogen, thus formed, reducing the chlorocyclohexane (or other chlorohydrocarbon present) which acts as a hydrogen acceptor.

The direct production of ketones from saturated hydrocarbons has been the subject of a number of industrial developments. Procedures are described by the I. G. Farbenindustrie A.-G.[101] for the synthesis of various ketones by treatment of paraffin or cycloparaffin hydrocarbons with acid chlorides, or with carbon monoxide under pressure, in the presence of a Friedel-Crafts condensing agent. The following examples are given of this process:

1. An autoclave is charged with 86 parts of a petroleum fraction, boiling between 60° and 70° C., together with 98 parts of phosgene and about 133 parts of aluminum chloride and heated to 100° C. A quantitative conversion into ketones of the polymethylene and paraffin series is said to take place.
2. Into a cool autoclave are charged 58 parts of n-butane and 85 parts of the double compound of phosgene and aluminum chloride, obtained by incorporating 5 parts of liquid phosgene with 2 parts of anhydrous aluminum chloride. The autoclave is then heated to 90° C. and kept at this temperature for 6 hours. After cooling, the pressure is released and the reaction products are separated in the usual manner. A yellow oil with an aromatic odor and which boils mainly between 120° and 150° C. at 15 mm. is obtained.
3. Seventy-eight parts of acetyl chloride and 100 parts of hexane (a slight excess above the quantity stoichiometrically required) are fed into an autoclave containing about 150 parts of anhydrous aluminum chloride. The mixture is heated for 2 hours at 100° C. The product obtained consists principally of ketones of the polymethylene series including octanone, for example.
4. One hundred parts of hexane are heated in an autoclave for 2 hours at 100° C. with 70 parts of benzoyl chloride and 66 parts of anhydrous aluminum chloride. The product of this reaction consists largely of ketones which boil between from 120° to 250° C. at 12 mm.
5. One hundred parts of cyclohexane are heated in an autoclave for 2 hours at about 100° C. with 66 parts of aluminum chloride and 39 parts of acetyl chloride. Ketones which boil between from 150° to 250° C. at atmospheric pressure are formed.

The manufacture of keto-acids by the reaction of petroleum fractions with dibasic organic acid anhydrides has been described by Bruson.[102] As an example of his procedure, 30 parts of phthalic anhydride and 100 parts of gasoline are made to react at 70° to 90° C. in the presence of 60 parts of aluminum chloride. After the evolution of hydrogen chloride ceases the hot product is treated with a solution of sodium carbonate, the unaffected gasoline is removed by distillation, and the precipitated aluminum hydroxide filtered out. An aqueous solution of the sodium salt of the keto-acid is thus obtained, from which the free acid may be precipitated by the addition of dilute sulphuric acid. The reaction between the petroleum hydrocarbons and phthalic anhydride may be represented by

---

[101] British Patent 327,411, 1928; *Brit. Chem. Abs.* **B**, 1930, 602. Hopff, German Patent 517,718, 1927; *Chem. Abs.*, 1931, 25, 1258. German Patent 520,154, 1927; *Chem. Abs.* **B**, 1932, 494; all patents assigned to Resinous Products and Chemical Co.

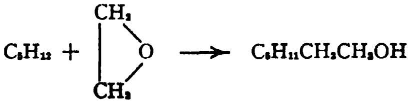
The heavy-metal salts of such acids are insoluble in water but soluble in organic solvents such as toluene, turpentine, and linseed oil. The cobalt, manganese, and lead salts are stated to be effective driers for drying oils. The esters of these acids, particularly the ethyl, butyl and bornyl esters, are high-boiling viscous oils which may be used as either solvents or plasticizers for nitrocellulose.

According to the I. G. Farbenindustrie A.-G.,[103] alkylene oxides, such as ethylene oxide, may be condensed with paraffin, cycloparaffin, and benzenoid hydrocarbons in the presence of a Friedel-Crafts condensing agent (anhydrous aluminum chloride) to yield primary alcohols. Besides ethylene oxide, other alkylene oxides, such as 1,2- and 1,3-propylene oxides, isobutylene oxide and trimethylethylene oxide, may be used. Substances capable of forming such oxides during the reaction, as for example glycol chlorohydrins, may also be employed. Hydrocarbons, including pentane, hexane, heptane, dodecane, octadecane, cyclohexane, hexahydrotoluene, benzene, and aromatic hydrocarbons in general, and other condensing agents, such as boron fluoride and anhydrous ferric chloride, can be used. The process is exemplified by the direct condensation of n-pentane with ethylene oxide yielding *n-heptanol* according to the equation:



$$C_5H_{12} + \begin{array}{l} CH_2 \\ \;|\;\;\diagdown \\ \;|\quad\; O \\ \;|\;\;\diagup \\ CH_2 \end{array} \longrightarrow C_5H_{11}CH_2CH_2OH$$

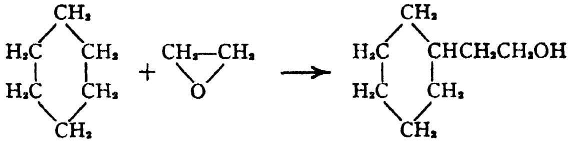
This procedure appears to offer a method for the preparation of the higher straight chain primary aliphatic alcohols, some of which seem to present commercial possibilities in the manufacture of special soaps. Examples of the application of this condensation are the production of phenylethanol from benzene and ethylene oxide; n-heptanol, from n-pentane and ethylene oxide; a mixture of higher primary alcohols from kerosene and ethylene oxide; and of hydroxyethylcyclohexane from cyclohexane and ethylene oxide. Thus, condensation of 500 parts of n-pentane with ethylene oxide at room temperature in the presence of 250 parts of anhydrous aluminum bromide produced 25 parts of an oil, boiling range 160° to 190° C., containing considerable amounts of n-heptanol. Higher primary alcohols can be made from kerosene in the following manner:

One hundred fifty parts of anhydrous aluminum chloride are added to 500 parts of kerosene in an autoclave. This mixture is treated with ethylene oxide at room temperature and at about 1.5 atmospheres until there is no further decrease in pressure. The reaction product consists of a brownish colored, very viscous lower layer and a colorless upper layer. The latter contains only unchanged petroleum and is withdrawn. The lower layer is mixed with ice and the resulting 32 parts of oily product are separated from the water. The oil boils between 150° and 200° C. at 12 mm. and consists principally of higher alcohols.

---

[103] British Patent 354,992, 1931; *Brit. Chem. Abs.* B, 1932, 12; see also Chapter 23.

The preparation of hydroxyethylcyclohexane is carried out by adding 50 parts of ethylene oxide, with cooling and agitation, to a mixture of 500 parts of cyclohexane and 132 parts of anhydrous aluminum chloride. The aluminum chloride is gradually converted into a viscous pasty mass. Unaltered cyclohexane is drawn off and the tough residue is decomposed with ice-water and steam-distilled, after the addition of 100 parts of concentrated hydrochloric acid. After extraction of the aqueous distillate with ether, the extract yields 70 parts of an oil boiling mainly between 95° and 105° C. at 13 mm., and consisting largely of hydroxyethylcyclohexane. Its formation may be represented thus:



hydroxyethylcyclohexane

Fohlen[104] described the condensation of paraffin hydrocarbons with phosgene to yield ketones or with phosgene and hydrogen to yield aldehydes. Various metals, metallic oxides, and salts are used as catalysts. The reactions believed to occur are exemplified by the following, representing the condensation of phosgene with methane and hydrogen:

$$2CH_4 + COCl_2 \longrightarrow CH_3COCH_3 + 2HCl$$

$$CH_4 + COCl_2 + H_2 \longrightarrow CH_3CHO + 2HCl$$

Trialkyl or triaryl borates have been suggested to replace the halogen derivatives generally used in the Friedel-Crafts reaction.[105] The reaction, for example, between tribenzyl borate and benzene to yield diphenylmethane may be represented by

$$(C_6H_5CH_2)_3BO_3 + 3C_6H_6 + AlCl_3 \longrightarrow 3C_6H_5CH_2C_6H_5 + 3HCl + AlBO_3$$

Miscellaneous Reactions of Paraffins and Cycloparaffins

According to Meigs,[106] *sulphur monochloride* reacts vigorously with unsaturated hydrocarbons, and at a slow rate with saturated hydrocarbons, the slow evolution of hydrogen chloride gas continuing with the latter for many hours. Subsequently, Lorand[107] examined the effect of sulphur monochloride on various saturated hydrocarbons and found that a reaction usually occurred. Various lubricating oils reacted violently with evolution of hydrogen chloride, higher kerosene fractions were attacked rather less vigorously, and various gasoline fractions changed color when mixed with this reagent, depositing a dark sediment on standing. A more energetic reaction occurred on heating. The branched chain diisoamyl was found to react energetically with sulphur monochloride at 100° C. After heating for six hours, during which time a slow evolution of hydrogen chloride took place, the color of the liquid became very dark and sulphur was deposited on cooling. Lorand believed that straight chain paraffin hydrocarbons are slowly chlorinated by sulphur monochloride. With branched chain paraffins this chlorination takes place somewhat more rapidly. On prolonged heating the chlorinated products lose hydrogen chloride and the resulting unsaturated substances are either chlorinated or polymerized. These reactions may be represented as follows:

---

[104] French Patent 680,586, 1928; *Chem. Abs.*, 1930, **24**, 3799.

[105] Kaufmann, German Patent 555,403, 1930; *Chem. Abs.*, 1932, **26**, 5101.

[106] *Ind. Eng. Chem.*, 1917, **9**, 655.

[107] *Ind. Eng. Chem.*, 1927, **19**, 733.

$$(1)\ >CH{-}CH_2{-} + S_2Cl_2 \longrightarrow HCl + S_2 + >CH{-}CHCl{-}$$

$$(2)\ >CH{-}CHCl{-} \longrightarrow >C{=}CH{-} + HCl$$

Antimony chloride ($SbCl_5$) reacts with hydrocarbons containing a tertiary hydrogen atom (e.g., 2-methylpentane, methylcyclohexane) after a short period, whereas a primary or secondary linking (e.g., in such compounds as n-heptane, 2,2-dimethylbutane, cyclopentane or hexane) is attacked only at a higher temperature. Hydrogen chloride is liberated and the products are probably addition compounds, according to Schaarschmidt and Marder.[108] This behavior with antimony chloride can be used to detect the presence of compounds containing tertiary hydrogen linkages, though reaction of hydrocarbons containing primary and secondary hydrogen atoms is induced by the presence of the former.

When many saturated hydrocarbons are heated to temperatures above about 200° C. with *elemental sulphur,* a reaction occurs with the production of hydrogen sulphide, together with other substances. The action of sulphur on petroleum hydrocarbons is more fully discussed in Chapter 19. From the products of the action of elemental sulphur on methylcyclohexane at elevated temperatures Friedmann[109] isolated thiocresol, and Markownikow[110] similarly obtained xylene from an octonaphthene. Though some of the simple saturated hydrocarbons, such as cyclohexane, are stable with sulphur at temperatures of about 200° C., many of the higher paraffins and heavy petroleum greases are vigorously attacked under these conditions.[111]

Chlorosulphonic Acid, HSO_3Cl, is a sulphonating agent.[112] Marx and Brodersen[113] prepared sulphonic acids by the action of chlorosulphonic acid on petroleum hydrocarbons. Products made by sulphonating brown-coal tar oils or mixtures of petroleum hydrocarbons with aromatic or hydroaromatic hydrocarbons or their derivatives in this manner have been suggested as insecticides and fungicides.

Saturated hydrocarbons are attacked by a number of oxidizing agents. *Benzoyl peroxide* oxidizes some of the lower paraffins yielding mixtures in which aliphatic alcohols have been identified. By heating benzoyl peroxide with a purified petroleum fraction, boiling between 95° and 100° C., Böeseken and Gaster[114] observed the production of carbon dioxide, benzene, benzoic acid, heptylbenzene and, probably, a tertiary heptanol. n-Octane begins to react with benzoyl peroxide at 100° C., and carbon dioxide, benzene and benzoic acid are formed initially. What appeared to be a mixture of secondary octanols was obtained by hydrolysis of the neutral products of this reaction.

Chapter 48

Occurrence, Properties and Uses of Naphthenic Acid

The naphthenic acids are carboxylic acids which are obtained from various crude petroleums or their distillates. The name is derived from the circumstance that they were first discovered in naphthene- (cycloparaffin-) containing crude oils from Russia and Rumania. The name naphthenic acids is also expressive of the chemical relationship of these acids with the naphthene hydrocarbons, a similarity which later work has fully substantiated.

The naphthenic acids probably occur to some extent in most petroleums but they are usually associated with those of Rumania, South Russia and the Caucasus. Great differences exist, however, between the naphthenic acid contents and the chemical characteristics of these acids from various crudes. Whereas, for example, Russian petroleums often contain quantities of relatively simple low-boiling naphthenic acids having a very persistent and somewhat disagreeable odor, the Gulf Coast (U.S.A.) petroleums contain higher-boiling acids which are practically odorless and can be salted out of their aqueous solutions readily.

The actual content[1] of naphthenic acids in various crudes, and distillates derived therefrom, has been very little investigated and little information is available on it. The crude acids obtained by alkali treatment of oils often contain considerable amounts of other substances, including dissolved hydrocarbons, phenols, and sulphonated products (if the oil has been previously acid-treated). According to some investigators the Rumanian crudes possess the highest content of naphthenic acids and the Russian and Galician oils rank somewhat lower in this respect. Naphthali[1a] gave figures for the naphthenic acid content of several oils ranging from 0.07 per cent to 2.4 per cent.

According to Lidow,[2] the naphthenic acid content of Russian crude and masout is 0.83 to 1.3 per cent. Schulz[3] obtained naphthenic acids from unrefined Galician distillates in yields corresponding to 0.05 to 0.84 per cent of the distillate. Krämer and Böttcher[4] examined a German petroleum from Oelheim and an Alsatian petroleum and found naphthenic acids (as well as small amounts of phenols) to the extent of 0.081 per cent and 0.136 per cent, respectively. A Russian crude from Balachani-Sabunchi examined by Goldberg and Gurvich[5] contained 1.06 per cent of naphthenic acids (average acid number 202 and average molecular weight 277), which were monobasic. The acidity and naphthenic acid content of the various distillates of this crude increased with rising boiling point and decreased at the upper end, the maximum being the distillate of 0.882. According to Vuistavkina[6] crude Emba (Russian) petroleum contains 0.43 to 0.74 per cent of naphthenic acids, while the distillates contain 0.18 to 1.44 per cent of these acids having molecular weights which vary from 218 to 466. The refining of a gas-oil distillate of a Japanese petroleum yielded about 0.14 per cent of crude petroleum acids, of which 7.7 per cent consisted of higher fatty acids.[7] Holzmann and von Pilat[7a] established the presence of myristic, palmitic, stearic, and arachidic acids in a spindle oil extract.

[3] *Chem.-Ztg.*, 1908, **32**, 596; *Chem. Abs.*, 1908, **2**, 2735. This investigator also reported that the acidity of distillates increased on standing due to oxidation. Muishkin (*Grozneski Neft.*, 1930-1931, 1, **2**, 44; *Brit. Chem. Abs.* **B**, 1931, 1035) reports values of 0.012 to 1.94 per cent for various crude distillates.

[4] *Ber.*, 1888, **20**, 596.

[5] *Azerb. Neft. Khoz.*, 1928. **5**, 46; *Chem. Abs.*, 1928, **22**. 3767.

Malyatskii and Margolis[7b] determined the solubility, acid number, molecular weight, and dissociation constant of naphthenic acids from naphtha, kerosene, and gas-oil fractions of Baku crude. Solubilities in water of the acids from the three fractions were 37, 22 and 7 milligrams per liter, respectively. Acid numbers were 316.5, 259.9 and 195.2; molecular weights, 176.8, 216, 287; and dissociation constants, 8.84×10^{-7}, 8.21×10^{-7}, 6.02×10^{-7}, respectively.

The Russian crudes apparently contain approximately 1 per cent of naphthenic acids but in the majority of crudes from other parts of the world the naphthenic acid content is much less, usually not more than 0.1 per cent. Naphthali[7c] gives the figures in Table 157 for the naphthenic acid content of some American crudes:

TABLE 157.—*Naphthenic Acid Content of American Crude Oils.*

Source	Naphthenic Acid Content Approximate Per Cent
Winkler County (Texas)	0.30
Howard County (Texas)	0.07
Runnels County (Texas)	0.03
Hosston (Louisiana)	0.70
Saginaw (Michigan)	0.03
Smackover (Arkansas)	0.03
Midcontinent (Pipe Line)	0.04
Midcontinent	0.03
Pennsylvania	0.03
Gulf Coast Crude	0.60
Distillate from Gulf Coast Crude (Viscosity, 300 sec.)	1.24
Distillate from Venezuela Crude (Viscosity, 500 sec.)	1.00
California (Southern California and San Joaquin Valley Crude)	0.1 to 3.0
Gillies Siding (Canada)	0.07
Bothwell (Canada)	0.16 to 0.46
Petrolia (Canada)	0.11

As regards the actual mode of formation of naphthenic acids from petroleum several theories have been put forward[8] but a number of facts appear to indicate that a large proportion, if not the whole, of the naphthenic acids obtained are actually produced by oxidation of certain readily oxidized cycloparaffins during the alkali wash of refining operations or during distillation.[9] As early as 1884,

[9] von Braun, *Ann.*, 1931, **490**, 100; *Chem. Abs.*, 1932, **26**, 2306. The soluble portion of sulphur dioxide extract of California kerosene, treated with alkali in the presence of air, gives naphthenic acids (A) which are only *poorly soluble* in sulphur dioxide. From the insoluble portion, or raffinate of the kerosene, treatment with alkali and air gives naphthenic acids (B) which are *very soluble*

Schaal[10] proposed oxidation of petroleum fractions by air in alkaline solution at high temperatures as a method of producing acid oxidation products. It was shown, moreover, by Charitschkoff[11] that oxidation of naphthene hydrocarbons, either photochemically or by the method of Schaal, resulted in the formation of monocarboxylic naphthenic acids as well as considerable amounts of polynaphthenic acids. The latter substances were viscous tribasic pseudo-acids, which are probably bicyclic condensation products of the naphthenic acids. The view that naphthenic acids are formed by alkaline oxidation of cycloparaffin hydrocarbons is fast gaining support, notably as a result of the important researches of von Braun, Petrow and others and opens up a wide field of practical possibilities in the direction of increasing the quantities of acids obtainable from petroleum fractions.

Pyhälä[11a] reported that distillates from a Russian petroleum contained 12 times as much naphthenic acids as the original oil, and a Rumanian oil gave a similar result. He believes, however, that the acids exist in the crude as an unsaponifiable complex. This view was supported by experiments in which the acid treatment of the crude was varied, resulting in a change in the content of naphthenic acids found in the distillate.

EXTRACTION OF NAPHTHENIC ACIDS FROM PETROLEUM

Naphthenic acids may be extracted from crude oils or distillates by the use of aqueous sodium hydroxide solutions in which the acids dissolve yielding sodium naphthenates.[12] In the acid refining of many petroleum distillates, however, the oil is first treated with a certain amount (which varies with the distillates to be treated) of concentrated sulphuric acid to remove asphaltic materials or sulphur compounds. The oil is then subjected to a dilute alkali wash to remove the last traces of acids and sulphonated products. The lyes from the latter treatment on acidification yield considerable amounts of free naphthenic acids.[13] The raw acids often contain considerable proportions of impurities such as hydrocarbons. The presence of these neutral hydrocarbons in the lye is to be ascribed to the difficulty of separating the aqueous lye from the main oil bulk on account of the high emulsifying character of the sodium naphthenates. The large-scale production of naphthenic acids free from neutral oils is for this reason rendered very difficult and the last traces of hydrocarbons can usually only be removed by special treatments.

It has been contended[14] that the concentrated sulphuric acid of the acid wash actually condenses with the naphthenic acids to yield sulphonic acids of the type

$$\begin{array}{l}\mathrm{R.SO_3H}\\ |\\ \mathrm{COOH}\end{array}$$

---

in sulphur dioxide. The high solubility of the (B) acids obtained from the initially insoluble raffinate clearly shows that naphthenic acids have been formed during the alkali treat. (Private communication from von Braun.)

which are thus extracted with the naphthenic acids during the alkali wash. However, Gurwitsch[15] found that the crude naphthenic acids extracted from a kerosene fraction by direct alkali treatment did not differ in chemical and physical properties from the acids extracted from the same distillate previously subjected to an acid refining. It is probable, however, that the acids present in the higher fractions of petroleums more readily undergo sulphonation during acid refining. Tanaka and Nagai[16] have also shown that the properties of the naphthenic acids obtained directly from a Japanese petroleum distillate without previous treatment with sulphuric acid were practically identical with those of the naphthenic acids from the waste lyes produced in the ordinary alkali refining of the same distillate after acid refining.

The production of naphthenic acids as a by-product of the acid refining of distillates was developed on a considerable scale in Russia before the War, notably by the firm of Nobel Bros. Many of the American petroleums are probably too poor in acid constituents to serve as a commercial source of these materials but the crudes of Galicia and Rumania have been utilized. The initial stage in the refining of many distillates consists in treatment with concentrated sulphuric acid, the quantity of acid used being somewhat variable but usually 0.5 to 1.0 per cent for benzines, 2 to 4 per cent for kerosenes, and 5 to 10 per cent for lubricants. The acid layer is then run into water to yield the well-known "acid-tar," a fruitful but almost untapped source of sulphonated products. The acid-treated oil is then washed with a dilute aqueous solution of sodium hydroxide, the whole mass being kept well agitated with a current of air or steam. From a technical point of view the separation of this dilute alkaline solution from the treated oil often presents considerable difficulties, since, as mentioned previously, very stable emulsions of the oil-in-water type are frequently formed. Methods of dealing with these emulsions vary with the characteristics of the oil under treatment.

From the dilute caustic solution used in the alkaline treatment of oils, the naphthenic acids may be obtained in the free state by acidifying with sulphuric acid. If instead of sulphuric acid, sulphur dioxide is used for this purpose the resulting sodium sulphite may be causticized with lime and sodium hydroxide is recovered.[17]

If the particular distillate does not need acid refining, or if other refining methods are more suitable, the naphthenic acid constituents may be removed by an alkali-wash without any preliminary treatment. There is an increasing tendency to displace the acid treatment in favor of refining methods depending upon the use of adsorbent earths, which can be easily revivified by roasting and used several times. An apparatus for the direct extraction of naphthenic acids from oils without preliminary acid treatment has been described by Emmuil.[18] This consists of a vertical cylinder the middle section of which is provided with a steam coil to heat the gas oil or other distillates under treatment, to 70°-75° C. The oil enters at the bottom through a perforated pipe and leaves at the top. The causic soda solution is introduced at the top of the cylinder counter-current to the oil and is discharged at the bottom together with the soap formed.

A typical process for the production of saponifiable products from mineral oils is that of Maitland,[19] which is conducted in the following manner: Twenty-three hundred barrels of lubricating stock are thoroughly agitated with about 75 barrels of 93.5 per cent sulphuric acid and then allowed to settle. Three distinct layers are formed, namely a top layer, "A," consisting of 2175 barrels of lubricating stock with approximately 0.75 per cent sulphuric acid in suspension; a middle layer, "B," composed of 180 barrels of a mixture of sludge and acid; and finally a bottom layer, "C," consisting mainly of acid with some dissolved sludge. These layers are separated and layer "A" is slowly agitated with about 300 barrels of dilute sodium hydroxide solution and permitted to settle. Two layers are formed, namely a top layer, "D," composed chiefly of lubricating stock amounting to about 1925 barrels, and 550 barrels of a bottom layer, "E," which is a mixture of lubricating oil, soap (alkali naphthenates), and alkaline salt solution. This lower layer is drawn off, agitated with about 150 barrels of 7 per cent sulphuric acid at 100° C. and then 150 barrels of hot water are added. On settling the mixture separates into two layers, the upper layer, "F," consisting of approximately 250 barrels of saponifiable acids admixed with some mineral oil, while the bottom layer, "G," is the salt water resulting from the decomposition of the soap. After drawing off this bottom layer, layer "F" may be saponified with a hot solution of about 51 Bé. caustic soda to yield a bright soap containing very little water. If sufficient care is taken to allow the product "E" to settle properly it will separate into three layers, namely a top layer "H" (18 per cent of total) containing mainly mineral oil, a middle layer "I" (39 per cent) containing the soap, and a bottom layer "J" (43 per cent) of alkali salts and water. The soaps obtained in this process are said to be applicable to all purposes for which soaps from animal or vegetable oils are adapted. Maitland also suggests that the acid sludge layer "B" may be worked up to give a soap which is similar to the product obtained by the alkali wash treatment and contains only about 0.4 per cent of sulphur. This soap is made by mechanical mastication of the sludge with warm water until the acid content has been reduced to below 2 per cent. The residual compounds settling to the bottom of the digester are saponifiable oils containing some dissolved and suspended matter.

As the alkali salts of the naphthenic acids are useful materials, the acids are usually worked up in this form. Partial concentration of ordinary alkali sludge can be effected and it is generally necessary to salt out the soaps from the concentrated solution. A plant for the separation of naphthenic acids from a kerosene alkali sludge was described by Shiperovich and Gurwitsch.[20] The sludge, containing about 10 to 25 per cent of naphthenic acids, is atomized with hot gases and concentrated to about 40 per cent naphthenic acids, which are then salted out. According to Stock[21] petroleum soaps are obtained by acidifying alkali sludge with sufficient sulphuric acid to separate a very small quantity of free naphthenic acids, after which the remaining soaps may be salted out of solution.

The direct production of naphthenic acid soaps by redistilling lubricating stocks (containing naphthenic acids) in the presence of caustic soda, or other alkalies, was described by Coleman and Hughes.[22] The hot distillation residues are discharged into water and the oil which separates from the aqueous metal naphthenates is taken off in stages.

Andrews and Lauer[23] extracted the alkaline residue, obtained from the distillation of naphthenic-base crudes, with 80 to 95 per cent alcohol. Separation and distillation of the alcohol yields the sodium soaps from which the naphthenic acids are recovered.

Rogers[24] suggested removing naphthenic acids from hydrocarbon oils by vaporizing the oil and passing the vapors upward through a tower, in the lower part of which molten caustic soda is present. A small amount of reflux is maintained in the upper part of the tower to prevent entrainment of sodium compounds. The residues may be treated with concentrated sulphuric acid to liberate the naphthenic acids and recover the contained oil.[25]

PURIFICATION OF CRUDE NAPHTHENIC ACIDS

The crude naphthenic acid soaps recovered from alkali sludge yield, on acidification, a mixture of naphthenic acids and other substances. The impurities present in the acids, or their soaps, are primarily neutral hydrocarbons which, on account of the high emulsifying properties of the naphthenic acids and their salts, are exceedingly difficult to remove. Besides hydrocarbons, petroleum resins and asphaltic materials are often present. However, from a technical standpoint the problem of removing neutral hydrocarbons from naphthenic acids is of primary importance.

Several methods of removing neutral hydrocarbon oils have been proposed. Redistillation of the crude naphthenic acids is hardly effective, since it has been shown that distillation of oils containing naphthenic acids carry over acids boiling up to 50° C. above the range of the respective petroleum cuts, the same effect being observed with steam or vacuum distillation.[26] According to Bauer,[27] crude naphthenic acids may be freed from neutral oils by stirring them with aniline or o-toluidine. After standing for some time the lower layer is separated and the solvent is distilled off. Naphthenic acids of 98-99 per cent purity remain in the still and a repetition of the process results in the production of acids almost completely free from mineral oils. The crude acids can be refined by extracting, with petroleum ether, a solution of them in alcohol containing 30 per cent sodium hydroxide and then distilling the alcohol. The residue is treated with dilute sulphuric acid, dissolved in petroleum ether, washed, dried over anhydrous sodium sulphate and phosphorus pentoxide, and distilled under a pressure of 3 mm.[28]

Alleman[29] developed a process for separating the mineral oil and petroleum resins in alkali sludge from lubricating distillates. The original alkali sludge, or soap emulsion, had the following typical composition:

	Per Cent
Soap (sodium salts)	11.6
Petroleum resins	17.1
Mineral lubricating oil	46.
Sodium sulphate	2.3
Water	23.

If this soap, oil and water emulsion is treated with gasoline, practically no separation takes place because of the presence of positively charged particles or droplets. Small amounts of certain salts of lithium, sodium, or potassium added to the emulsion in gasoline effect an immediate separation. In practice the purification consists in dissolving the soap emulsion in hot gasoline and then adding

10 per cent of a concentrated aqueous solution of common salt. On allowing to stand, separation takes place and the top gasoline layer (containing the mineral lubricating oil originally held by the emulsion) is drawn off. After three such extractions with gasoline and salting out with sodium chloride solution, the soap solution is substantially free from mineral oils but still contains some petroleum resins. On evaporating this purified soap solution, and cooling to 5° C. or below, the soaps may be separated leaving the sodium sulphate in solution. On decomposing these soaps with mineral acids, the free organic acids are obtained with an acid number of about 103.5, as contrasted with the value of 30 for the crude acids before treatment.

Another procedure of Alleman[80] deals with the purification of alkali sludges, similar to those just described. The sludge is introduced into a closed upright boiler, water is added until it is approximately 58 per cent of the whole mixture, and the mass is then heated to a steam pressure of 60 pounds for 2 hours. Cooling is allowed to take place in the presence of compressed air (also at a pressure of 60 pounds) to prevent agitation of the liquid which otherwise would occur because of boiling as the pressure became less during the cooling step. A permanent separation is said to result, the top layer consisting of mineral oil and the bottom, a water layer containing soap, resin, and sodium sulphate. Soap is obtained by evaporating the lower aqueous layer and cooling the concentrated solution.

Coleman[81] described a process consisting essentially in a vacuum distillation of the mixture of oil and acids. Heavy fractions of, for example, Gulf Coast petroleum are washed with hot sodium hydroxide solution to remove acids as sodium salts. Addition of sulphuric acid to the aqueous alkaline wash precipitates the oily acids, which are again converted into their sodium salts. The sodium salts are dried, fluxed with 2 volumes of gas oil (boiling range, 250° to 350° C.) and the mixture is then heated rapidly to 510° F. and flashed into a vessel maintained under a vacuum of 1.5 mm. of mercury. The oil-free residue of naphthenates is run into water and naphthenic acids are recovered by acidification.

Bransky[82] proposed a method of separating naphthenic acids from lubricant distillates, e.g., from Louisiana crude, which involves treating the distillate with sufficient soda ash solution to neutralize the oil. The neutralized oil is then extracted with 10 to 20 per cent of methanol, ethanol, or isopropanol. The alcoholic extract is separated and distilled, and the alkali naphthenates remaining in the residue are purified by acidification and steam distillation. The viscous oily acid product yields a sodium salt which can be used as a detergent and a green copper salt applicable in naphtha solution as a wood preservative.

It will be seen from the foregoing that the purification of naphthenates (usually alkali salts), or free naphthenic acids, from dissolved or emulsified mineral oils can usually be effected by such processes as alkaline distillation, extraction of alkali salts with solvents, or extraction of adherent mineral oils from aqueous solutions of naphthenates by means of gasoline in the presence of emulsion-precipitating salt solutions.

The free naphthenic acids of Russian, Galician and Central European origin are frequently low-boiling liquids of very offensive odor, and in order to utilize such acids in the manufacture of detergents it becomes necessary to minimize this disagreeable odor. On the other hand, the naphthenic acids derived from American crudes, especially those of the lubricant distillates, are higher boiling, possess higher molecular weights, and are often without odor. For the deodorization of naphthenic acids of the Russian type, chemical treatment is usually necessary. Breda [33] recommended oxidizing agents, such as potassium permanganate, followed by distillation with superheated steam. It is stated that the objectionable odor of some naphthenic acids may be destroyed by the use of agents such as nitrous acid or hypochlorous acid, or their salts.[34] Pohl [35] suggested treating naphthenic acids, or their soaps, successively with reducing and oxidizing agents. Naphthenic acid soaps are also said to be deodorized by treatment with about ½ per cent of the alkali salts,of the peracids (percarbonate, persulphate or perborate), or with sodium peroxide.[36] Heating the soap solutions to 200° C. or higher in an autoclave has been advocated as a method of purification.[37]

Schmitz [38] noted that hexa- and hepta-naphthenic acids which had been prepared synthetically had an odor similar to that of petroleum naphthenic acids. The odor of the petroleum acids was reduced by treatment with dilute aqueous sodium carbonate solution. The oxygen compounds in the acids, which were apparently phenols, were insoluble in sodium carbonate but soluble in potassium hydroxide solution, and had a dark color and an intense penetrating odor. Hydrogenation did not affect the odor of the crude acids but treatment with ozonized air for 1½ to 2 hours at 14° to 17° C. caused a slight reduction in the odor.

Crude naphthenic acids or their salts frequently possess a deep color which is undesirable in many respects. Various adsorbent materials, such as the hydrosilicate, tonsil, are said to effect decolorization. According to Gurwitsch,[39] naphthenic acids can be improved in color and odor by treatment with concentrated or fuming sulphuric acid. On the addition of a regulated amount of water, the sulphuric acid separates as a moderately mobile tar. Schrauth [40] described a method of making, from crude naphthenic acids, products of bright yellow color and having a better odor and higher acid value than the original acids. The crude naphthenic acids are condensed with formaldehyde or substances yielding formaldehyde, if necessary at elevated temperatures and pressures with or without the addition of condensing agents. Another procedure for the removal of impurities consists in the precipitation of naphthenic acids (either in the form of the acids themselves or as their salts) from aqueous solutions by.the addition of a volatile electrolyte (hydrogen chloride, acetic or nitric acid, or ammonia). The impurities are said to remain in solution.[41] Schmitz [42] noted that ozone at 50° C. bleached the acids slightly, a yellow precipitate being formed at the same time. At 100° C. the ozone caused a polymerization, the color of the acids changing to a wine-red.

Distillation under reduced pressure of Russian-type naphthenic acids minimizes both the odor and the dark color,[43] but it is doubtful if this treatment alone is sufficient.

CONSTITUTION AND CHEMICAL PROPERTIES OF INDIVIDUAL NAPHTHENIC ACIDS

The separation of individual chemical substances from the complex mixture of acids obtained from petroleum is a problem of great difficulty and it is not surprising to find that many of the statements concerning them are often contradictory and the physical constants of the isolated acids, presumably chemical individuals, frequently widely divergent. The difficulty of isolating pure naphthenic acid individuals increases as the boiling point and molecular complexity increases, owing to the possibilities of isomerism and the probable occurrence of acids of different series. Heretofore our knowledge of the constitution of individual naphthenic acids was in a chaotic condition but the work of von Braun has shed much new light on the subject and has revealed a number of fundamental errors in the older conceptions. It is both convenient and instructive to discuss the gradual progress of fundamental chemical research on the naphthenic acids from a purely historical standpoint.

As mentioned, separation of individual naphthenic acids by straight distillation of the mixed acids is a matter of great difficulty and the problem has usually been attacked by first converting the free acids into derivatives which can be subjected to fractional distillation with less possibility of decomposition. For this purpose the esters, especially the methyl esters, have been most frequently employed. The esterification of naphthenic acids by an alcohol, such as methanol, can be effected by heating the mixture of acids and alcohol in the presence of about 3 per cent of dry hydrogen chloride or a small quantity of concentrated sulphuric acid.[44]

Eichler[45] was one of the first workers to employ esterification in the separation of the oily acids of Sarachany (Caucasian) petroleum, from which he extracted twelve different acids. Hell and Medinger[46] fractionated the ethyl esters of naphthenic acids extracted from a Rumanian crude and obtained what was considered to be an individual ethyl ester, boiling at 236° to 240° C. and having the formula $C_{11}H_{19}O_2C_2H_5$. Saponification of this ester yielded a naphthenic acid of the formula $C_{11}H_{20}O_2$, boiling at 258° to 261° C.

A great impetus to the chemical investigation of naphthenic acids was supplied by the work of Markownikow and Oglobin[47] on the saturated hydrocarbons of Russian naphtha. Markownikow[48] fractionated the methyl esters of Russian naphthenic acids and isolated several individual acids. Aschan[49] also isolated the same acids by a similar process of fractionation. It was shown by Markownikow[50] that the fraction of the methyl esters distilling at 160° to 165° C. consisted essentially of the compound $C_7H_{11}O_2CH_3$ which on hydrolysis yielded the heptanaphthenic acid, $C_7H_{11}COOH$, boiling at 213° to 214° C. This acid was assumed to be a stereoisomer of 1-methylcyclopentane-2-carboxylic acid,

as the synthetic acid prepared by Coleman and Perkin[51] boiled at 219.5° to 220.5° C. The octanaphthenic acid, boiling point 237° to 239° C., of the formula $C_7H_{13}COOH$, was isolated by both Markownikow and Aschan. The latter worker also succeeded in isolating a number of the higher members among which may be mentioned a monanaphthenic acid, boiling point 251° to 253° C., and a decanaphthenic acid, boiling point 260° to 264° C. The research of these and other workers therefore showed that the naphthenic acids present in a number of crude petroleums, mostly of Russian or Rumanian origin, could be resolved, e g., by fractionation of their methyl esters, into a whole series of monobasic carboxylic acids of the general formula $C_nH_{2n-2}O_2$ with strong presumptive evidence of the existence therein of a polymethylene ring. The probable absence of hexahydrobenzoic acid (cyclohexane carboxylic acid) was indicated by the work of Aschan, and this fact, coupled with the results of Markownikow, further indicated that the essential basis of the naphthenic acid molecule is a cyclopentane ring.

Following the work of Aschan and Markownikow a number of investigators concentrated on the isolation of individual acids from the naphthenic acids derived from various petroleum oils or their distillates, though their efforts contributed little to our knowledge of the constitution of these substances. Thus, Krämer and Böttcher[52] converted the naphthenic acids of Alsatian petroleum into their methyl esters and subjected the latter to fractionation. Methyl esters corresponding to the two monobasic acids $C_{15}H_{28}O_2$ and $C_{18}H_{24}O_2$ were obtained. The former acid had d_4^{15} 0.951 and boiled without appreciable decomposition at 300° to 310° C. under atmospheric pressure. Distillation of the calcium salt with an excess of soda-lime resulted in the production of a mixture of hydrocarbons boiling between 180° and 230° C., and having the average formula $C_{14}H_{26}$. These hydrocarbons, however, rapidly absorbed bromine so that the expected formation of a saturated cycloparaffin was not realized.

The naphthenic acids present in Rumanian kerosene were examined by von Frangopol,[53] who isolated hepta-, octa-, and nona-naphthenic acids besides smaller amounts of deca-, undeca-, and dodeca-naphthenic acids. Somewhat later Petrow[54] subjected the mixed methyl esters of naphthenic acids to careful fractionation and obtained the following fractions:

Fraction 1, boiling point 161° to 163° C. at 748 mm. and yielding on hydrolysis a free acid of boiling point 211° to 213° C. (heptanaphthenic acid?).

Fraction 2, boiling point 169° to 171° C. at 748 mm., yielding a free acid of boiling point 218° to 220° C. (methylcyclopentane-2-carboxylic acid?).

Fraction 3, boiling point 177° to 178° C. at 736 mm. (methyl ester of an octanaphthenic acid?).

Similarly a series of napthhenic acids from octanaphthenic acid up to pentadecanaphthenic acid (boiling from 236° up to 303° C.) was isolated by von Kozicki and von Pilat,[55] by distillation of the methyl esters of acids derived from Galician petroleum distillates. The crude acids were first purified by the method of Ardan,[56] which consists in adding low-boiling petroleum ether to an alcoholic solution of the mixed alkali naphthenates followed by isolation of the alkali naphthenates, free from neutral hydrocarbons, from the alcoholic solution.

[56] Über Naphthene und Naphthensäuren, Diss. Karlsruhe, 1910.

The ethyl esters of naphthenic acids from Potok petroleum[57] yielded two fractions, one boiling at 95° to 170° C. (3 mm) and the other at 170° to 220° C. (3 mm). Reduction of these esters gave the alcohols, $C_{11}H_{22}O$ and $C_{17}H_{34}O$, respectively. Each alcohol was converted to the bromide, and these bromides on condensation with malonic ester, followed by treatment with urea and sodium ethylate, furnished the corresponding barbituric acid, $C_{16}H_{26}O_3N_2$ (m.p. 218°-220° C.) and $C_{22}H_{38}O_3N_2$ (m.p. 173°-177° C.). Reduction of ethyl naphthenates with sodium and ethyl alcohol in benzine resulted in the formation of a large proportion of glycols.

Zelinsky[58] made an attempt to settle the vexed question of the nature of the cycloparaffin ring present in the naphthenic acids. The acids from Baku petroleum were fractionated and converted into their methyl esters. From the lower-boiling portion of the esters, two fractions were isolated, having analytical compositions in accordance with those required for methyl heptanaphthenecarboxylate (octanaphthenate) and methyl octanaphthene carboxylate (nonanaphthenate), respectively, but the wide boiling range showed them to be mixtures of isomers. These fractions were reduced by sodium and alcohol to the corresponding primary alcohols, which were converted by iodine and red phosphorus into the iodides, and subsequently reduced by zinc dust to the hydrocarbon. The latter were saturated hydrocarbons, stable toward permanganate and concentrated sulphuric acid. When passed over platinum black at 300° C., conditions under which cyclohexane derivatives undergo thermal dehydrogenation, these hydrocarbons yielded very little hydrogen. It was concluded by Zelinsky that the original naphthenic acids cannot contain more than small amounts of cyclohexane derivatives. The main ring system is probably a cyclopentane ring. Investigation of the octa-, nona-, and deca-naphthene carboxylic acids in the same way showed that these also cannot contain more than a trace of cyclohexane derivatives.[59]

Von Braun[60] examined the naphthenic acids in distillates from Rumanian, Californian, Galician and German crudes and found that acids from these different sources exhibited the same characteristics, namely: those containing up to 6 or 7 carbon atoms were aliphatic, those possessing from 7 to 12 carbon atoms were monocyclic, while those which had more than 12 carbon atoms per molecule were dicyclic. No evidence was obtained for acids of more highly condensed systems. It was also observed that acids of approximately the same empirical composition occurred in the corresponding fractions from different crudes. Galician oils were exceptions in that the acids having more than 11 carbon atoms were aliphatic or monocyclic The low-molecular weight acids found in the distillates from Rumanian crudes were absent in the crude oil, from which largely secondary acids were isolated. This suggested that the low-molecular acids are the products of pyrogenic decomposition.

The work of Tanaka and his associates[61] was carried out on naphthenic acids derived from Japanese crudes as well as from a Californian distillate. The mixture of naphthenic acids was converted into methyl esters which were then

fractionated and the purified acids regenerated; or the mixed methyl esters were saponified to give the purified free acids which were submitted to fractionation. The most interesting result of this work from the structural point of view is that definite differences of density were found to exist between pure naphthenic acid fractions of the same boiling range but from different petroleums. Naphthenic acids from gas oil distillates of California (Long Beach and Santa Fé Springs) crudes had specific gravities somewhat lower than those derived from Kurokawa petroleum and a little higher than acids from Nishiyama petroleum. The explanation advanced for such facts is that two series of isomeric naphthenic acids, differentiated by specific gravities, exist and that the acids from Californian petroleum are probably a mixture of the two series of acids. All the acids appeared to be monocarboxylic acids of the formula $C_nH_{2n-2}O_2$. From the crude naphthenic acids of Echigo-Nishiyama petroleum, Tanaka and Nagai[62] isolated, by means of the methyl esters, a homologous series of acids from dodeca- to pentadecanaphthenic acids.

Komppa[63] isolated an undecanaphthenic acid, $C_{10}H_{19}COOH$, by fractionation of the methyl esters of naphthenic acids from Baku petroleum. The purified acid boiled at 271°-272° C. (764 mm.) and yielded ethyl and methyl esters boiling at 247°-248° C. (762 mm.) and 236°-237° C. (763 mm.), respectively. Reduction of the ethyl esters yielded an undecanaphthenol which was converted by phosphoryl chloride and phosphorus pentachloride into the corresponding chloride, $C_{10}H_{19}CH_2Cl$, boiling at 74° to 78° C. at 7 mm. This chloride, on reduction with sodium in alcohol, furnished an undecanaphthene $C_{11}H_{22}$, boiling point 183.5°-184.5° C. at 765 mm., d^{20}_{4} 0.81284 and n^{20}_{D} 1.44834, identical with the hydrocarbon found by Markownikow and Oglobin in Baku naphtha. Komppa concluded that the undecanaphthenic acid of the naphtha is a carboxylated derivative of the undecanaphthene hydrocarbon present in the same type of petroleum.

Carboxylic acids derived from lubricating fractions of Texas crudes have been described by Alleman,[64] who stated that these acids are not naphthenic acids proper since they do not conform to the equation $C_nH_{2n-2}O_2$. It is true that formerly the term naphthenic acid usually implied carboxylic acids of that general formula but later work, especially that of von Braun, has shown the essential artificiality of such a classification and has indicated the desirability of extending the term naphthenic acid to include not only monocyclic carboxylic acids of the formula $C_nH_{2n-2}O_2$ but also bicyclic and possibly polycyclic monocarboxylic acids ($C_nH_{2n-4}O_2$ and $C_nH_{2n-6}O_2$). In short, the term naphthenic acid is employed to designate all carboxylic acids which are to be found in crude petroleums, but more especially monocyclic acids of the formula $C_nH_{2n-1}COOH$ (or $C_nH_{2n-2}O_2$). The acids described by Alleman have 16 to 25 carbon atoms per molecule, molecular weights ranging from 250 to about 376, and belong predominantly to the series $C_nH_{2n-4}O_2$ and $C_nH_{2n-6}O_2$. One acid out of the eleven isolated from the mixed acids appeared to belong to the series $C_nH_{2n-8}O_2$. These acids are described as viscous liquids of high refractive index (1.48563 to 1.49654), distillable between 160° and 245° C. at 4 mm. but distilling with decomposition at ordinary pressure. Alleman is apparently the first investigator to obtain an indication of the existence in petroleum of bicyclic and tricyclic monocarboxylic acids, but the presence of the former was later firmly established by the work of von Braun.

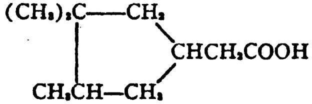
Naphthali[65] reported that the following acids have been isolated from Rumanian and Galician naphthenic acids:

$CH_3C_5H_8(CH_2)_2COOH$ $(CH_3)_2C_5H_7(CH_2)_2COOH$ $(CH_3)_3C_5H_6CH_2COOH$

The latter acid consists of a substance of the constitution



and is related to the 3,3,4-trimethylcyclopentanone obtainable from creosote oil.

The occurrence of aliphatic acids of the paraffin series has been noted by a number of workers. Tanaka and Kuwata[66] found that the crude petroleum acids derived from Ishikari (Hokkaido) gas-oil distillates contained, in addition to true naphthenic acids, a mixture (7.7 per cent of the total acids) of palmitic (4.5 parts), stearic (2 parts), myristic (2 parts), and arachidic acids (traces), which were separated by means of their lithium salts and subsequently the methyl esters. Similar fatty acids are said to occur in other Japanese petroleums, and also in those from California and Borneo. Crystals of arachidic acid were obtained by Holzmann and von Pilat,[67] by cooling the acid mixture extracted from a spindle oil. The presence of paraffin carboxylic acids in the lower fractions of Baku naphthenic acids was observed by Chichibabin.[68] Von Braun, as previously noted, has also found saturated acids of the formula $C_nH_{2n}O_2$ in the lowest fractions.

Before proceeding to discuss the results of von Braun it is desirable to tabulate the physical properties of the simple monocyclic naphthenic acids of the formula $C_nH_{2n-2}O_2$ which have been isolated by various workers from petroleums. It can hardly be doubted that these acids are mainly cyclopentane monocarboxylic acids, though many of the acids listed in Table 158 were probably not homogeneous chemical individuals and consisted of at least two isomers.

The work of von Braun has materially extended our knowledge of the chemical constitution of the naphthenic acids. The results obtained by previous workers seemed to indicate that the typical formula was $C_nH_{2n-2}O_2$ and that these acids were monocarboxylic acids derived from cycloparaffin hydrocarbons in which the COOH group was attached directly to the carbon ring. The work of Zelinsky and others, moreover, indicated that the ring system present was generally a cyclopentane ring. Von Braun[69] has shown as a result of his extensive experiments that these conclusions are erroneous in several particulars. It was found that the naphthenic acids are indeed monocarboxylic acids, derivatives mainly of cyclopentane and conform in general to the formula $C_nH_{2n-2}O_2$; but bicyclic saturated naphthenic acids of the empirical formula $C_nH_{2n-4}O_2$ also exist (possibly also polycyclic ones $C_nH_{2n-6}O_2$), while in the lowest fractions saturated aliphatic acids of the formula $C_nH_{2n}O_2$ occur. Von Braun concentrated his attention mainly on the question of the constitution of the monocyclic naphthenic acids of the formula $C_nH_{2n-2}O_2$, which were shown to consist not only of compounds of the type

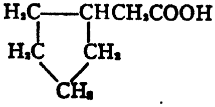
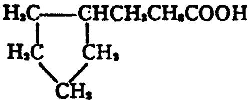
as was previously believed, but mainly of the types



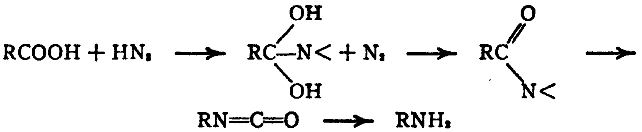
and



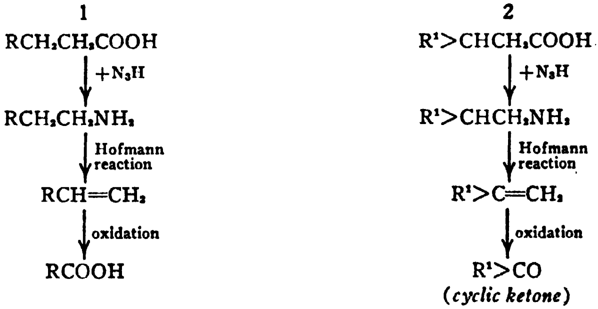
in which the carboxyl group is linked indirectly to the ring system through a chain of one, two, three, or even more, CH_2 groups. Direct evidence was also adduced that in the monocyclic naphthenic acids the ring structure involved is most frequently a cyclopentane ring.

The methods employed by von Braun in elucidating the structure of these acids are of sufficient interest to warrant a brief description. Three distinct methods of attack were employed.

(1) *The Amine-Olefin Method.* Treatment of a naphthenic acid with hydrazoic acid by the method of Schmidt leads to the formation of an amine (a naphthenamine) according to the reactions:



The naphthenamine, produced in 80 to 90 per cent yield by this method, can be readily purified through its oxalate or other salt and contains one carbon atom less than the parent naphthenic acid. Exhaustive methylation of this amine followed by the Hofmann degradation yields an olefin, which on oxidation with ozone furnishes *either* an acid with two carbon atoms less than the original naphthenic acid *or* a ketone with two carbon atoms less than the parent acid. These reactions are illustrated by the two following cases.[70]



---

[70] The symbol $R^1{>}C$ indicates that the carbon atom forms a part of the cyclopentane structure contained in the radical R^1. This accounts for the formation of a ketone on oxidation.

Obviously, if the parent naphthenic acid consists of a mixture of isomers of the two above-mentioned types, the series of reactions will result in the production of a mixture of an acid and a ketone easily separable by chemical means.

(2) *Progressive Degradation Method.* This method produces an acid with one carbon atom less than the parent naphthenic acid whereby a progressive degradation of the carboxylated side chain in the naphthenic acid molecule could be effected. The method is illustrated by the following case:

$$\begin{array}{l}
\mathrm{RCH_2COOH} \\
\Big\downarrow \text{ esterification} \\
\mathrm{RCH_2COOC_2H_5} \\
\Big\downarrow \text{ reduction} \\
\mathrm{RCH_2CH_2OH} \\
\Big\downarrow + \mathrm{HBr} \\
\mathrm{RCH_2CH_2Br} \\
\Big\downarrow + \mathrm{(CH_3)_3N} \\
\mathrm{RCH_2CH_2N(CH_3)_3Br} \\
\Big\downarrow \text{ decomposition of quaternary base} \\
\mathrm{RCH{=}CH_2} + \mathrm{(CH_3)_3N} + \mathrm{H_2O} \\
\Big\downarrow \text{ oxidation} \\
\mathrm{RCOOH}
\end{array}$$

(3) *Lactone Method.* In cases where the carboxyl group is linked to the ring through three CH_2 groups the following series of reactions lead to the formation of a lactone readily identifiable by oxidation.

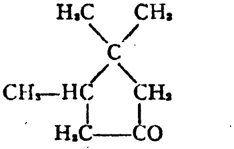
$$\begin{array}{l}
\mathrm{RCH_2CH_2CH_2COOH} \\
\Big\downarrow \text{ esterification and bromination} \\
\mathrm{RCH_2CH_2CHBrCOOC_2H_5} \\
\Big\downarrow \text{ elimination of HBr} \\
\mathrm{RCH_2CH{=}CHCOOH} \\
\Big\downarrow \text{ rearrangement} \\
\mathrm{RCH{=}CHCH_2COOH} \\
\Big\downarrow
\end{array}$$

$$\underbrace{\mathrm{RCH{-}CH_2{-}CH_2{-}CO}}_{\mathrm{O}}$$

Lactone

Of the three methods of attack the most valuable are the first and second, which lead to a degradation of the side chain with the production of acids or ketones of lower molecular weight. By this process of progressively shortening the side chain the constitution of the side chain containing the carboxyl group can be definitely determined.

Von Braun has applied the above methods to the elucidation of the constitution of naphthenic acids of Rumanian, Galician, German, Californian, and Texan origin, with the following results. Investigation of *Galician* naphthenic acids showed that the acids boiling between 125° C. (12 mm.) and 210° C. (0.1 mm.) belong to the class of monocyclic acids. The fraction of boiling point 145°-150° C. (12 mm.) possessed the formula $C_9H_{17}COOH$ and was shown to consist of acids of the two types $C_7H_{13}CH_2CH_2COOH$ and $C_7H_{14}CHCH_2COOH$ since on treatment by Method 1 a mixture of ketones $C_7H_{14}CO$ and an acid $C_7H_{18}COOH$ was obtained. From the mixtures of ketones, a small amount of one having the following constitution (as shown by later work)[71] was obtained:



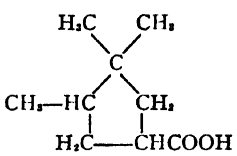
3,3,4-trimethylcyclopentanone-1

The fraction boiling from 190° to 200° C. (12 mm.) of Galician naphthenic acids was proved to contain a monocyclic acid of the formula $C_{13}H_{25}CH_2COOH$, since on degradation by Method 1 it yielded a monocyclic ketone, $C_{12}H_{24}{>}CO$. The fraction boiling from 195° to 205° C. (0.1 mm.) corresponded with the formula $C_{18}H_{34}O_2$ and was proved to contain a monocyclic acid of the formula $C_{14}H_{27}CH_2CH_2CH_2COOH$ by the lactone method.

Examination of Rumanian naphthenic acids by von Braun yielded the following results.

Fraction boiling from 118° to 127° C. at 12 mm. contained a mixture of various monocyclic acids of 7 and 8 carbon atoms.

Fraction boiling from 139° to 140° C. at 12 mm. contained several isomeric acids of the formula $C_8H_{15}COOH$. A small proportion of these acids was of the $C_7H_{14}CHCOOH$ type, such as the acid

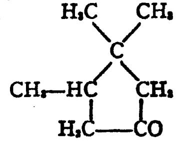


but a greater proportion contained acids of the type $C_7H_{13}CH_2COOH$. Degradation of the latter acid by Method 1 resulted in the production of an acid $C_6H_{11}COOH$ and a ketone $C_6H_{12}{>}CO$, so that both the molecular types of $C_6H_{11}CH_2CH_2COOH$ and $C_6H_{12}{>}CHCH_2COOH$ were present.

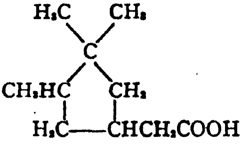
Fraction boiling from 150° to 155° C. at 12 mm. ($C_9H_{17}COOH$) was examined exhaustively by all the three methods outlined previously. Method 3—the lactone method—showed the presence of acids of the type $C_6H_{11}CH_2CH_2CH_2COOH$ containing isomeric methylcyclopentyl residues. The use of Method 2 resulted in the formation of a mixture of isomeric acids of the type $C_8H_{15}COOH$, this demonstrating the absence in the original acids of any acids in which the carboxylic group is linked directly with the cyclic system. Finally, Method 1 yielded an acid of the formula $C_7H_{13}COOH$ (derived from an original acid of the type $C_7H_{13}CH_2CH_2COOH$) and a mixture of ketones, $C_7H_{14}>CO$, in which was identified a compound of the formula

---

[71] Von Braun, Mannes and Reuter, *Ber.*, 1933, 66, 1499.



This ketone could only have been derived from a $C_{10}H_{18}O_2$ acid of the formula



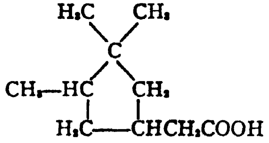
which is also present in the C_{10} acids of Galician and Californian naphthenic acids. Summarizing, it can thus be inferred that in this fraction of $C_{10}H_{18}O_2$ acids, molecules of the type $C_6H_{11}CH_2CH_2CH_2COOH$, $C_7H_{13}CH_2CH_2COOH$, and $C_8H_{15}CH_2COOH$ were present, but no acids containing a carboxyl group linked directly to the cyclic system.

The fraction boiling from 180° to 200° C. at 12 mm. of Rumanian acids corresponded to the formula $C_{14}H_{24}O_2$ and was evidently bicyclic. Conversion into the amine $C_{13}H_{23}NH_2$ and then into olefin $C_{13}H_{22}$, followed by oxidation, yielded ultimately a bicyclic ketone $C_{11}H_{20}>CO$ so that the original acid possessed the constitution $C_{11}H_{20}>CHCH_2COOH$. The character of the bicyclic system involved has not been determined.

Fraction boiling from 200° to 220° C. at 12 mm. ($C_{16}H_{28}O_2$) contained a bicyclic acid which yielded, by a treatment similar to that described above, a bicyclic ketone of the formula $C_{13}H_{24}>CO$.

Fraction boiling from 220° to 240° C. at 12 mm. of the formula $C_{18}H_{32}O_2$, furnished another bicyclic ketone of the formula $C_{15}H_{28}>CO$.

Californian Naphthenic Acids. *The fraction boiling from 145° to 155° C. at 12 mm.* consisted of monocyclic C_{10} acids which yielded, by Method 1, a mixture of monocyclic ketones, $C_7H_{14}>CO$. In this ketone mixture it was found possible to identify 3,3,4-trimethylcyclopentanone so that the original acid mixture undoubtedly contained an acid of the structure



as well as other isomeric acids with a $-CH_2COOH$ side chain.

Fraction boiling from 162° to 172° C. at 12 mm. contained monocyclic C_{12} acids. Conversion into the amine $C_{11}H_{21}NH_2$ and olefin $C_{11}H_{20}$, followed by oxidation, furnished a mixture of ketones of the formula $C_9H_{18}>CO$, from which a single individual ketone, $C_{10}H_{18}O$, was extracted. This ketone is isomeric with menthane and contains a five-membered ring.

Fraction boiling from 180° to 200° C. at 12 mm. possessed the formula $C_{13}H_{22}O_2$, and degradation by the amine method yielded a bicyclic ketone, $C_{11}H_{18}O_2$.

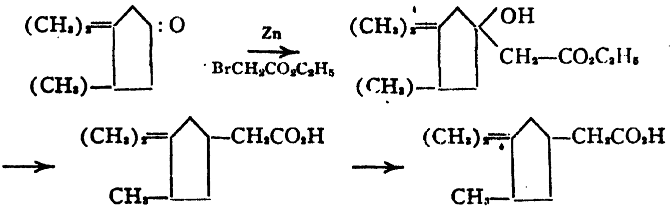
Fraction boiling from 200° to 220° C. at 12 mm. consisted of bicyclic monocarboxylic acids of the formula $C_{14}H_{24}O_2$. The usual amine degradation furnished a mixture of bicyclic ketones, $C_{11}H_{20}>CO$, from which a single individual was isolated which proved to be identical with the ketone derived from the $C_{14}H_{24}O_2$ acids of Rumanian naphthenic acids. Both the original acids, therefore, possessed the constitution $C_{12}H_{21}CH_2COOH$, in which the $C_{12}H_{21}-$ radieal represents a bicyclic hydrocarbon residue.

The fraction boiling from 260° to 280° C. at 12 mm. from Rumanian petroleum constituted the highest molecular weight acids isolated by von Braun. This fraction consisted of bicyclic acids of the formula $C_{20}H_{36}O_2$.

Examination of naphthenic acids in Texas crudes showed that the acid fractions with 12 carbon atoms were monocyclic while the higher fractions contained only bicyclic acids.

The results of von Braun indicate that Rumanian, German, Californian, and Texan naphthenic acids consist of both monocyclic and bicyclic monocarboxylic acids, the bicyclic acids preponderating in the higher fractions with 13 and 14 carbon atoms. In the case of the Galician acids, however, the monocyclic types appear to persist even in fractions as high as C_{18} fractions, these being the highest monocyclic acids encountered by von Braun. Tri- and polycyclic acids have not yet been identified in the fractions so far examined, but their existence is indicated by the work of Alleman and Maitland.

Later, von Braun, Mannes and Reuter[72] prepared a pure naphthenic acid, 3,3,4-trimethylcyclopentylacetic acid. This acid was formed from 3,3,4-trimethylcyclopentanone-1. The course of the synthesis is indicated by the following:



CHEMICAL AND PHYSICAL PROPERTIES OF NAPHTHENIC ACIDS

Crude naphthenic acids from different crude oils and distillates vary greatly in physical and chemical characteristics. Acids of low molecular weight such as those obtained from Baku petroleum are volatile oils of penetrating odor, while high molecular weight acids such as those obtained from lubricating stocks are viscous, and in some cases semi-solid, materials. Crude acids frequently contain relatively large amounts of foreign substances including neutral compounds and resins and for this reason often exhibit an iodine absorption value. However, all purified naphthenic acids appear to be fully saturated substances so that the iodine values of crude acids is a sign of their contamination with foreign materials. In Table 159 will be found Pyhälä's[73] data on the properties of various commercial naphthenic acids from Baku petroleum:

TABLE 159.—*Properties of Commercial Naphthenic Acids from Baku Petroleum.*

Source of Acid	Acid No.	d^{15}	Iodine No.	Viscosity at 30° C.
Kerosene	255	0.9650	0.9	4.23° Engler
Same	230	0.9504	2.62	—
Light solar oil	170.0	0.9513	2.42	15.00° E
Vaseline oil	152.0	0.9471	—	—
Heavy solar oil	136.0	0.9418	2.50	18.96° E
Spindle oil	108.0	0.9358	6.17	34.76° E
Machine oil	87.5	0.9350	7.18	47.71° E
Cylinder oil	32.6	0.9294	11.36	97.92° E

In many instances crude acids are of a very dark color, particularly those from the higher fractions of petroleum. Schwarz and Marcusson[74] described a crude naphthenic acid from Russian lubricating stock which was a brownish-black, thick, oily liquid with an acid number of 118.3 and an iodine number (Waller) of 5.5, soluble in benzine and containing much combined sulphur. Acids from Galician and Rumanian lubricating stocks were brownish-black resinous substances, soluble in benzine, and having acid numbers of 87.6 and 157.4, respectively.

[74] *Chem. Rev. Fett.- u. Harzindustrie*, 1908, 15, 165; *Chem. Zentr.*, 1908, 2, 352.

The acids obtained from American lubricating stocks by the Alleman process[75] are dark in color and have an acid number of 103, but the acid numbers of the distilled acids is generally higher. For example, distillation of the acids under 4 mm. pressure yielded the following fractions:

Boiling Range °C. (4 mm.)	Acid No.
Up to 180	187
180–190	174.4
190–200	160
Residue (containing resins)	61

Other acids, obtained by hydrolyzing the naphthenic soaps with steam under pressure followed by acidification with hydrochloric acid and distillation under reduced pressure, were very dark in color and had an acid number of 85. Acids obtained in the same way, but further purified by means of alcohol, had an acid number of 124 and were of a light amber color. These are polycyclic monocarboxylic acids containing 16 to 25 carbon atoms, and are low-melting viscous oils.

Purified naphthenic acids from various sources also exhibit a wide variation in physical properties, but their chemical properties are more uniform and differ only in degree. A large number of purified naphthenic acid fractions (most of which undoubtedly contained mixtures of isomers and frequently of homologues) have been described. All these acids appear to be colorless, or faintly colored oily liquids, distillable unchanged at 200° to 300° C. and volatile in steam. Their densities are all less than 1 but appear to decrease with increasing molecular weight—at least in the case of the monocyclic acids of the formula $C_nH_{2n-2}O_2$. They are insoluble or sparingly soluble in water, but are soluble in hydrocarbons and in many organic solvents. Their viscosities increase with increasing molecular weight, while their surface tensions decrease.[76] They exert a corrosive action on many metals especially lead, zinc, copper, and tin, but aluminum is resistant to their action.[77] Corrosion of refinery equipment due to naphthenic acids has been reported by Vuiborova.[78]

Despite statements to the contrary, it seems that the simple monocyclic acids dissolve readily in concentrated sulphuric acid but may be precipitated unchanged by addition of water.[79] A remarkable case of irreversible adsorption of naphthenic acids by fuller's earth has been recorded by Gurwitsch,[80] who found that filtration of the acids through this material resulted in the adsorption of about 6 per cent which could not be extracted from the adsorbent by organic solvents.

The antiseptic properties of the (monocyclic) naphthenic acids, exhibited also by many of their salts, was noted by Charitschkow,[80a] who ascribed this property to the presence of a cyclopentyl ring since benzoic and hexahydrobenzoic acids do not possess antiseptic powers. The subject was further investigated by Spalwing,[80b] who found that 1 per cent of free acids, or their salts in a concentration of 1:100, exerted as powerful an effect on various pathogenic organisms as 3 per cent of phenol. The free acids appear to be the most effective, followed by their copper, iron, zinc, and aluminum salts in the order of their activities. According to Kupsis,[80c] the naphthenic acids exhibit toxic properties particularly toward fish. That the toxicity of some crude petroleums and residues is destroyed by washing with alkali indicates that such toxicity is due to their naphthenic acid content.

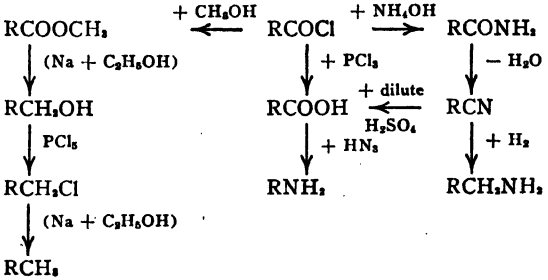
In chemical properties the naphthenic acids exhibit the characteristic properties of monocarboxylic saturated aliphatic acids. They are stable and do not combine additively with halogens. Under certain conditions, however, they are attacked by bromine with the formation of bromine substituted compounds accompanied by the evolution of hydrogen bromide. Their ease of esterification by aliphatic alcohols in the presence of a catalyst, such as concentrated sulphuric acid or hydrogen chloride, has already been mentioned and a considerable number of such esters, more especially the methyl esters, have been prepared. It is interesting to note that dimethyl sulphate (or other dialkyl sulphates) may be used for esterification of these acids.[81] The methyl and ethyl esters of the monocyclic acids are oily liquids possessing somewhat fruity odors. Esters of naphthenic acids with glycerol have also been prepared by heating three molecules of the acid with one molecule of glycerol to 250° C. for several hours.[82] Reduction of the methyl or ethyl esters by the method of Bouveault and Blanc leads to the production of a primary alcohol.[83] For example, the reduction of the ethyl ester of undecanaphthenic acid (from Baku petroleum) by sodium and ethyl alcohol resulted in the formation of the corresponding alcohol, undecanaphthenol, boiling point 236.5°-237.5° C.[84]

$$C_{10}H_{19}COOC_2H_5 + 2H_2 \longrightarrow C_{10}H_{19}CH_2OH + C_2H_5OH$$

A considerable number of simple derivatives of the monocyclic acids containing 7 to 14 carbon atoms have been prepared by various workers and their formation may be summarized in the following scheme:



$$\begin{tikzcd}
RCOOCH_3 \arrow[d, "(Na + C_2H_5OH)"] & RCOCl \arrow[l, "+ CH_3OH"'] \arrow[r, "+ NH_4OH"] \arrow[d, "+ PCl_3"] & RCONH_2 \arrow[d, "- H_2O"] \\
RCH_2OH \arrow[d, "PCl_5"] & RCOOH \arrow[d, "+ HN_3"] & RCN \arrow[l, "+ \text{dilute}"', "H_2SO_4"] \arrow[d, "+ H_2"] \\
RCH_2Cl \arrow[d, "(Na + C_2H_5OH)"] & RNH_2 & RCH_2NH_2 \\
RCH_3 & &
\end{tikzcd}$$

Of the derivatives of the monocyclic acids, the amides are white crystalline solids and the acid chlorides are liquids which can be distilled without decomposition at 200° to 260° C. The two amines produced according to the above scheme are strongly basic liquids with an ammoniacal odor. In this connection it is interesting to note that the salts of the amine $C_{19}H_{35}NH_2$ produced from the bicyclic acids, $C_{20}H_{36}O_2$, of a higher fraction (boiling from 250° to 270° C. at 12 mm.) of Rumanian naphthenic acids were found (by von Braun) to possess marked emulsifying properties in aqueous solution, just like solutions of the alkali salts of the higher fatty acids except that the former react acid in solution. Arylamino derivatives of naphthenic acids have been prepared by reacting the acids with aromatic amines.[84a] On sulphonation the sulphonic acid group is said to enter the aromatic ring of such compounds.

The work of von Braun has furnished numerous methods of converting these acids into other substances such as amines,[84b] ketones and lower acids, and will no doubt lead to an extension of our knowledge of hydrocarbons possessing a cyclopentane ring and possibly also of saturated bicyclic hydrocarbon structures.

The possibility of converting naphthenic acids into ketones, which may be utilized as solvents, has engaged the attention of a number of workers. Stadnikov and Donde[85] made use of the method of Grün,[86] which consists in heating high-boiling organic acids to a temperature of 200° to 300° C. Caucasian naphthenic acids, boiling between 140° and 190° C. at 25 mm., were introduced drop by drop into a reaction tube containing a catalyst of ferric oxide on asbestos. The acids were unchanged at 360° to 370° C., but at 450° C. underwent a reduction of acid number from 220 to 47 and the catalyst was soon rendered inactive. From 525 grams of naphthenic acid there were finally obtained 340 grams of a product with an acid value of 94, consisting of a mixture of unsaturated hydrocarbons and oxygenated compounds in which ketones were only present in an insignificant amount. Greater success was achieved by Zelinsky and Rjachina,[87] who passed a mixture of acetic acid and mixed naphthenic acids, from Balachany (Caucasus) petroleum, over a catalyst of mixed manganous and zinc oxides at 410° to 420° C. and obtained as a product a mixture of acetone, ketones derived from naphthenic acids and acetic acid, and ketones derived from naphthenic acids only. The reactions, in which RCOOH represents a naphthenic acid, may be represented as:

$$2CH_3COOH \longrightarrow CH_3COCH_3 + CO_2 + H_2O$$
$$R.COOH + CH_3COOH \longrightarrow RCOCH_3 + CO_2 + H_2O$$
$$2RCOOH \longrightarrow RCOR + CO_2 + H_2O.$$

Passage of a mixture of 240 grams of naphthenic acids (boiling from 235° to 250° C.) and 304 grams of acetic acid quickly over the above catalyst at 410° to 420° C. yielded 170 grams of crude ketones and 110 grams of unchanged acids. Slower passage of a mixture of 430 grams of naphthenic acids with 500 grams of acetic acid over the same catalyst at the same temperature furnished 470 grams of ketones and only 29 grams of unchanged acids.

The ketones regenerated from the bisulphite compounds were mixtures of isomers derived from the acids C_5H_9COOH, $C_7H_{13}COOH$, and $C_8H_{15}COOH$, and acetic acid. The following ketones are described by Zelinsky and Rjachina, all of the type $C_nH_{2n-1}COCH_3$:

[84a] Soc. des produits chimiques et matières colorantes de Mulhouse, French Patent 711,952, 1930; *Chem. Abs.*, 1932, **26**, 1943.

[84b] *Cf.* Schmidt, German Patent 500,435, 1928; *Chem. Abs.*, 1932, **26**, 2198; German Patent 544,890, 1930; *Chem. Abs.*, 1932, **26**, 3515; both patents assigned to Knoll A.-G. Chem. Fab.

[85] *Trans. Karpov Inst. Chem.*, 1925, No. 4, 188; *Chem. Abs.*, 1926, **20**, 2152.

[86] German Patent 295,657, 1914; *J.S.C.I.*, 1917, **36**, 569.

[87] *Ber.*, 1924, **57B**, 1932; *Chem. Abs.*, 1925, **19**, 647.

$C_7H_{12}O$ b.p. 177°–184° C., semicarbazone m.p. 105°–107° C.

$C_8H_{14}O$ b.p. 184°–190° C., d^{15}_{4} 0.8836, semicarbazone m.p. 135° C.

$C_9H_{16}O$ b.p. 204°–207° C., d^{15}_{4} 0.8921, semicarbazone m.p. 142° C.

$C_{10}H_{18}O$ b.p. 210°–212° C., d^{21}_{4} 0.8861, semicarbazone m.p. 140° C.

The ketones which did not combine with sodium bisulphite were separated by distillation into a series of fractions each containing a large number of isomers. Ketones boiling from 190° to 207° C. were derived from the naphthenic acids, $C_7H_{13}COOH$. Those boiling in the ranges, 207° to 210° C., 212° to 215° C. and 220° to 235° C., corresponded with the acids $C_8H_{15}COOH$, $C_9H_{17}COOH$, and $C_{10}H_{19}COOH$, respectively.

The formation of small amounts of ketones by the oxidation of crude naphthenic acids (of acid number 267) in ammoniacal solution with hydrogen peroxide has been noted by Naphthali.[88] Beckman[89] described a method of producing ketones from naphthenic acids which consists in passing the oil vapors through two reaction chambers containing lime. The first chamber is maintained at 200° C. and the second at 400° C. Ketones of the formula $C_nH_{2n}O$ are said to be formed.

The cracking of naphthenic acids under pressure in the presence of water and alumina has been investigated by Ipatiew and Petrov.[90] The products consisted of acetone, acetic and formic acids in the aqueous layer and an oily layer containing paraffinic, naphthenic and unsaturated hydrocarbons, ketones, and naphthenic and paraffinic acids. The following three reactions were suggested to explain the various products: (1) Splitting off of the carboxyl group with the formation of a naphthene which may be further degraded; (2) formation of lower molecular weight naphthenes by fission of the side chain containing the carboxyl group; and (3) formation of fatty acids from the carboxylated side chains so eliminated.

APPLICATIONS OF NAPHTHENIC ACIDS

The most important use of naphthenic acids is in the manufacture of soaps, detergent compositions, greases and water-soluble oils, for which purposes the sodium salts are most frequently employed.[91] A number of other metallic salts have also found important application for various purposes. The free naphthenic acids have been proposed as suitable solvents for vulcanized rubber,[92] various resins and gums such as copal, dammar, sandarac, and mastic,[93] and for aniline dyes.[94] According to Petit,[95] the viscosities of concentrated colloidal solutions (generally containing at least one organic solvent) can be reduced, without further modification of their properties, by the addition of naphthenic acids. It was stated that the fluidity of printing inks may be improved by the addition of these acids.[96] Their use in clarifying agents for petroleum oils has been suggested by Swartz.[96a] Evans [96b] recommended nitrated or sulphonated naphthenic acids for breaking petroleum emulsions. Pyhälä [96c] described the separation of crude-oil emulsions with naphthenic acids. The incorporation of 5 to 40 per cent by volume of naphthenic acids with hydrocarbons to yield motor fuels is described by Kleinschmidt.[97] Sulphonation of these acids with chlorosulphonic acid gives materials which are cleansing, emulsifying and wetting agents.[98] Materials with similar properties can also be made by condensing sulphonated naphthenic acids with amines, amino acids, or aminoalcohols.[98a] Naphthenesulphonic acids have been recommended as catalysts in the preparation of acrolite resins.[98b] Transparent sheets have been made from gelatin, a mineral oil, and sulphonated naphthenic acids.[98c] Naphthenic glycerides have been recommended as ingredients of coating compositions for stencil sheets.[99] A mixture prepared by heating at 240° C. oleic acid (which had been preliminarily heated to 150° C.), seal or cod-liver oil, naphthenic acids and sufficient glycerol for esterification, has been suggested for removing fats from hides.[99a] The free acids have been proposed as constituents for insecticides.[100] Addition of about 15 per cent of naphthenic acids to wood (tung) oil prevents gelatinization during heating and a thick clear oil is obtained which dries without cracking or yielding a web-like formation.[101] The free acids can also be incorporated in detergent compositions,[102] and esters of the bromo- or chloroacids or cyclohexyl esters [102a] of naphthenic acids may be employed as plasticizers.[103] The penetrating or wetting power of mercerizing lyes can be improved by the addition of naphthenic acids,[104] the naphthenic esters of the lower monohydric alcohols,[105] or of naphthenic alcohols obtained by the reduction of the corresponding acids.[106] Alcohols containing more than three hydroxyl groups (e.g., pentaerythritol) are esterified with a mixture of naphthenic and resin acids and then blown with air or vulcanized.[107] The products may be used as coating compositions or in the preparation of lacquers.

gen under pressure in the presence of heavy metal naphthenates.[108] Another procedure consists in treating naphthenic esters with metallic sodium and an alcohol.[109] Chlorination or sulphonation (with chlorosulphonic acid) of these alcohols yields materials which are wetting, emulsifying or dispersing agents;[110] or the alcohol may first be converted to the chloride (with hydrochloric acid) and afterwards heated (under pressure) to 150° to 180° C. with an aqueous-alcoholic solution of sodium sulphite.[111]

THE NAPHTHENIC ACID SOAPS AND THEIR USES

Of the salts of the naphthenic acids, the sodium soaps are by far the most important. The commercial sodium soaps usually possess the consistency of greases but the purified soaps of the lower monocyclic acids are frequently crystalline solids. Thus, sodium octanaphthenate has been described as a non-hygroscopic solid, crystallizable without water of crystallization. The sodium salts of the monocyclic acids are soluble in water but their solubility decreases with increasing molecular weight of acid. They may be salted out of solution with common salt, but not as readily as the soaps derived from coconut oil and other vegetable acids.[112] Furthermore, the naphthenic acid soaps are hydrolyzed in aqueous solution only to a very slight extent as compared with the fatty acid soaps.[112] The naphthenic soaps combine excellent emulsifying and foam-producing properties with a low hydrolytic dissociation and therefore are of value as mild detergents, for example for use in the textile industries. The power possessed by naphthenic soap solutions of readily forming emulsions with water-insoluble mineral oils has been referred to. Gurwitsch[113] found that the solubility of the oil increases as the concentration of the soap in the aqueous solution is increased and with increasing molecular weight of naphthenic acid used, but decreases with rising temperature. The dissolved oil is removed only with the greatest difficulty by shaking with petroleum ether, and is not precipitated by free naphthenic acids, but is easily separated by the addition of an equal volume of alcohol. The indications are, therefore, that solutions of mineral oils in naphthenic acid soap solutions are the result of adsorption of the oil on the micelles of the soap.

The properties of a sodium soap prepared from a mixture of Japanese naphthenic acids (d_4^{15} 0.9708 and acid number 249.2) have been described by Mikumo,[114] more especially with reference to surface and interfacial tensions and emulsifying, lathering and detergent properties. The naphthenic acid soap was extremely soluble in cold water and was superior to coconut oil soap in lathering power. It was, however, soft and far inferior to an oleate soap in detergent action, and appeared to occupy a position intermediate between fatty and rosin soaps.

Kawakami[115] examined the properties of the sodium salt of mixed naphthenic acids (boiling between 195° and 200° C. at 10 mm., d_{15}^{25} 0.9605, mean molecular weight 246.5 and acid number 228.0) which was used in the soap industry. The detergent action and lathering power of the naphthenic soap were compared with those of sodium palmitate and mixed toilet soap, the latter two proving to be a little superior to the former. The gelation capacity of the sodium naphthenate was found to be extraordinarily great. Cooling a 40 per cent aqueous solution of this soap to 0° C. for 30 minutes did not cause complete solidification, thus demonstrating its applicability in neutral soft and liquid soaps. Larger amounts of common salt were required to salt the sodium naphthenate out of aqueous solution than in the case of a coconut oil soap. The sodium naphthenate was hydroscopic in moist air.

White and Knopf[116] described a gear lubricant (having a MacMichael viscosity of 70 to 85 poises at 38° C.) comprising an oxidized light lubricating oil, heavy flux and sodium naphthenates substantially free from water. Rudigier[117] proposed to compound a heavy residual oil containing sodium naphthenates with a mineral lubricating distillate of viscosity 65 to 200 sec. (Saybolt) at 38° to yield a product of viscosity above 125 sec. (Saybolt) at 100° C. and a pour test not above 3° C. Velikovskii[117a] prepared greases by heating small proportions of lead oxides with naphthenic acids to about 270° C. under increased pressure together with fatty acids, glycerol and castor oil in the presence of iron. To eliminate separation of constituents in greases made from naphthenic soaps and mineral oils,[117b] he proposed converting the naphthenic acid into its glycerol ester, which is saponified in the subsequent heating.

The property of sodium naphthenates of stabilizing oil-water emulsions may be employed in the manufacture of benzene, and other hydrocarbon, emulsions in water for use as detergents, defatting agents or spraying compositions,[118] as well as emulsions of asphaltic substances which are applicable as paving materials or binding agents.[119] In the preparation of some of these products the marked disinfectant properties of the naphthenic acid soaps are of considerable value.[120] The addition of 6 to 8 per cent sodium naphthenates to an alkaline cold-swelling starch produces a dry painters' size which does not deteriorate on storage.[121] Graphite mixed with a solution of gum tragacanth, triethanolamine, and a small proportion of sodium naphthenates gives a lubricant.[122]

OTHER NAPHTHENIC ACID SALTS

A general method of preparation of the calcium and heavy metal salts of the naphthenic acids consists in mixing an aqueous solution of an alkali naphthenate with a solution of a salt of calcium or heavy metal.[123] Thus, by the addition of a solution of calcium chloride to an alkali naphthenate solution, the calcium naphthenate is usually precipitated by double decomposition:

$$2RCOONa + CaCl_2 \longrightarrow (RCOO)_2Ca + 2NaCl$$

The calcium and barium salts of the monocyclic acids are obtained either in the form of crystalline solids or as viscous pasty masses. They are soluble to a slight extent in water, insoluble in hydrocarbons, but usually somewhat soluble in alcohol. The calcium salts have been proposed as constituents of various fats and greases and for the manufacture of water-soluble oils or cutting compounds. The calcium salt of the polycyclic acid, obtained from American crudes by the Alleman process,[124] are light sticky tenacious masses practically insoluble in water. They are very soluble in ethyl acetate, carbon tetrachloride, gasoline, benzene, or ether, dissolve to some extent in turpentine and linseed oil, but are only slightly soluble in ethyl and methyl alcohols and acetone. The calcium salts may be used in waterproofing compositions, adhesives, wood fillers, grafting waxes, cements, varnishes, etc. The barium and calcium salts are particularly useful, however, in the preparation of color lakes to be used in the manufacture of lithographic and printing inks, colored paints, and varnishes.[125]

A considerable number of metallic naphthenates have been described and some of these are of technical importance. In connection with the double decomposition method of preparation used by practically all workers, it has been pointed out that precipitation is best carried out at the boiling temperature of the solution and that the precipitate may be dried at 130° C.[126] Of the salts of the *monocyclic acids,* the copper compounds are remarkable in that they dissolve in benzine, yielding a green solution.[127] This reaction (the so-called Charitschkoff test) has been used as a method of identification of naphthenic acids.[127a] Most of the heavy metal salts are amorphous solids, frequently highly colored, are only slightly soluble in water, but dissolve in hydrocarbons. A number of salts of trideca-, tetradeca-, and pentadeca-naphthenic acids have been prepared by Tanaka, Horiuchi, and Oyama.[128] The lead salts are transparent resinous solids. The manganese tridecanaphthenate is a pink powder, soluble in ether but practically insoluble in hot or cold water. Aluminum naphthenates are transparent colorless porous masses, the magnesium and zinc salts being white powders. Chromium salts were obtained in two modifications, namely, a violet powder at temperatures below 40° C. transformed into a green viscous mass by warming. The solubilities of the salts decrease with increasing molecular weight of acid. According to Yamada,[129] the solubilities of metallic oleates and naphthenates are on the whole very similar. Exceptions are mercury and lead naphthenates which are easily soluble in alcohol at 5° C. (over 33 per cent and 29 per cent, respectively), while the corresponding oleates are practically insoluble. Again, acetone at 5° C. dissolves over 22 per cent of zinc naphthenate but less than 0.4 per cent zinc oleate.

A number of the metallic salts of the (monocyclic) acids have found application in industry and arts. Copper naphthenate is a wood preservative[130] as well as an insecticide and fungicide.[131] The copper salt may be prepared by decomposing sodium naphthenate with copper sulphate in aqueous solution. It is soluble in gasoline and mineral oil distillates and may be applied in the form of these solutions. The zinc[132] and lead[133] salts may also be employed as wood preservatives. Solutions of aluminum naphthenates in organic solvents, with or without the addition of wetting agents, are said to be insecticides.[134] Metallic naphthenates, e.g., those of zinc, magnesium and lead, which are difficultly soluble in water, have been proposed as insulating materials.[135] According to Yamada,[136] the addition of 0.1 per cent of tin naphthenate to transformer oils exerts an inhibitory effect on sludge formation. Deterioration of lubricating oils in service is lessened by the addition of mercury naphthenates.[137] Lead naphthenates have been suggested as drying agents in varnishes,[138] as a catalyst[138a] for the reaction between unsaturated fatty acids and sulphites in the presence of air, and as substances for admixture with lubricating oils to produce "chatterless" oils.[139] Mercury compounds of naphthenic acids or their esters are said to be antiknock ingredients.[140] The use of chromium and aluminum naphthenates as siccatives is described by Ruth and Asser.[141] An emulsion of ammonium naphthenate and solvent naphtha can be employed for spraying plants, and is said to be less harmful than free naphthenic acids or their alkali or alkaline-earth salts.[142] Lead, zinc or tin naphthenates, together with a small proportion of aluminum naphthenate, can be melted with a small amount of ceresin, naphthenic acid glycerides and castor or mineral oil to give insecticides.[143]

An interesting application of the heavy metal salts (particularly the cobalt, manganese, and lead salts) in the form of their solutions in the fatty acids of drying or non-drying oils[144] or in mixtures of fatty acids and drying oils[145] is as paint and varnish driers. The so-called "Soligen" driers consist of such solutions of heavy metal naphthenates (from Russian naphthenic acids), particularly the cobalt salts. According to Stock,[146] linseed oil varnishes containing 0.14 per cent to 0.29 per cent of cobalt, as naphthenates, dry in 1 to 10 per cent less time than those containing a resinate drier. Petrov[146a] suggested the addition of heavy metal salts of naphthenic acids to improve the odor of petroleum distillates.

The copper, chromium, and nickel salts of the (polycyclic) naphthenic acids, obtained from American lubricating stocks by the Alleman and Maitland processes,[147] are green in color and may be used as paints. The cobalt salt, which is purple, can be used in a similar manner. The manganese salt is mahogany in color and hardens on exposure to air.

The heavy metal salts have also been suggested as ingredients of rust-proof coating compositions for metals,[148] particularly those containing benzyl cellulose, as preservatives for threads, cordage and textiles,[149] and as agents to reduce or suppress the viscosity or sticky nature of asphalts.[150] Refined petroleum asphalts, mixed with natural or synthetic resin and iron naphthenate, can be employed in the manufacture of rubberized cloth.[151]

Chapter 49

Analysis of Natural Gas and Cracking Gas

The methods ordinarily employed for the analysis of the usual industrial gaseous fuels, such as coal gas and producer gas, are not generally applicable to the precise analysis of natural petroleum gases or of gases obtained during the pyrolysis of hydrocarbons, e.g., in commercial cracking operations. This is because of the fact that the two types of petroleum gases often contain very large proportions of several individual gaseous hydrocarbons which are difficult to separate from one another on a laboratory scale. Thus, natural gas usually contains large proportions of methane together with ethane, propane, butanes, and even higher paraffin hydrocarbons, whereas the analysis of cracking gas is still further complicated by the presence of unsaturated hydrocarbons, as well as of hydrogen. With the exception of carbon dioxide and hydrogen sulphide, which often occur to some extent in natural petroleum gases, none of the constituents of natural gas can be estimated by the rapid and accurate absorption methods used for other industrial gases. Moreover, the analysis of industrial gases (e.g., coal gas) is not beset by the necessity of separating a number of homologous hydrocarbons, since methane is their preponderant hydrocarbon constituent.

The importance of accurate and reliable methods for the analysis of the complex gas mixtures encountered in the petroleum industry cannot be overemphasized. Analytical control of the natural-gasoline extraction industry has made possible the accurate assessment of plant efficiency, establishing scientific control of operations which were formerly governed more or less empirically.[1] The need of reliable analytical data relating to hydrocarbon gases is also obvious in some of the newer applications of such materials in industry, e.g., in the large-scale fractionation of hydrocarbon gases for the isolation of one or more constituents in a substantially pure condition. The increasing importance of unsaturated constituents of cracking gas in chemical synthesis, particularly the utilization of gaseous monolefins in the production of alcohols, makes it imperative to use reliable analytical methods. The development of procedures for the analysis of complex hydrocarbon mixtures has greatly facilitated the progress of research in certain branches of petroleum chemistry, especially the scientific study of pyrolytic reactions.

The following discussion is intended primarily as a brief account of the general methods available for the analytical investigation of hydrocarbon gas mixtures but it will also be necessary to refer, cursorily, to the estimation of certain non-hydrocarbon constituents of petroleum gases, most important of which are carbon dioxide, hydrogen sulphide, and, in the gases from cracking operations, hydrogen and carbon monoxide.[1a] It will be understood that most of the analytical methods discussed in this chapter are subject to a degree of experimental error which is probably never less than ±0.1 per cent and frequently much greater.

---

[1] See Burrell, "The Recovery of Gasoline from Natural Gas," Chemical Catalog Co., Inc., New York, 1925.

[1a] Carbon monoxide may be produced from petroleum gases, for example, in the catalytic high-temperature decomposition of hydrocarbons in the presence of steam, as discussed in Chapter 10.

In the analysis of coal gas and allied gases, two main methods of procedure have been employed, namely, absorption and combustion (or explosion). Later, methods for the analysis of hydrocarbon gas mixtures made use of a third mode of operation, that of low-temperature fractionation (or in some cases, fractional condensation). Besides the above, several special methods, which depend upon the accurate determination of various physical constants, are available for the estimation of hydrocarbons in mixtures. However, since these latter methods are only applicable in general to mixtures of two (or, at most, of three) components, their value in the investigation of natural and cracking gases is limited.

ANALYSIS BY ABSORPTION

The first methods available for the analysis of gases depended upon the removal of an individual constituent or group of components of the mixture by appropriate liquid reagents in a definite order. From the quantity of gas removed after each absorption, the composition of the mixture was determined. The choice of absorbing liquids is frequently a somewhat difficult one, particularly for unsaturated hydrocarbons. Some of the reagents employed in gas analysis are capable of absorbing several constituents. However, by adopting a definite order of absorption it is possible to eliminate this difficulty to a large extent.

It is not necessary in a work of this scope to enter into a detailed description of the various types of apparatus employed for gas analysis by absorption. In brief, the usual method is to measure the volume of the gas at constant pressure in a eudiometer (gas burette) enclosed in a water-jacket (for temperature control) and supplied with a levelling device containing mercury, water, or other liquid (for pressure control). The gas is forced into a pipette containing the absorbent liquid where it remains for a definite period, after which it is withdrawn and its volume re-measured. Other constituents are removed and their volumes determined in the same manner. The percentage composition can be calculated from the losses in volume on absorption. One of the simplest forms of apparatus for absorption gas analysis is that of Orsat, of which numerous modifications and improvements have been elaborated.[2] In other forms of apparatus, somewhat different methods are employed. Bone and Wheeler [3] described an apparatus which combined a high degree of accuracy with a number of other advantages.[4] In this apparatus changes in the pressure of the gas at constant volume after absorption are observed instead of changes in volume at constant pressure, as in other methods. By this procedure, greater accuracy and faster manipulation are attainable. In the Orsat apparatus, for example, the absorptions are generally carried out in a number of large pipettes, each containing a particular reagent which is used again in successive analyses. On the other hand, in the Bone and Wheeler apparatus the absorptions are carried out in a vessel over mercury, with a comparatively small volume (2 to 5 cc.) of fresh reagent, which is discarded after use. By this method not only is the reagent fresh each time it is used, but the minimum quantity is employed, thus minimizing possible errors resulting from solution of other gaseous constituents in a large volume of liquid.

[2] A precise form of Orsat Apparatus, developed at the U. S. Bureau of Mines, is described in *U. S. Bur. Mines Bull.* **197** (1926); see also Shepherd, *Bur. Standards J. Research,* 1931, **6**, 121; *Chem. Abs.,* 1931, **25**, 1455.

[3] *J.S.C.I.*, 1908, **27**, 10.

[4] For a detailed description of the Bone and Wheeler apparatus, see Blair and Wheeler, *J.S.C.I.,* 1922, **41**, 187T; also Grice and Payman, *Fuel,* 1924, **3**, 236; *Chem. Abs.,* 1924, **18**, 3296.

Reagents for the absorption of the constituents of gas mixtures are described below in the order of their use in analysis. The period of contact of gas with reagent depends upon the amount to be absorbed and the activity of the reagent, but, in general, 2 to 5 minutes is sufficient.

Carbon dioxide is absorbed in a concentrated aqueous solution of potassium hydroxide, prepared by dissolving 500 grams (one pound) of stick potassium hydroxide (not that described as "purified by alcohol") in 500 cc. of distilled water. This reagent also absorbs hydrogen sulphide[5] and other acid constituents. Ambler[5a] used "ascerite" for the absorption of carbon dioxide.

Acetylene is best estimated by absorption in Lebeau's reagent,[6] an alkaline solution of potassium mercuric iodide, prepared by dissolving 25 grams of mercuric iodide and 30 grams of potassium iodide in 100 cc. of water. A small quantity of solid potassium hydroxide is added to this solution immediately prior to the absorption.

Several other reagents have been employed for the absorption of acetylene, for example, ammoniacal cuprous and silver salt solutions.[7] Since they also absorb olefins, diolefins, carbon monoxide, and other gases to some extent, they can have only a limited application.

Oxygen is estimated by absorption in an alkaline solution of pyrogallol, prepared immediately before use by adding a concentrated potassium hydroxide solution to about one-fourth of its volume of an aqueous solution of pyrogallol (28 grams in 100 cc. of water) in the absence of air.

Unsaturated hydrocarbons are next absorbed either in a dilute solution of bromine in fuming sulphuric acid or in concentrated sulphuric acid containing 1 per cent of silver sulphate. In this way the total unsaturated hydrocarbon content is obtained. An account of the analytical separation of the individual olefins is given later.

For the determination of the total unsaturated gases with bromine water, a saturated solution of bromine in 5 per cent aqueous potassium bromide is usually recommended but this solution should be diluted at least twice when mercury is used in the apparatus since mercury is attacked by the reagent. Oberseider and Boyd[8] found that bromine water has a tendency to attack paraffin hydrocarbons (in cracking gases) on exposure to daylight or artificial light. To overcome this a blackened absorption pipette was suggested. After the unsaturated constituents have been absorbed in bromine water, the gas must be washed with potassium hydroxide solution to remove bromine vapor.

Fuming sulphuric acid is a rapid absorbent for all olefins, but it also slowly absorbs paraffin hydrocarbons.

Carbon monoxide is absorbed in an ammoniacal cuprous chloride solution, prepared by passing ammonia gas into a suspension of 75 grams of pure cuprous chloride in 200 cc. of distilled water containing 25 grams of ammonium chloride in solution until all the cuprous salt has dissolved. The reagent must be freshly prepared and kept out of contact with air. For the complete removal of carbon monoxide at least two absorptions with fresh reagent are necessary. The gas is then washed with 5 per cent sulphuric acid to remove ammonia vapor before the gas volume is measured. Even after two or three treatments with ammoniacal cuprous chloride, small quantities of carbon monoxide often remain in the gas.

---

[5] Hydrogen sulphide is best estimated in a separate analysis. The determination of hydrogen sulphide and organic sulphur is discussed in Chapter 50.

[8] *Ind. Chem. Eng., Anal. Ed.,* 1931, 3, 123.

These traces [8a] may be estimated (as carbon dioxide) in the subsequent combustions of hydrogen over copper oxide.

Blacet, MacDonald and Leighton [8b] described a method for the microanalysis of gases by absorption with dry reagents instead of liquids. Yellow phosphorus is used for absorbing oxygen, potassium hydroxide for carbon dioxide, fused phosphorus pentoxide for water, silver oxide for carbon monoxide, fuming sulphuric acid for ethylene, and a mixture of cuprous chloride and potassium hydroxide for acetylene.

As a method for the analysis of air, Pozner and Melikova [8c] suggested the absorption of unsaturated hydrocarbons in lead acetate, aromatic hydrocarbons in sulphuric acid containing silver, and paraffins and naphthenes by activated charcoal.

ANALYSIS BY COMBUSTION AND EXPLOSION

The gas, after removal of the absorbable constituents, contains paraffin hydrocarbons, hydrogen and nitrogen. In the analysis of coal gas and other similar gases, in which the preponderating paraffin gas is methane, the determination of this residual gas is a comparatively simple matter. The hydrogen is preferentially oxidized to water either by copper oxide at 280° C. or by palladium sponge at 100° C. and the residual methane-nitrogen mixture (containing only small amounts of ethane) is then exploded with excess of air as described below. When the gas consists principally of methane with smaller proportions of ethane and practically no higher homologues, this gives sufficient data for calculating the proportions of hydrogen, nitrogen, and paraffin hydrocarbons. However, with natural and cracking gases, in which a number of homologous paraffin hydrocarbons are present, the above method is not directly applicable. It therefore becomes necessary to effect some fractionation of the constituents. A number of procedures for fractionating such mixtures of homologous gaseous paraffins on an analytical scale are discussed later. It is sufficient here to note that a simple low-temperature condensation procedure is capable of separating the hydrogen, nitrogen, and methane (as one fraction) from the residual homologues of methane. This mixture of hydrogen, nitrogen, and methane may then be submitted to treatment as described below.

Estimation of Hydrogen. In a mixture of hydrogen, nitrogen and paraffins (mainly methane), the hydrogen may be quantitatively estimated by taking advantage of its relatively much greater ease of oxidation. The hydrogen is eliminated as water and the reduction in volume (or, in pressure at constant volume) of the gas corresponds to the hydrogen content. A method developed for this purpose by King [9] consists in passing the gas mixture very slowly over fresh copper oxide maintained at a temperature of 280° C. in a silica tube. This treatment effects a complete and rapid oxidation of hydrogen and leaves the methane unattacked. The treatment is continued until no further diminution of volume occurs, which usually requires about 30 minutes. If any carbon monoxide is present in the gas, under these conditions it is oxidized to carbon dioxide, which may be estimated in the usual way. This method is satisfactory for gas mixtures containing methane as the main gaseous paraffin constituent. Ethane and its higher homologues, on the other hand, are oxidized slowly in this manner, and therefore, in the presence of large proportions of these constituents, the method is unreliable. The oxidation of ethane may be minimized by operating at 250° C. but, at this temperature, the hydrogen oxidation proceeds rather slowly.

[8a] Booth and Campbell (*Ind. Eng. Chem., Anal. Ed.*, 1932, 4, 131) determined traces of carbon monoxide in ethylene by means of the reaction of the former with oxygenated blood. The change in the oxygenated blood is measured colorimetrically after the addition of a mixture of equal parts of pyrogallic and tannic acids.

The other method which has been previously mentioned consists of a preferential elimination of the hydrogen by oxidation in the presence of "oxidized" palladium sponge at 100° C. On being heated to a dull red heat, palladium sponge undergoes superficial oxidation and then has the property, when maintained at 100° C., of removing hydrogen and leaving the paraffin hydrocarbons untouched. Its action is partly oxidation and partly occlusion. The palladium sponge requires fairly frequent re-oxidation by heating in contact with air. The details of this method have been described by Grice and Payman.[10]

According to Rischbieth,[11] hydrogen may be completely separated from methane by passing the mixture together with air over a palladium wire heated almost to glowing.

Hydrogen may also be quantitatively absorbed by a colloidal solution of palladium, as described by Paal and Hartmann[12] and by Beet.[13] Hague and Wheeler[14] carried out hydrogen estimations by this method at a temperature of 50° C., employing an absorption time of 30 minutes.

Determination of Paraffin Hydrocarbons by Oxidation.—Several methods are available for the analysis of the nitrogen and paraffin hydrocarbon mixture remaining after removal of the absorbable gases and hydrogen. All of them depend upon the complete oxidation of the paraffins to carbon dioxide and water. The volume of the carbon dioxide produced from a given volume of the mixture is measured by absorption in potassium hydroxide solution. The residual gas may then be considered to consist of nitrogen, helium and other inert gases.

It is important to note that complete combustion methods of analysis of mixtures of paraffin hydrocarbons and nitrogen give merely the proportions of nitrogen and total paraffin hydrocarbons. The analytical data are sufficient for calculation of the average molecular weight of the paraffin hydrocarbons, or in other words, of the mean value of "n" in the formula C_nH_{2n+2}. Accordingly, if not more than two homologous paraffins are present, the percentage of both individual paraffins can be computed. When the mixture contains more than two paraffin hydrocarbons, the analytical data obtained by combustion methods are inadequate for a complete calculation of the proportion of each individual paraffin.[15]

Explosion methods of analysis consist essentially of the ignition of a portion of the residual gas with a measured excess of air in a glass explosion chamber by a high-tension electric spark passing between two electrodes. The explosion is generally effected under reduced pressure and the electrodes are usually of platinum, fused into the glass chamber. From the diminution of volume which occurs and the amount of carbon dioxide produced, the composition of the initial gas mixture can be calculated. After the explosion the volume of gas is remeasured. The carbon dioxide and excess oxygen are then determined by absorption in potassium hydroxide and alkaline pyrogallol solutions, respectively. The residual gas consists of the nitrogen in the original sample together with that of the added air.

[12] *Ber.*, 1910, **43**, 243.

[13] *Fuel*, 1928, **7**, 45; *Chem. Abs.*, 1928, **22**, 2123.

[14] *Fuel*, 1929, **8**, 560; *Brit. Chem. Abs.* **B**, 1930, 90.

[15] Three hydrocarbons in a mixture (C_aH_b, C_cH_d, and C_eH_f) can be determined by combustion methods provided that ad + be + cf is not equal to af + bc + de; see Kobe, *Ind. Eng. Chem., Anal. Ed.*, 1931, **3**, 262.

If A = volume[16] of hydrocarbon and nitrogen mixture
B = volume of air added
C = contraction in volume after explosion
D = volume of CO_2 produced
E = volume of residual oxygen
F = volume of residual gas (nitrogen)
n = number of carbon atoms in the paraffin hydrocarbon (C_nH_{2n+2}) or average number in the mixture.

then[17]

$$(1)\quad \frac{\text{Carbon dioxide}}{\text{Contraction}} = \frac{D}{C} = \frac{2n}{n+3}$$

and

$$(2)\quad \frac{\text{Carbon dioxide}}{\text{Oxygen used}} = \frac{D}{0.206B - E} = \frac{2n}{3n+1}$$

From both of these equations the average value of "n" can be calculated. Provided the explosion had been carried out satisfactorily and that only paraffin hydrocarbons were present, these two values should agree. Values of "n" calculated by equation (1) are usually somewhat more accurate than those obtained by equation (2).[17]

The actual amount of total paraffin hydrocarbons can be readily deduced, since

$$(3)\quad \text{Volume of paraffins} = \frac{CO_2\text{ produced}}{\text{Mean "}n\text{"}} = \frac{D}{n}$$

This calculation may be checked by the following equation:

$$(4)\quad \text{Volume of total paraffins} = \text{initial volume} - \text{residual nitrogen} = A - F + 0.794\,B$$

From the proportion of total paraffins in the gas mixture and the mean value of "n," the proportion of each constituent can be readily calculated, provided that not more than two homologues were present.

The practical details of the explosion procedure are described in various manuals[18] but a few of the obvious difficulties may be mentioned. The proportion of air necessary for complete combustion of gases of unknown composition is often difficult to determine. A too violent explosion must be avoided since it tends to promote the formation of oxides of nitrogen and the deposition of carbon. Instead of air, mixtures of air and oxygen may be used. If the proportion of oxygen in such mixtures becomes too high, there is a definite risk of contamination by the products of combustion of grease on the walls of the explosion vessel and stopcocks.[19] In the explosion of homologues of methane the difficulties are somewhat enhanced by the considerably greater quantity of oxygen required. For accurate explosion analyses, a sufficient excess of air or oxygen should be added to provide for complete combustion and to prevent too violent an explosion. When in doubt, a considerable excess of air or air-oxygen mixture should be employed. Should the mixture prove to be non-explosive on passing a spark, it can easily be made flammable by the addition of a small amount of electrolytic gas (a mixture of 2 volumes of hydrogen and 1 volume of oxygen). Although the explosion method is quite satisfactory for gas mixtures containing methane and ethane, its application to those having a large content of higher paraffins is attended with difficulty.

---

[16] These "volumes" can be expressed in volume units at constant pressure or (as in analysis on the Bone and Wheeler apparatus) in pressure units (mm. of mercury) at constant volume.

[17] These equations apply only when air (O_2 = 20.6%) is used as the oxidizing agent. When oxygen or air-oxygen mixtures are used, the numerical factors in equations (2) and (4) are altered correspondingly.

[18] See, for example, White, "Technical Gas and Fuel Analysis," McGraw-Hill Book Co., Inc., New York, 1913, 41; Dennis, "Gas Analysis," Macmillan Co., New York; Gill, in Scott's "Standard Methods of Chemical Analysis," D. Van Nostrand Co., Inc., New York, 1917, 703.

[19] However, MacGillivray (*J.C.S.*, 1932, 941) states that pure oxygen may be employed for the explosion analysis of methane-ethane mixtures provided appropriate precautions are taken.

Another method of conducting the complete oxidation of gas mixtures containing nitrogen and paraffin hydrocarbons consists in repeatedly passing the mixture together with a very large excess of air or air-oxygen mixture over a heated platinum spiral. This method is particularly applicable to the determination of methane in relatively small concentrations (for example, the air of coal mines).[20]

For the complete combustion of gas mixtures containing appreciable proportions of higher paraffins, passing the mixture over hot copper oxide has been found satisfactory. However, this method is not quite quantitative but for most purposes it furnishes results of sufficient accuracy. The copper oxide appears to retain some of the carbon dioxide produced but this may be removed by washing out the hot copper oxide with a stream of air or oxygen-containing gas. The method is superior to explosion procedures in that it avoids the necessity of determining satisfactory proportions of air for complete combustion. The activity of copper oxide in oxidizing gaseous hydrocarbons by this method may be increased by the addition of lead chromate and cobalt oxide.[21]

By complete oxidation in the presence of hot copper oxide, the hydrocarbons are completely converted into carbon dioxide and water. The resulting gas mixture can be withdrawn from the copper oxide by evacuation. During the evacuation, however, small quantities of oxygen, which result from the thermal dissociation of copper oxide, are removed with the gases. The carbon dioxide and oxygen in the mixture can be determined by absorption, the gas remaining after this procedure being nitrogen.

Krogh [21a] determined butane in a gas mixture by the rate of flame propagation. Baxter and Beckham [21b] suggested a diffusion method to be used in conjunction with combustion analysis. The hydrocarbon mixture is allowed to diffuse into the air for a definite time, a sample is then withdrawn from the remaining mixture and this, as well as a sample of the original gas, is subjected to combustion. From the results of the two combustions the percentage composition of the gas can be calculated.

ANALYSIS BY CONDENSATION

As previously pointed out, the usual absorption and combustion analyses are in themselves quite inadequate for a complete analysis of natural gases, gases from cracking plants and hydrogenation units and similar complex hydrocarbon gas mixtures. To analyze such mixtures completely it becomes necessary to subject them to some type of physical separation, for example, to low-temperature condensation and fractional distillation of the liquefied mixture. The first efforts to apply low-temperature technique to the analysis of gaseous hydrocarbon mixtures involved a series of fractional condensations at low pressures in a series of bulbs maintained at several appropriate low temperatures. Later developments, however, demonstrated the superiority of methods of fractional distillation over those of fractional condensation.

---

[20] See Jones, *U. S. Bur. Mines. Rep.* 299-B-70, 1922. Ambler (*Analyst,* 1931, 56, 635; *Brit. Chem. Abs.* A, 1931, 1391) determines small amounts of methane in a gas mixture by oxidizing the hydrogen and carbon monoxide with copper oxide at 300° C. and absorbing the water and carbon dioxide in calcium chloride and "ascarite." The methane is then determined by combustion in the presence of platinum.

The analytical separation of any individual hydrocarbon from a mixture of homologous hydrocarbons by fractionation becomes more difficult as the series is ascended. This fact becomes obvious from a study of the variation in vapor pressure of the homologous hydrocarbons with temperature[21c] (see Figs. 34 and 35). As the series is ascended the individual vapor pressures tend to approach one another more closely, whereas great differences exist between the vapor pressures of the first few members of the series. The difficulties associated with the fundamental analysis of hydrocarbon mixtures are thus quite obvious.[22] Fortunately, there are only about twenty known gaseous hydrocarbons whose boiling points at atmospheric pressure are within a range of 170° C., and only a rare mixture would probably contain them all.

(Maxwell.)

Ramsey and Travers[23] separated and analyzed nitrogen, oxygen, helium, argon and other rare gases of the atmosphere by condensation and distillation at low temperatures. The principles of this method later found application in hydrocarbon gas analysis. Stoltzenberg[24] and Erdman and Stoltzenberg[25] developed an apparatus for investigation of gas mixtures such as ethylene and hydrogen, ethylene and oxygen, or carbon dioxide and oxygen. The gas was passed through baths maintained at such a temperature that one of the constituents was condensed while the other was collected in a eudiometer. Lebeau and Damiens[26] employed Ramsey and Travers' method, that is, they maintained the gas mixture at a temperature at which the vapor pressure of one or more of its components is inappreciable and withdrew the others. They separated the individual gases in pairs and

FIG. 35.

made no mention of the necessity of refractionating to obtain pure constituents. However, they designated the temperatures at which pairs of paraffin and olefin gaseous hydrocarbons could be separated.

Burrell, Seibert, and Robertson,[27] who described the application of low-temperature methods to the analysis of natural gas, employed a procedure based on simple distillation of the liquefied hydrocarbon mixture at low temperatures and pressures. The manipulation was tedious and time-consuming and many series of simple distillations were necessary to separate the individual hydrocarbons. The gas sample was liquefied at the temperature of liquid air and the uncondensed portion and most of the methane were removed by means of a Töpler pump. The residue was vaporized and again liquefied at liquid-air temperature and more methane pumped off. This sequence of operations was repeated until no methane was extracted and the system was under high vacuum. At the temperature of liquid air, ethane and higher paraffins possess a negligible vapor pressure so that it is possible to separate completely the methane and uncondensible gases from other paraffin hydrocarbons.[28] The separation of homologues of methane by this simple distillation process is much more difficult and requires many redistillations. Burrell and his collaborators accomplished the separation of ethane from propane by a series of low-pressure distillations at —153° C. to —140° C. and propane was separated from butanes and higher homologues by a similar procedure at —135° C. to —120° C. The residual liquid, consisting of butanes and higher hydrocarbons, was then vaporized, pumped away, and its volume was measured.

An apparatus, developed by Shepherd and Porter,[29] employs the same principle as that used by Burrell. It was designed to shorten the number of manipulations and the time necessary for analysis. In this apparatus no column is used, the fractionation being insufficient to separate butanes from pentanes or to determine the individual isomers, isobutane and isopentane. The apparatus and procedure are complex, so that it has only been employed for special research purposes. The application of this apparatus to the determination of the gasoline content of natural gas has been described by Shepherd.[30] A modification of the Shepherd-Porter apparatus was employed by Frey and Yant[31] for the analysis of gases from low-temperature carbonization of coal. Fractions obtained from a sample using the Shepherd apparatus were further analyzed by absorption and combustion methods. Frey and Yant[32] introduced an addition to the Shepherd apparatus, a fractionating column for the further separation of the butanes and heavier fractions.

Methods of analysis of mixtures of gaseous hydrocarbons of two or more carbon atoms, which do not involve the use of an efficient fractionating column, appear to be accurate only when complicated apparatus and lengthy procedures are employed. For the separation of methane and uncondensible gases from higher hydrocarbons, the simple distillation method under high vacuum at the temperature of liquid air is reliable since ethane and higher hydrocarbons have inappreciable vapor pressures under such conditions. With ethane and its homologues, however, it becomes increasingly difficult, if not impossible, to effect com-

FIG. 36.—Podbielniak Standard Precision Apparatus for low-temperature fractional-distillation analysis.

plete separation by such simple procedures since the vapor pressures of these hydrocarbons at any temperature approach one another, as has been mentioned. It is not possible to choose a temperature at which one hydrocarbon has an appreciable vapor pressure while that of its immediate lower homologue is negligible. The separation of methane and uncondensible gases from gaseous hydrocarbons of two or more carbon atoms by simple distillation at liquid-air temperature at low pressures has been described by a number of investigators.[33]

For the analysis of complex hydrocarbon mixtures, Tropsch and Dittrich[34] employed low-temperature fractional condensation to yield a number of fractions, each of which contained not more than two paraffin hydrocarbons associated with the corresponding olefins. The fractions thus obtained were further analyzed by absorption and combustion methods and, since not more than two homologous paraffins were present in each fraction, a complete analysis was possible. This method of fractional condensation thus differs essentially from that of Lebeau and Damiens,[35] Wellers,[36] and Burrell and his collaborators,[37] who used slow distillation under high vacuum. In the method of Tropsch and Dittrich, all the condensible hydrocarbons are liquefied at liquid-air temperature and the uncondensible gas, together with most of the methane, is withdrawn by a Töpler pump. The last traces of methane are removed from the liquefied hydrocarbon mixture by repeated vaporization and condensation followed by evacuation at liquid-air temperature. The gaseous fraction obtained in this way consists of uncondensible gas (nitrogen and hydrogen) and methane. The residual liquefied hydrocarbons

are vaporized in a bulb and the gas is passed slowly into a series of three bulbs under high vacuum, each receiver being maintained at a temperature lower than that of the preceding bulb. The bulbs are maintained successively at temperatures of —90° C., —120° C., and at that of liquid air. Tropsch and Dittrich asserted that a partial concentration of the hydrocarbon constituents is thus effected. The bulb maintained at about —90° C. contains paraffins and olefins of four or more carbon atoms, that at —120° C. contains only paraffins and olefins of three and four carbon atoms (i.e., a mixture of propane, butanes, propylene and butylenes) and that cooled to liquid-air temperature contains a mixture of ethane, propane, ethylene and propylene. The last two fractions are vaporized, pumped off, and analyzed separately by absorption and combustion. The liquid volume of the condensate in the bulb at —90° C. may be measured directly.

Undoubtedly some degree of separation may be effected by the procedure of Tropsch and Dittrich, but it is rather doubtful whether this is sufficient for accurate analyses. Because of the marked difference between their vapor pressures, methane and uncondensible gases may be readily separated from higher hydrocarbons by this simple procedure. A great disadvantage of methods of analysis such as that advanced by Tropsch and Dittrich is the necessity of subjecting the fractions to further analysis so that considerable time is consumed.[38]

Low-Temperature Fractionation Methods

The development of efficient fractionating columns and experimental technique has made possible the analysis of complex gaseous hydrocarbon mixtures by fractionation of liquefied gases at low temperatures. The success attained in this direction is largely due to the work of Podbielniak.[39] His apparatus, which has undergone various improvements,[40] is being widely used in the natural-gas, natural-gasoline, and petroleum refining industries, for research purposes as well as for routine analysis of both gaseous and volatile liquid hydrocarbon mixtures. For this reason the apparatus deserves detailed description.

Podbielniak Apparatus. The Podbielniak apparatus[41] consists essentially of a vacuum-jacketed fractionating column, designed for high efficiency at reflux temperatures below atmospheric, together with an accessory apparatus for introducing gas or liquid samples into the column and for temperature and volume measurement. The main features of the apparatus are represented diagrammatically in Figure 37. Figure 38 shows the design of standard precision columns for low- and high-temperature fractionations which possess considerably increased fractionating efficiency and greater sensitivity than previous columns. Both columns are of separate sleeve-type vacuum-jacket construction supplied with a radiant or dry reflux cooling vessel. A variety of distilling tubes and flasks of different diameters can be used interchangeably with either standard vacuum jacket. The vacuum jacket includes only smooth seals and the distilling tube is completely free from bulking seals or other discontinuities. For the low-temperature column, the distilling tubes range from 2.6 mm. to 4.5 mm. in diameter, and for the high-temperature columns, from 2.6 mm. to 8.0 mm. A larger high-temperature column has also been developed, in which tubes of 8.0 mm. up to 15 mm. are used. Single-wire coils up to 6 mm. in diameter and double-wire coils, flat-strip coils or other special continuous type of packing may

be used. It is only necessary with this separate vacuum-jacket distilling tube combination to change the distilling tubes to carry out a small or large capacity determination. The low-temperature column contains a single perforated reflector in the vacuum space of the vacuum jacket. The high-temperature column has a chamber reflector plus a compensatory miniature resistance wire heater inside the jacket inner tube. The low-temperature column depends on initial bowing of the Pyrex inner tube to compensate for differential contraction and the high-temperature column contains a quartz inner tube to withstand extreme temperature ranges. Larger distilling tubes can be used with the high-temperature jacket than with the low-temperature. The dry reflux cooling arrangement is said to be superior to any type of gasoline or other liquid bath. The low-temperature cooling vessel is provided with a soldered-on cap and packing gland to exclude atmospheric moisture which might otherwise condense and freeze in the reflux chamber. The high-temperature cooling vessel has no cap and is brazed to withstand high temperatures. The low-temperature cooling vessel may be used alternatively with refrigerants such as liquid air, liquid carbon dioxide, brine, water, compressed air. The vapor temperature at the head of the column is measured with an accurately calibrated thermocouple connected to a millivoltmeter. The distilling bulb is insulated by a vacuum jacket and to it is supplied a regulated heat input by an external resistance wire arranged as shown in the diagram. The droplets of refluxed liquid falling down the column may be counted by means of a drip indicator with small perforations, which are necessary to avoid flooding of the column. At the bottom of the column is a hairpin precooling tube which may be immersed in a cooling bath when a gaseous or volatile liquid sample is being introduced into the column.

The principle of the operation of the Podbielniak Apparatus is simple, although the practical details and experimental technique are only acquired by practice. Essentially, the process consists in subjecting the liquefied sample to slow fractionation under standard conditions of reflux ratio and withdrawing the vapors continuously at a definite pressure. The vapors pass into a vessel of known volume maintained in a thermostat and changes of the absolute pressure in this container are observed on a manometer. The analytical results are best expressed in the form of a graph in which the pressure readings are plotted against the corresponding temperatures recorded by the thermocouple. The operation of the apparatus may be varied to permit analytical distillation of components of volatility varying from methane to hexanes or heptanes. The distillation of octanes and heavier fractions is not usually practicable in this apparatus. The distillations are generally conducted isobarically at atmospheric pressure, but hydrocarbons of five or more carbon atoms are usually fractionated under diminished pressure. It is important that reflux temperatures never approach atmospheric temperature. The recommended distillation pressures are as follows:

For all compounds of boiling point lower than atmospheric temperature	Atmospheric pressure
Pentanes and pentenes	300 mm. (absolute)
Hexanes and hexenes	100 mm.
Heptanes	20 mm.

As previously indicated, the distillate is usually collected in vapor form in evacuated glass bottles maintained at constant temperature. The amount of distillate is computed from the calibrated volume of the receiver bottle and from the temperature and pressure of the contained vapor, using known physical constants and ideal gas laws. Errors introduced by the deviation of the higher hydrocarbons from the ideal gas laws[42] may be avoided by collecting the hydrocarbons below standard maximum partial pressures as shown in Table 160:

TABLE 160.—*Maximum Partial Pressures in Vapor Receiving Bottle.*

Hydrocarbon	Max. Partial Pressure Mm.
Methane	760
Ethane	760
Propane	760
Butanes	400
Pentanes	80
Hexanes	20
Heptanes	5

The gas to be analyzed is introduced into the evacuated apparatus through the precooling tube attached to the bottom of the distilling bulb. The sample, which should usually be about 6 liters vapor volume, is preferably subjected to total condensation by allowing it to pass slowly into the precooling tube and distilling bulb, both of which are cooled with liquid air. By this procedure, practically all the methane and higher hydrocarbons are condensed. Another method of introducing the gas sample consists in precooling the sample in a bath of gasoline cooled with liquid air. This latter method requires less time, since the bulk of the methane in the sample is discharged from the top of the column simultaneously with the introduction of the gas, instead of being condensed and subsequently distilled off slowly. It is absolutely essential that all water vapor and carbon dioxide be removed from the gas sample prior to its introduction into the apparatus, since these constituents would freeze in the column and consequently obstruct the distillation. The removal of these constituents is effected by passing the gas through a potash trap and a phosphorus pentoxide bulb.[43]

The method of carrying out an analysis is described by Podbielniak as follows: Once a sample is entered into the column, the analytical procedure is essentially the same, whether the sample is natural gas, coal gas, liquefied petroleum gas, natural gasoline, or ordinary motor fuel. The pressure in the column is brought to atmospheric by applying heat to the distilling-bulb heating element (regulating with the transformer shown), or by cooling the reflux with liquid air, depending on whether the column pressure is below or above atmospheric. The vapor formed passes up the column and is condensed at the reflux. In order to maintain this flow of reflux liquid down the column it is necessary to extract heat from the reflux by periodically blowing more liquid air into the reflux cooling vessel. The supply of current to the column-heating element and the cooling of the reflux should be so balanced that (1) the column pressure is practically atmospheric, and (2) the entire wire packing of the column is wet with the minimum amount of reflux to form capillary liquid films.

When the proper conditions have been established in the column, distillation may be commenced by cracking stopcock 4 to allow the fractionated overhead vapor to pass slowly through the stopcock train into the receiving bottle which had been evacuated previously to a fairly low pressure. The barometric manometer connected to the receiving bottle indicates the rise in pressure in this bottle as it fills with vapor. This rate of distillation is controlled by changing the setting of stopcock 4 so as to secure the best possible fractionation compatible with a maximum permissible total time for the distillation. In practice this is equivalent to slowing the distillation rate to a very low value whenever the vapor temperature tends to rise at constant pressure, and increasing the distillation rate when the temperature tends to stay constant. In this way, one hydrocarbon after another is distilled with very sharp temperature rises until the entire sample is distilled or until an undistillable residue remains. Frequent simultaneous readings, (1) of the thermocouple e.m.f.'s indicated by the millivoltmeter, (2) of column pressure on the open-arm manometer, and (3) of the pressure on the receiving-bottle manometer, are taken to enable the operator to construct subsequently a plot of vapor temperature (corrected to a standard pressure) against the amount of vapor distilled.

---

[42] Rogers and Brown, *Ind. Eng. Chem.*, 1930, 22, 258.

[43] When unsaturated hydrocarbons are present, phosphorus pentoxide cannot be used as it absorbs these gases. Magnesium perchlorate trihydrate is satisfactory in such cases.

The vapor temperatures at the top of the column are read by the analyst on the millivoltmeter, which is graduated to tenths of a millivolt.

The column-pressure readings on both arms of the open-arm manometer connected to the fractionating column are recorded. When the mercury stands at the same level in both arms, the pressure in the column is atmospheric.

The pressure on the closed arm of the closed-arm manometer connected to the vapor-receiving bottle used in the analysis are recorded as bottle pressure. These readings must be taken with care and estimated to tenths of a millimeter. Each series begins with an initial low pressure in an evacuated vapor-receiving bottle and ends with the maximum permissible pressure in the bottle. After each final reading the bottle is reevacuated and another series of readings taken. This is done as often as required.

Several times during an analysis, readings (correct to 0.1° C.) are taken of the temperature of the water bath in which the vapor-receiving bottles are immersed. These readings should be taken preferably at the break points on the fractional distillation curve, as evidenced by sudden temperature rise. Failure to record these readings may lead to considerable error in analysis, especially when the laboratory temperature fluctuates considerably.

The corrected temperatures are obtained by multiplying the vapor-temperature readings by 10 (the calibration curve of the thermocouple should be used for precise work), and converting to temperatures at atmospheric pressure by means of a chart.

The calculated pressures are obtained from the bottle-pressure readings by the following procedure. The initial reading of the first series in the bottle-pressure column (which is not necessarily zero) is subtracted from itself and then successively from every other reading of the series to yield the corresponding calculated pressures. To convert the second series of bottle-pressure readings, the final calculated pressure of the first series is subtracted from the initial reading of the second series $(0.0 - 94.0 = -94.0)$, and from every other reading of the series in succession. The third and following series are converted similarly. The effect of this procedure is to arrange all the millimeter intervals in the bottle-pressure columns of the tables into one continuous series beginning with zero to be proportional at any point to the total volume (in vapor form) of the sample distilled.

The results so obtained are plotted in graphical form to yield a fractionation curve as shown in Figures 39 and 40. The ideal fractionation curve would consist of perfectly horizontal plateaus and rectangular rises in temperature. The curves actually obtained approximate this ideal quite closely except for hydrocarbons having boiling points not far apart. In order to determine the proper cut points on the temperature rises in the curve, Podbielniak advises the use of a so-called "equal area" method[44] rather than the mid-point method. Each plateau on the curve corresponds to a pure hydrocarbon which can be identified by its boiling point, and the amounts of hydrocarbons are proportional to the lengths of these plateaus. In the analysis of gaseous products with no liquid residue, the gas per cent by volume is readily calculated simply by dividing each plateau length (A mm.) by the sum of the lengths of all the plateaus for the entire sample and multiplying by 100. Liquid per cent by volume for normally liquid hydrocarbons may also be calculated from these curves.

Other Fractionation Columns. Frey and Yant[45] used a column for the fractionation of the four-carbon atom fraction of low-temperature coal carbonization gas, which was of Pyrex glass, 50 cm. high and 9 mm. in diameter filled with 5 mm. brass rings. Controlled reflux was obtained by regulated heat withdrawal from the uppermost 10 cm. of the column. This was effected by cooling with liquid air through a 1 mm. thick annular interspace filled with hydrogen at a regulated pressure. Since the heat transmission through the interspace depends mainly upon the pressure of the hydrogen, the rate of cooling can be controlled merely by adjusting the hydrogen pressure. The fractionating column proper was thermally insulated by means of a vacuum jacket.

[45] *Loc. cit.*

A simple fractionating column capable of being used for the estimation of various unsaturated hydrocarbons has been described by Davis.[46] This column, represented in Figure 41, consists of 3 to 5 meters of 5 mm. glass tubing bent into a low-pitched spiral of 30 to 40 turns. Thermal insulation and mechanical rigidity is secured by surrounding the column with a glass jacket which is highly evacuated and silvered, unsilvered strips being left on opposite sides for observation. Reflux cooling is obtained by surrounding the upright column head by a glass jacket containing a cooling mixture. Other features of this column, which is not satisfactory for the investigation of gases with boiling points lower than that of ethane, include an immersion-type electrical heating device and a cooled receiver for condensation of distillate vapors.

FIG. 42.—MacGillivray Fractionating Column.

Schaufelberger[47] described the analysis of hydrocarbon mixtures by fractionation with a column similar to that of Podbielniak. The vacuum-jacketed column (silvered completely except for one window at the drip indicator, which is placed high in the column) is joined by a cork to a separate reflux chamber, which is cooled with a gasoline bath agitated by a turbine-type stirrer.

For the preparation of pure ethane, methane, and hydrogen, MacGillivray[48] used a column similar to that of Podbielniak. The column, which is represented in Figure 42, can be employed for the analysis of complex hydrocarbon mixtures, particularly for the separation of saturated from unsaturated hydrocarbons. In this apparatus the reflux is controlled by a variable-pressure hydrogen buffer. MacGillivray recommended that liquid nitrogen be used as the refrigerating liquid instead of liquid air, for in the event of a break or crack occurring in the apparatus, with consequent mixing of liquid hydrocarbons and liquid air, a dangerous explosion may result.[49]

A short-cut method of analysis of hydrocarbon mixtures, satisfactory for routine control analyses, has been described by Rosen and Robertson.[50] The applicability of this procedure is limited to the analysis of ternary mixtures containing ethane, propane, and butanes and to mixtures of these hydrocarbons containing methane and fixed gases. The extension of the method to more complex mixtures of hydrocarbons is indicated, however. With a ternary mixture such as that mentioned, the analysis is said to be reliable to 0.5 per cent on any constituent. The essential principles of the method are as follows: The liquefied hydrocarbon mixture is first freed from fixed gas and methane by evacuation at the temperature of liquid nitrogen, and the resulting liquid is submitted to distillation into a receiver of known volume connected to a mercury manometer. The temperature of the liquid hydrocarbon mixture is measured with a thermocouple junction which passes to the bottom of the condensation bulb and so records liquid temperature. Distillations are conducted at 760 mm. pressure and at a fairly constant rate of about 15 cc. of gas per minute. During the distillation, simultaneous readings on the thermocouple potentiometer and on the manometer are taken as the voltage changes 0.1 to 0.2 millivolt, or as the

pressure rises 5 to 10 mm. Heat input to the still is controlled by lowering a Dewar flask placed round a cooled aluminum cylinder (which is fitted snugly round the distilling bulb), thus increasing the surface of the aluminum cylinder exposed to room temperature. A simple apparatus for conducting this process is shown in Figure 43, in which C is the vessel for measuring the gas sample,[51]

FIG. 45.—Enlarged Section of Master Graph, for Mixtures of Ethane, Propane and Butane. (Rosen and Robertson.)

D is the condensation vessel and still, and J is the receiver of known volume, connected to the manometer H. The rate of distillation is controlled by stopcock X_3 and the distillation pressure is recorded on manometer E. It will be noticed that no fractionating column is employed, the operation being merely one of simple distillation. Any methane or condensible gas in the sample is removed by a mercury vapor pump K. When the distillation is completed, stopcock X_3 is opened and the total pressure, P_2, on the manometer H is noted. From the barometric pressure, the volumes of the measuring flask and expansion bulb, the pressure P_1, corresponding to the volume of the sample taken, is calculated by the formula:

---

[51] The gas sample must be freed from carbon dioxide, hydrogen sulphide and water vapor before introduction into C.

$$P_1 = \frac{\text{volume of sample} \times \text{atmospheric pressure}}{\text{volume of (distillation bulb + lines + expansion bulb)}}$$

The difference between P_1 and P_2 represents the pressure due to methane and fixed gases pumped away prior to the distillation, and $\frac{(P_1 - P_2)\,100}{P_1}$ = Percentage of fixed gases and methane in the sample analyzed.

The method of computing the composition of the mixture of ethane, propane, and butanes distilled is as follows: By plotting the temperature recorded on the potentiometer against the receiver pressure in mm., a curve is obtained from which the temperature corresponding to any percentage distilled off may be read. The results are then compared with a master graph showing all possible compositions of the three hydrocarbons. An outline of the master graph is shown in Figure 44 and Figure 45 and gives a section of this in detail. Several typical distillation curves are shown in Figure 46. The temperatures at which, for example, 10 per cent and 80 per cent of the mixture is distilled off at 760 mm. pressure are read from the analytical distillation curve and then, by referring these temperatures to a master chart, the composition of the original sample may be calculated.

FIG. 46.—Typical Distillation Curves obtained with Rosen and Robertson Apparatus.

OTHER PHYSICAL METHODS FOR THE ANALYTICAL SEPARATION OF HYDROCARBON MIXTURES

Several methods of analytical rectification of hydrocarbon mixtures, depending upon adsorption and solution effects, have been advanced. Kuhn[82] described a method of analysis of coal gas or natural gas in which the dried gas is first cooled under reduced pressure to liquid air temperature to condense carbon dioxide and hydrocarbons higher than methane. The uncondensed gases are then subjected to adsorption in silica gel cooled to the temperature of liquid air, which removes methane, carbon monoxide, oxygen and nitrogen, leaving a residual gas composed almost entirely of hydrogen with a little oxygen. The gases condensed in the first liquid air cooler are then separated by fractional distillation at 0.1 mm. pressure, ethane and ethylene being removed at —150° C., acetylene, propane, propylene, and carbon dioxide at about —120° C., and butane, pentane and benzene at —25° C.

---

[82] *Z. angew Chem.*, 1931, 44, 757; *Chem. Abs.*, 1931, 25, 5875. *Cf.* Coppens, *Bull. soc. chim. Belg.*, 1932, 41, 525; *Chem. Abs.*, 1933, 27, 2075; Horstmann and Scheffer, *Rec. trav. chim.*, 1932, 51, 143, 153; *Chem. Abs.*, 1932, 26, 1873.

A method of analytical rectification of hydrocarbon mixtures which depends upon the selective solvent action of toluene or toluene-nitrobenzene mixtures on various gaseous hydrocarbons has been described by van Dyck.[58] This method is said to be satisfactory for the determination of pentane, butane and propane in hydrocarbon gas mixtures. With a fractionating apparatus, the various gases are removed from the mixture in the order of their solubilities, starting with the most soluble. The analysis is effected by scrubbing a known volume of gas with a stream of liquid hydrocarbon, fed into the top of the apparatus (Fig. 47) at a definite rate. Solution of some of the gas takes place and the liquid hydrocarbon descends into a spiral column which is heated by vapors of a boiling liquid. A greater part of the dissolved gas is accordingly expelled in this heated spiral so that there is established a gas phase flowing countercurrent to a liquid stream, thus effecting fractionation. The efflux rate of the liquid solvent from the spiral heater is maintained at a steady value during analyses. A great advantage of this type of apparatus is that no liquid air or nitrogen is required, only water cooling and electrical heating being used. The results are said to be accurate to within 0.5 per cent, though the minimum quantity of any component which can be identified with certainty is about 2.5 per cent. The absorption is conducted at constant temperature in a regulated slow stream of liquid solvent, the amount of gas absorbed being measured by volume changes at constant pressure. Analytical results are calculated from graphs obtained by plotting the volume of absorption liquid passed at definite stages of the analysis against the corresponding volume of gas absorbed.

Inverted fractional-distillation analysis, which permits separation of gases or liquids beginning with the components with the highest boiling point has been described by Bosschart.[58a] The apparatus designed for this purpose has a range from +200° C. to —170° C. and the fractions can be collected as liquids or gases. As in the van Dyck absorption method, the reflux is a gas instead of a liquid phase. This type of analysis is especially recommended where the principal interest is in the heaviest components rather than in the light fractions.

DETERMINATION OF UNSATURATED HYDROCARBONS IN GAS MIXTURES

The quantitative estimation of unsaturated hydrocarbons in mixtures is attended with considerable difficulty and can only be accomplished in one or two cases without using some method of fractionation, either of the hydrocarbons themselves or of their derivatives (e.g., of their dibromides). Much work has been reported on methods of analysis of olefin mixtures by absorption in various concentrations of sulphuric acid, with or without the addition of certain metallic salts. With sulphuric acid of appropriate concentration it is undoubtedly possible

FIG. 47.—Van Dyck Apparatus for Gas Analysis.

to effect an analytical separation of ethylene, which is absorbed with the most difficulty by sulphuric acid, from its higher homologues. However, the rates of absorption of propylene and the two straight-chain butylenes approach one another so closely that any analytical separation of them by sulphuric acid is apparently out of the question.

The problem of the estimation of the total unsaturated hydrocarbon content of gaseous mixtures is in reality identical with that of the complete absorption of the ethylene from the gas. Ethylene is only completely absorbed with difficulty, whereas the complete absorption of other unsaturated hydrocarbon gases is a relatively simple matter. Bromine water and fuming sulphuric acid are the reagents usually employed for this purpose. Of the two, bromine water is the better, especially if the absorption is carried out in a darkened pipette. Fuming sulphuric acid rapidly absorbs all unsaturated hydrocarbons, including ethylene, but unfortunately it also absorbs paraffin hydrocarbons.[54]

According to Tropsch and Dittrich,[55] the addition of vanadic acid or of uranyl sulphate to concentrated sulphuric acid renders it a satisfactory absorbent for ethylene (and thus for the total unsaturated content) in gases. Even better is a mixture of 15 parts of a 0.6 per cent solution of silver sulphate in 87 per cent sulphuric acid with 2 parts of a saturated solution of nickelous sulphate in 87 per cent sulphuric acid. This solution is said to absorb ethylene readily but not saturated hydrocarbons.[56]

ABSORPTION OF OLEFINS BY SULPHURIC ACID OF VARIOUS CONCENTRATIONS

A number of methods have been proposed for the preferential absorption of various individual olefins by successive treatments with sulphuric acid of increasing concentrations. Tropsch and von Philippovich[57] developed a method of estimating propylene and its homologues in the presence of ethylene by absorption in 87 per cent sulphuric acid. This concentration of acid exerts but slight absorptive effect on ethylene but rapidly absorbs its homologues. However, when large concentrations of ethylene are present in the gas, the results are subject to greater error, since under these conditions the absorption of the ethylene becomes appreciable. The residual ethylene, after absorption of the homologues, can be absorbed in bromine water. Tropsch and von Philippovich stated that the relative rates of absorption of ethylene and propylene in 87 per cent sulphuric acid are as 1 to 100. According to Suida and Wesely,[58] the analytical separation of ethylene from its homologues can be successfully accomplished by absorption of the latter in 87 per cent sulphuric acid, provided the gas mixture does not contain more than 25 per cent of total olefins. The determination of the total olefin content is stated by them to be carried out best by using 0.04 per cent bromine water.

Tropsch and Dittrich[59] subjected the complex hydrocarbon gas mixture to a fractional condensation under such conditions that each fraction contained only two homologous olefins (admixed with the corresponding paraffins). For the absorption of ethylene homologues, these investigators employed 87 per cent sulphuric acid and subsequently absorbed the ethylene in 87 per cent sulphuric acid activated with silver and nickel sulphates. To estimate the relative proportions of the two unsaturated hydrocarbons (higher than ethylene) absorbed from each fraction by 87 per cent sulphuric acid, the solution of these olefins in that acid was oxidized with an excess of potassium iodate. The amount of potassium iodate over that required for oxidation was determined by adding potassium iodide and titrating the liberated iodine with sodium thiosulphate solution.

---

[54] For example, Davis and Quiggle (*Ind. Eng. Chem., Anal. Ed.*, 1930, 2, 39) showed that during the absorption of olefins with fuming sulphuric acid (30% SO_3), as much as 3 per cent of n-butane in the mixture was also absorbed.

From a study of the rates of absorption of ethylene, propylene, and isobutylene in various concentrations of sulphuric acid, Dobrjanski[60] developed a method of determining the proportions of these gases in mixtures by bringing the gas successively into contact with (1) 63 to 64 per cent acid, which absorbs only the isobutylene; (2) 83 to 84 per cent acid to absorb propylene;[61] and (3) 100 to 200 per cent acid to absorb ethylene. In a modified procedure for use in the presence of butadiene, isobutylene is absorbed in 45 to 46 per cent acid, propylene and butadiene in 83 per cent acid, and ethylene in dilute fuming sulphuric acid (2% SO_3). A separate sample of the gas is then subjected to a bromine addition estimation by the bromide-bromate method (described later) in order to determine the butadiene.

FIG. 48.—Absorption of Ethylene and Propene (Orsat Pipet) into Pure 87 per cent Sulphuric Acid and into same Acid Saturated with Catalysts (Silver and Nickel Sulphates). (Davis and Quiggle.)

The estimation of unsaturated hydrocarbons by the sulphuric acid absorption method has been critically examined by Davis and Quiggle,[62] and some of its limitations have been exposed. The rates of absorption of propylene and of the two straight-chain butylenes (1- and 2-butene) are so close that separation by selective absorption is impossible. On the other hand, separation of ethylene from propylene is obtained by absorption of the latter in 87 per cent sulphuric acid. Saturation of this concentration of acid with silver and nickel sulphates, as recommended by Tropsch and Dittrich[63] was found by Davis and Quiggle to diminish the effectiveness of this acid for separating ethylene from propylene in an Orsat pipette more than one hundredfold. The results on the absorption of ethylene and propylene in an Orsat pipette in pure 87 per cent acid, and in the same acid saturated with silver and nickel sulphates, are shown graphically in Figure 48.

A survey of the published work on the estimation of unsaturated hydrocarbons by successive absorptions in graded concentrations of sulphuric acid leads to the conclusion that the process is only applicable to the accurate analytical separation of ethylene from its homologues. With the possible exception of isobutylene, which can be absorbed in about 50 per cent acid, the rates of absorption of gaseous homologues of ethylene are too close to one another for effective separation. Catalysts, such as a mixture of silver or nickel sulphates, added to the sulphuric acid are of value only for the determination of ethylene or total unsaturated hydrocarbons and diminish the effectiveness of separation of the individual members.

It has been recommended that with 87 per cent sulphuric acid the absorptions be timed and repeated and carried out with fresh acid until the rate becomes small and constant, indicating that ethylene is being absorbed. The final result can then be corrected for this ethylene absorption.[64] Manning, King and Sinnatt[65] proposed the following procedure for the analytical separation of ethylene from propylene and higher homologues in gas mixtures obtained by decomposing dibromides with a zinc-copper couple. A portion of the gas is treated successively in the Bone and Wheeler apparatus with 2 cc. of 87 per cent sulphuric acid for 5 minutes at each treatment. The olefins higher than ethylene are absorbed completely in the first 20 minutes (four treatments) at ordinary temperature. After this period the absorption during each 5 minutes treatment becomes small and constant and is due entirely to the ethylene content. A determination of this ethylene absorption rate enables a correction to be made for the ethylene absorbed during the first four treatments (20 minutes).

Dubois[65a] used sulphuric acid in the separation of hydrocarbons in connection with a calorimetric determination. The heats of combustion are determined for the original mixture, the mixture after unsaturated compounds are removed by fuming sulphuric acid, and the mixture from which propylene and higher homologues are removed by 87 per cent sulphuric acid solution.

ANALYSIS OF GASEOUS UNSATURATED HYDROCARBONS BY BROMINATION

A bromine addition method for the estimation of butadiene in gas mixtures, which makes use of the bromide-bromate reagent of Francis,[66] has been described by Dobrjanski.[67] The gas is introduced into an air-tight apparatus containing a solution of potassium bromide and sulphuric acid in water. A weighed quantity of potassium bromate is allowed to react with the liquid with the result that bromine is slowly evolved according to the equation:

$$KBrO_3 + 6KBr + 3H_2SO_4 \longrightarrow 3K_2SO_4 + 3H_2O + KBr + 3Br_2$$

The bromine thus produced adds directly to the unsaturated gases, forming dibromides with monolefins and tetrabromides with diolefins. The excess bromine is determined by adding a sufficient quantity of potassium iodide to the solution and titrating the librated iodine with standard thiosulphate solution. From this, the quantity of bromine absorbed by the gas can be calculated. Having determined the total quantity of unsaturated hydrocarbons (by total absorption, e.g., with bromine water), the amount of olefin and diolefins can be calculated from the bromine addition results.

A critical examination of this bromination method for the examination of unsaturated gases and liquid was made by Davis, Crandall, and Higbee.[68] The presence of oxygen was found to interfere with the quantitative titration of acetylenes and probably of some diolefins. A standard procedure was developed by which ethylene and acetylene and some of their higher homologues can be titrated quantitatively by bromide-bromate solution. A measured volume of the gas was introduced into a previously evacuated reaction bottle containing the bromide-bromate solution. Dilute sulphuric acid was added to this from a Mohr burette. By slow addition of the acid, the bromine is liberated gradually and is taken up by the unsaturated compounds as fast as it is formed. In this manner, the concentration of the halogen is kept low throughout the process and substitution reactions are avoided. The excess bromine can be estimated in the usual way, with potassium iodide and thiosulphate solution. Under these conditions, monolefins absorb two equivalents of bromine, whereas acetylenes and diolefins absorb four equivalents.

A considerable number of workers have used the bromine addition products of unsaturated hydrocarbons for the qualitative or rough quantitative detection of individual unsaturated hydrocarbons.[69] Manning, King and Sinnatt[70] developed a method of evaluation of unsaturated gases which depends upon bromination to a mixture of dibromides, followed by refractionation of these dibromides and regeneration of the unsaturated products. A large volume of gas is usually necessary for the determination, and sufficient should be used to furnish at least 100 grams of bromine addition products. The gas is first scrubbed with gas oil to remove vapors of higher normally liquid hydrocarbons and then passed through two absorption bottles, each containing 25 to 75 cc. of bromine covered with 100 cc. of 10 per cent potassium bromide solution. The bottles should be cooled with ice and it is desirable to condense any bromides, carried forward with the gas stream, in two spiral condensers cooled in a freezing mixture of ice and salt. The bromine compounds are subsequently mixed, washed with dilute caustic soda and water, respectively, dried, and fractionally distilled under 20 mm. pressure. The following fractions are collected:

(1) Up to 80° C. at 20 mm., containing all the ethylene and propylene dibromides, and most of the butylene dibromides.
(2) 80° to 130° C. at 20 mm., which contains remaining butylene dibromides together with bromine derivatives of higher olefins.
(3) Residue, which consists, in the case of cracking gas, almost entirely of butadiene tetrabromide.

The procedure recommended involves the liberation of the mixed olefins from known weights of fractions (1) and (2) by means of a zinc-copper couple, followed by an examination of the gases produced, as follows:

(1) The total olefin content is determined by absorption in fuming sulphuric acid or bromine water.

(2) A second portion of the gas is burned completely over copper oxide at 700° C. and the carbon dioxide produced is determined.

(3) Another portion of the gas is treated successively with 2 cc. of 87 per cent sulphuric acid (5 minutes for each treatment). The olefins higher than ethylene are absorbed completely in 20 minutes at ordinary temperatures. After this period the absorption during 5 minutes becomes small and constant and is due to ethylene only, as before stated.

From the above data it is possible to calculate the actual percentage of the individual olefins in a mixture of ethylene, propylene and butylenes.

The butadiene content of the original gas may also be estimated by extracting the residue (3) with hot alcohol and cooling the filtered solution to 0° C., when the higher melting crystalline butadiene tetrabromide separates out quantitatively and can be filtered rapidly and weighed. Under these conditions of bromination, a second (lower-melting) butadiene tetrabromide is also produced in about equal amount so that to obtain the total butadiene tetrabromide present in the residue, the weight of the higher-melting form must be doubled. (See Chapter 27.)

Roginski and Rathmann[70a] analyzed a mixture of cyclopropane and propylene by taking advantage of the rapidity with which the latter is absorbed by aqueous iodine-bromine solution. Under the same conditions cyclopropane is absorbed but slowly.

SPECIAL METHODS OF ANALYSIS OF VARIOUS UNSATURATED GASES

For the analytical absorption of acetylene, Hague and Wheeler[71] employed an ammoniacal solution of silver chloride and conducted the absorption for 2 minutes in the Bone and Wheeler[72] apparatus. This reagent also tends to absorb quantities of olefins and diolefins, however.

As previously indicated, ethylene is best absorbed either in bromine water or by concentrated sulpuhuric acid or fuming acid. Morris,[73] however, recommended a 20 to 40 per cent aqueous solution of silver nitrate for absorbing ethylene from gas mixtures. The ethylene may be recovered from the concentrated silver salt solution by evacuation. Heymans[74] determined ethylene in cracked products (after absorption of carbon dioxide by potassium hydroxide and higher olefins by 87 per cent sulphuric acid) by absorbing it in a solution of mercuric nitrate saturated with sodium nitrate, after which benzene vapors are estimated by treatment with bromine water.

According to Nametkin,[75] unsaturated gaseous hydrocarbons are quantitatively absorbed from gas mixtures in a concentrated aqueous solution of potassium permanganate without the saturated hydrocarbons being affected. This method is satisfactory for the determination of the total unsaturated hydrocarbon content of gas mixtures but special apparatus must be used since the permanganate solution attacks mercury.

For the estimation and analytical separation of the isomeric butenes no simple methods are available. All three unsaturated hydrocarbons are found in frac-

tions of cracking gas boiling at about 0° C. Of these, isobutene is by far the more reactive. Dobrjanski[76] showed that it can be separated from the other two by absorption in 63 per cent sulphuric acid. This separation is complicated, however, by the presence of certain other hydrocarbons boiling in the same range, especially butadiene. In the presence of butadiene, isobutylene is best estimated by absorption in sulphuric acid of concentration lower than 60 per cent (satisfactorily in 45 to 46 per cent).

Frey and Yant[77] determined isobutylene in mixtures of the three butenes (obtained by fractionation of low-temperature carbonization gas) by absorption in a mixture of 2 volumes of sulphuric acid (specific gravity 1.84) and 1 volume of water.

Investigations of mixtures of butenes as their dibromides have been made by a number of workers. Frey and Yant[77] carried out the bromination of a butene mixture by adding bromine, drop by drop with agitation, into the liquid hydrocarbon mixture previously cooled to —80° to —100° C. until addition was nearly complete. The temperature was then allowed to rise to —20° C. and the addition of bromine continued until the color persisted. The dibromides were then distilled under reduced pressure at temperatures below 60° C. (residue temperature). For the determination of 1-butene in this mixture, Frey and Yant employed a method in which the dibromide mixture was heated with a 15 per cent solution of potassium hydroxide in absolute alcohol at about 100° C. in a sealed tube. Under these conditions, only the dibromide of 1-butene is decomposed, whereas the dibromides of 2-butene and isobutene are unattacked.[78] 1-Butene dibromide is decomposed to the extent of about 51 per cent (this yield is roughly constant for periods of heating varying from 2 to 5 hours) into ethylacetylene according to the reaction:

$$CH_2BrCHBrCH_2CH_3 \longrightarrow CH{\equiv}CCH_2CH_3 + 2HBr$$

After cooling the reaction mixture to —75° C., the contents were slowly distilled through a condenser into an excess of 5 per cent alcoholic silver nitrate. Two volumes of water were added to decrease the solubility of the precipitated $C_4H_5Ag_2NO_3$, which was filtered off, washed with water and dissolved in dilute nitric acid. The silver was then determined by titration with standard potassium thiocyanate solution, with ferric nitrate as indicator.

A qualitative method of examining butene mixtures, which consists in a careful fractionation of the dibromides under 50 mm. pressure, has been described by Lucas, Dillon and Young.[79] Bromination of the butene mixture was effected by slowly introducing bromine into the well-agitated liquid butene mixture, cooled to —15° to —20° C.

According to Dillon, Young and Lucas,[79a] mixtures of the three normal butenes can be analyzed by means of the densities of their dibromides and the reaction rate of these latter compounds with potassium iodide. The method depends on the fact that each of the three butenes is quantitatively converted to the dibromide by treatment with bromine, and each of the dibromides has a different second-order reaction rate with potassium iodide in methanol at 75° C. A combination of the reaction rate with the density is sufficient for the analysis of any mixture of the three dibromides, and from this the content of the three butenes can be computed.

Davis[80] indicated the possibility of developing a method of analysis of mixtures of 1- and 2-butene by taking advantage of different rates of bromination of these olefins in carbon tetrachloride thoroughly dried over phosphorus pentoxide. In a perfectly dry medium, in the absence of strong light, 1-butene and 2-butene react at different rates, the former slowly and at approximately the same rate as propylene and the latter more rapidly and at about the same rate as isobutene.

Several methods of estimating butadiene in gas mixtures have already been discussed in Chapter 27. Tropsch and Mattox[81] developed a method for the determination of butadiene in complex gas mixtures, from which the diolefin is absorbed in molten maleic anhydride at 100° C.

Chapter 50

Methods of Analysis of Gasoline and Other Petroleum Distillates

Petroleum oils consist essentially of complex mixtures of hydrocarbons but also contain as minor constituents oxygenated bodies, nitrogen and sulphur compounds and, to a very small extent, mineral matter (see Chapter 1). All non-hydrocarbon materials may consequently be classed as impurities, since all or part of them must be removed in refining because of their injurious character in various industrial applications of petroleum fractions. Thus, gasoline for use in internal combustion engines is usually made substantially free of sulphur compounds, because of the offensive odor of some of these substances and the corrosive nature of some of the products of combustion.[1] Kerosene for use in wick-fed lamps for domestic purposes is generally refined to remove all material which is likely to give objectionable odors. It is therefore convenient to consider, first of all, the analysis and examination of refined petroleum oils, i.e., those containing but small amounts of the impurities mentioned above.

HYDROCARBON ANALYSIS

Petroleum oils generally consist of mixtures of the four principal classes of hydrocarbons—namely, olefin, aromatic, naphthene and paraffin hydrocarbons. The relative amounts of these types of hydrocarbons in any oil vary with its source and, to a lesser extent, with the methods used in refining. For example, as has been pointed out in Chapter 1, the distillates from Appalachian petroleums consist almost entirely of paraffins, many Russian petroleums yield distillates containing a preponderance of naphthenes, and certain other petroleums give volatile fractions containing appreciable proportions of aromatic hydrocarbons. Of these classes, the paraffins and naphthenes, with few exceptions, are the predominating ones.

Olefin hydrocarbons are not found in crude petroleums, but only in their distillates. Light oils obtained by cracking heavier oils contain unsaturated aliphatic hydrocarbons, the amount depending upon the type of oil being cracked and the temperature and pressure employed in the process. Thus gasolines obtained by cracking heavy oils in the liquid phase may contain up to 20 per cent of olefin hydrocarbons, whereas those resulting from cracking in the vapor phase, i.e., at a higher temperature, may contain as much as 60 per cent of these hydrocarbons. Cracked distillates also contain appreciable proportions of aromatic hydrocarbons.

It is desirable from many points of view to be able to determine the proportions of the various hydrocarbons in any petroleum oil or distillate. With higher fractions this assumes importance, because of the well-known antiknock effect

---

[1] See Chapter 19.

Acknowledgment is made of assistance rendered by Dr. D. A. Howes in connection with the preparation of parts of this chapter.

of aromatics and olefins in gasoline (Chapter 44), the potential gum- and resin-forming properties of some of the more unstable olefins (Chapter 40), and the characteristic of aromatics of imparting a smoky flame to kerosenes.[2] Developments in the utilization of petroleum fractions as raw materials in chemical synthesis necessitate still more careful study in this direction.

The problem of devising methods for the determination of aromatic, olefin, naphthene and paraffin hydrocarbons in petroleum distillates is complicated by the fact that the chemical reactivity of the hydrocarbons of any class generally changes comparatively rapidly with rise in molecular weight and boiling point. Reactions which proceed rapidly with the lower members of the series will often proceed only with difficulty with higher homologues. Thus, the basis of a well-known method for the determination of olefins is the reaction of these hydrocarbons with halogens—bromine or iodine—and although the halogenation occurs readily with the lower olefins, e.g., the pentenes and hexenes, it is appreciably slower with, for example, the diamylenes and triamylenes. Under conditions which convert these latter hydrocarbons quantitatively into halogen derivatives, there is a possibility of the halogen attacking hydrocarbons of other classes. Another factor adding to the difficulties of such analyses is the fact that as the boiling points of the hydrocarbons increase, the members of the four hydrocarbon classes gradually approach one another in chemical properties. Thus there is a great similarity between the higher α-olefins and the paraffins. Because of this, the methods of analysis are only applicable to petroleum distillates boiling up to 300° C., unless otherwise stated. With distillates boiling above 300° C., the chemical properties of the individual classes are so nearly identical that it is difficult to differentiate sharply between them.

ESTIMATION OF UNSATURATED HYDROCARBONS BY ABSORPTION IN SULPHURIC ACID

It is usual to class the aliphatic and naphthenic olefins, as well as those aromatics which contain an unsaturated aliphatic side-chain, as unsaturates. The determination of such hydrocarbons may be accomplished by methods which depend upon the following:

(1) Solution in sulphuric acid.
(2) Absorption of halogens.
(3) Reaction with mercury salts.
(4) Other typical reactions of unsaturated hydrocarbons.

Unsaturated hydrocarbons are attacked by sulphuric acid of lower concentration than that necessary for aromatic and other hydrocarbons. This fact has long been used as a basis for a rapid and convenient, if not accurate, analytical method. The reaction of sulphuric acid with unsaturated hydrocarbons is a complex process, details of which have been previously discussed in Chapters 12, 14, 16, 26, 46 and 49. It is sufficient here to repeat that this reaction may yield (depending upon the conditions employed, e.g., time of contact, temperature, and concentration of acid) polymers of the original hydrocarbons, alkylsulphuric esters, alcohols, and oxidation products. The polymers are completely miscible with the oil layer unless an acid of such strength is used that they are removed, whereas the alkylsulphuric esters are only partly soluble in the acid layer. These are the sources of the major errors to which the acid method is subject.

---

[2] The influence of the chemical composition of kerosene and its burning properties was discussed by Virobyantz and Sentzov, *Neft. Khoz.*, 1932, **22**, 331; **23**, 91; *Chem. Abs.*, 1933, **27**, 1741; Grote and Hundsdörfer, *Petroleum Z.*, 1932, **28** (28), 9; *Brit. Chem. Abs.* **B**, 1932, 1016; Danaila, *Petroleum Z.*, 1933, **29** (7), 1; *Brit. Chem. Abs.* **B**, 1933, 338.

The choice of the strength of acid to employ must of necessity be a compromise. As pointed out in Chapter 26, the polymers of the unsaturated hydrocarbons still contain a double bond but are much more resistant to sulphuric acid than the parent olefins and consequently a more concentrated acid is required to remove them. On the other hand, the strength of the acid must not be high enough to attack aromatic hydrocarbons. Opinion on this point is divided. Ormandy and Craven[3] found, by treating gasolines with sulphuric acid of various strengths, that the density and refractive index of the residue rose until the acid strength reached 88 per cent. This they ascribed to removal of unsaturates and formation of polymers. With higher strengths of acid, extraction of aromatics occurred and the density and refractive index fell. Hence, they concluded that 88 per cent appears to be the critical strength of acid at which extraction of unsaturates approaches completion and the extraction of aromatics begins.[4] This work has been confirmed by Moore and Hobson,[5] who found that 88 to 90 per cent acid was essential for the complete removal of unsaturates. The strength of acid used for this estimation should be adjusted, however, to the kind of light oil under examination. In general, gasolines obtained by distillation from crude oils, i.e., straight-run gasolines—which generally contain only traces of unsaturated hydrocarbons—need treatment with a stronger acid than gasolines produced by cracking. For example, in the method proposed by Riesenfeld and Bandte,[6] 100 per cent sulphuric acid is used for determining the unsaturates in medium and heavy straight-run gasolines, 94 per cent acid for the lighter gasolines of this type,[7] and 85 per cent sulphuric acid for cracked gasoline.

Because of the polymerization which always takes place to some extent when unsaturated hydrocarbons are treated with sulphuric acid, it is not sufficient to measure only the loss in volume of the sample when shaken with acid. A result obtained in that manner is low by the amount of polymers remaining dissolved in the oil layer. A correction to be applied for this error was introduced by Egloff and Morrell,[8] who recommended the redistillation of the acid-treated sample, after washing with water and caustic soda, to estimate the amount of polymers formed. If $a =$ per cent volume loss on treating with acid, and $b =$ amount of polymerized material obtained on redistillation, the content of unsaturated hydrocarbons is $a + b$. Unfortunately, however, although this method gives more accurate results than the simpler method in which loss in volume on acid treatment alone is measured, it does not account for the polymerized material formed which boils within the original boiling range of the oil treated. For instance, trimethylethylene, boiling at 38° C., polymerizes to a mixture of diamylenes boiling between 150° and 160° C., whereas gasolines have a final boiling point of 190° to 200° C. Consequently, if a gasoline of this boiling range containing trimethylethylene is analyzed according to the method of Egloff and Morrell, the polymerization of this hydrocarbon is not measured, and the result is low by this amount. The dipolymers of the hexenes boil between 190° and 200° C., whereas the dipolymer of isoheptene has a boiling point of 220° to

[7] Winkler (*Przemysl Chem.*, 1930, 14, 1; *Brit. Chem. Abs.* B, 1930, 272) recommended 92 to 94 per cent acid for the absorption of unsaturated constituents from straight-run benzine. However, 4 per cent of unsaturates are unabsorbed when this concentration of acid is used for a benzine produced by cracking. Nametkin and Robinzon (*Neft. Khoz.*, 1929, 14, 775; *Chem. Abs.*, 1929, 23, 3802) also observed that aromatic hydrocarbons were removed by 98 per cent sulphuric acid at 0° C.

[8] *Ind. Eng. Chem.*, 1926, 18, 354. *Cf.* Egloff, *Chem. Met. Eng.*, 1917, 16, 262.

224° C. and a mixture of 1- and 2-octenes gives a mixture of dipolymers boiling between 275° and 285° C. A more accurate method consists in fractionating the gasoline into narrow cuts, treating each separately with acid and measuring the natural loss and then redistilling each fraction separately to estimate the extent of polymerization. This procedure is tedious and time-consuming, however.

For the estimation of unsaturated hydrocarbons in kerosenes, Carpenter[9] recommended the use of 4 volumes of 83 per cent sulphuric acid followed by redistillation to estimate the amount of polymers formed.

The formation of olefin polymers is not, however, the only difficulty in this general method of estimation. It was observed by Krämer and Spilker[10] that, in the presence of sulphuric acid, styrene and the xylenes condense to form styroxylenes. Later, Brochet[11] found that aliphatic unsaturated hydrocarbons condensed with benzene homologues in the same way, e.g., benzene and hexene give hexylbenzene. Toluene and xylene also condense similarly and other unsaturates probably react like hexene. It is possible for condensations of this type to take place in the methods of analysis described above.

Other reactions also may occur at the same time. Unsaturated hydrocarbons containing more than one double bond are more easily polymerized than monolefins. Thus, allylene in contact with concentrated sulphuric acid yields trimethylbenzene and crotonylene gives hexamethylbenzene.[12] Methylcyclohexene produces methylcyclohexane and two isomeric diheptenes, together with some toluene.[13]

These considerations show that the estimation of unsaturated hydrocarbons by absorption in sulphuric acid gives but an approximately correct estimation even under the most favorable conditions, because the chemical reactions involved are so numerous and complex and because hydrocarbons of other groups can react under the conditions employed.

ESTIMATION OF UNSATURATED HYDROCARBONS BY HALOGENATION

The ease with which unsaturated hydrocarbons absorb halogens has led to the development of many methods of estimation based upon this behavior. The reaction involved is a simple addition, except in aqueous solution, when part of the halogen reacts with water to give a hypo-acid which adds to the olefin, producing a halogen derivative of an alcohol. Thus, with hypobromous acid:

$$RCH{=}CH_2 + HBrO \longrightarrow RCHBrCH_2OH \text{ (see Chapter 20).}$$

When addition of two halogen atoms takes place a simple titration indicates the "double-bond equivalent" of the unsaturates present. From this may be obtained an approximate value for the unsaturation or unsaturated hydrocarbon content of the sample under examination. It is not possible to estimate accurately the unsaturated hydrocarbon content in this way unless the molecular weight or average molecular weight of the constituents is known. Results are usually expressed in terms of bromine or iodine numbers which are defined as the number of centigrams of the halogen absorbed per gram of material.

Substitution of halogen atoms often proceeds at the same time as the halogen addition, as is shown by the evolution of hydrogen bromide. It is probable that the ease with which substitution occurs increases with rising molecular weight of the hydrocarbons. The presence of moisture and the influence of light-rays affect the course of the reaction and the time required for its completion. Thus, Davis[14] found that the bromination of ethylene takes hours, and even days, to reach completion if moisture and light are excluded. He also observed that temperature has little effect on the dry bromination of trimethylethylene or diisobutene, and that large amounts of hydrogen bromide are evolved.

The more common methods of estimating unsaturated hydrocarbons by halogen absorption are those developed by Hübl,[15] Wijs[16] and Hanus,[17] but these methods, though of considerable use in the examination of animal, fatty and vegetable oils, are not entirely satisfactory for the examination of petroleum oils. The method of Hübl makes use of a solution of iodine and mercuric chloride in alcohol and that of Wijs, a decinormal solution of iodine monochloride in glacial acetic acid. The Hanus reagent consists of a solution of bromine and iodine in molecular proportions in glacial acetic acid. Of these methods, that of Hanus is still used to some extent. However, it is being replaced rapidly by newer methods.

Another halogenation method, that proposed by McIlhiney,[18] which permits the separate determination of halogen addition and substitution, is dependent upon the fact that for each atom of hydrogen replaced by bromine, one molecule of hydrogen bromide is formed. By estimation of this free acid, therefore, as well as the total amount of bromine absorbed, data are obtained for calculating both the bromine taken up by direct addition and that taken up by substitution. The estimation of the hydrobromic acid is accomplished by the addition of potassium iodate to the solution after the excess bromine has been destroyed by potassium iodide and sodium thiosulphate. The reaction ($KIO_3 + 5KI + 6HBr \rightarrow 6KBr + 3H_2O + 3I_2$) is brought about by the addition of a small amount of dilute sulphuric acid.

Experiences with the McIlhiney method of determining unsaturation have been described by Morrell and Egloff,[19] Dean and Hill,[20] Waterman, Spijker and van Westen[21] and Waterman and van Westen.[22]

The reagent used in a method developed by Francis[23] is a standard solution of potassium bromide and bromate, which in acid solution produces bromine:

$$KBrO_3 + 5KBr + 3H_2SO_4 \longrightarrow 3K_2SO_4 + 3H_2O + 3Br_2,$$

the rate depending upon the strength of acid employed. By making the solution only slightly acid, bromine can be generated slowly. With vigorous shaking the bromine can be consumed fast enough to keep it at a low concentration in the solution and thus prevent substitution reactions. It is important, for accurate results, that the concentration of free bromine be maintained low. Precise methods for the determination are as follows:

A slight excess (usually not more than 1 cc. as estimated by a trial titration) of the bromide-bromate solution, containing 14 grams of potassium bromate and 80 grams of potassium bromide per liter, is measured into a small Erlenmeyer flask and a pipetted sample of the oil to be examined is added. The solution is quickly acidified with about 5 cc. of 10 per cent sulphuric acid and the flask is stoppered and shaken for one minute as vigorously as may be necessary to keep the color of the solution a pale yellow. If the color is dark yellow in spite of vigorous shaking, too much bromide-bromate solution has been added, and the analysis should be considered only a trial titration. In any case, to complete the liberation of bromine, 15 cc. more of acid are added and the shaking is continued for another minute. If the solution remains completely colorless, a little more bromide-bromate solution is added. The final color should be light yellow. One or 2 cc. of saturated potassium iodide solution are then added, and the liberated iodine is titrated with thiosulphate in the usual way. Results may be calculated with the equation:

$$N=\frac{0.08}{VD}(T_1N_1-T_2N_2),$$

in which N = Bromine number in grams per gram of sample
V = Volume of the sample used in cc.
D = Density of sample in grams per cc.
T_1 = Volumes in cc. of the bromide-bromate solution used in titration
N_1 = Normality of the bromide-bromate solution
T_2 = Volume in cc. of the thiosulphate solution used in titration
N_2 = Normality of the thiosulphate solution.

The content of unsaturated hydrocarbons can be calculated from the bromine number with the equation:

$$\%\ \text{Unsaturates}=\frac{MN}{160}$$

in which M = Mean molecular weight of the unsaturated hydrocarbons
N = Bromine number calculated as above.

If the unsaturated hydrocarbons are evenly distributed throughout the boiling range of the light oil examined, which is rarely the case, the mean molecular weight is approximately equal to 54 plus half the mean boiling point in degrees Centigrade.

Francis[24] checked this method of analysis by examining pure hydrocarbons and mixtures of straight-run and cracked gasolines. The results obtained were quite satisfactory. The method has also been examined critically by Cortese,[25] who concluded that it can be used for aliphatic olefins and diolefins, whether conjugated or otherwise, but that the method does not give accurate results with certain compounds with ring structures or with substances of unknown constitution. A modification of the Francis method of bromine number determination was used by Bacon[26] for the estimation of the unsaturation of lubricating oils. The original method gave difficulty with dark colored oils because it was impossible to determine when all the bromine was absorbed and when the last traces of iodine had reacted completely with the thiosulphate. The modification adopted by Bacon consists of adding to the sample of lubricating oil to be tested 10 cc. of pure benzene or gasoline of known unsaturated content. A slight excess of bromide-bromate solution is then added, as shown by the color of the water layer, with potassium iodide as indicator. The visible end point is then passed in titration with thiosulphate, the two layers are allowed to separate and starch is added to the lower water layer so that a titration with iodine indicates the excess thiosulphate. Vigorous shaking is essential throughout the determination.

A 4 per cent by volume solution of bromine in carbon tetrachloride has been used in diffused light by Morrell and Levine[27] for the determination of olefins. The solution is standardized against a sample of which the olefin content is known and the titration is conducted under identical conditions. For the estimation of unsaturated compounds, Rosenmund and Kuhnhenn[28] suggested the use of pyridine sulphate dibromide, and Galle[29] recommended an alcoholic iodine or an aqueous chloramine (sodium-p-toluenesulphochloroamide) solution. A method, devised by Angeli, Alessandri and Pegna,[30] depends upon the color change produced by the oil in the presence of nitrosobenzene.

The bromine absorption method of estimating unsaturation is of special use in determining the purity of unsaturated hydrocarbons of which the molecular weight is known. Wilkinson[31] employed the McIlhiney method of bromine number determination as a check on the purity of a series of α-olefins with complete success.

The possible action of bromine upon members of the other hydrocarbon classes must not be neglected. Bacon[32] asserted that benzene is brominated somewhat when exposed to strong light or sunlight, even under the action of only small concentrations of bromine. He found that pure benzene had a bromine number of 0.027 in moderate light and 18.00 in sunlight, as determined by the Francis method. Gustavson[33] observed that benzene was attacked by dry bromine, whereas the action with bromine containing moisture and hydrobromic acid was even more pronounced. Higher homologues of benzene react still more readily with bromine. Bigot and Fittig[34] stated that, even with efficient cooling, bromine acts upon amylbenzene and more rapidly upon amyltoluene and amylxylene. Bromine also reacts with a few naphthenes. According to Gustavson,[35] dry bromine reacts slowly upon cyclopropane, the reaction also being accelerated by the presence of water and hydrobromic acid. The substituted cyclopropanes are attacked more readily,[36] but cyclobutane is stable towards bromine in chloroform solution,[37] in which respect it resembles the cyclopentanes and cyclohexanes.

ESTIMATION OF UNSATURATED HYDROCARBONS BY REACTION WITH MERCURIC SALTS

A well-known reaction of the unsaturated hydrocarbons is that with mercuric salts.[38] Depending upon the molecular weight and configuration of the hydrocarbons, reaction can take place in two different ways: the hydrocarbons are either oxidized and destroyed or else they form complex addition compounds. Paraffin and naphthene hydrocarbons do not react in this way. Although some aromatic hydrocarbons also react to a slight extent, the reaction has been used as a basis for an analytical estimation of unsaturated hydrocarbons.

The gaseous olefins readily form complex addition compounds with mercuric salts at ordinary temperatures, from which they may be recovered by the action

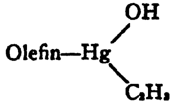
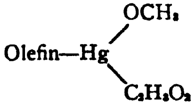
of acid.[39] Unsaturated hydrocarbons of low molecular weight react easily at ordinary temperatures, but those of higher molecular weight, e.g., octene and diamylene, react only slowly on boiling. According to Hugel and Hibou,[40] when aqueous solutions of mercuric acetate are used, the addition compounds have the general formula



$$\text{Olefin—Hg}\begin{matrix}\diagup\ \text{OH}\\ \diagdown\ C_2H_3O_2\end{matrix}$$

The higher-boiling olefins can be made to react more rapidly when methanol is used as a solvent. In this case the addition compounds have the formula



$$\text{Olefin—Hg}\begin{matrix}\diagup\ \text{OCH}_3\\ \diagdown\ C_2H_3O_2\end{matrix}$$

Hugel and Hibou prepared the addition compounds of olefins as high as hexadecene. Mercuric acetate was used in their experiments, although mercuric sulphate, palmitate, and stearate also react. The mercuric salts that are not hydrolyzed, e.g., mercuric cyanide, do not react in this manner. The reaction with mercuric salts unfortunately is not applicable to all olefins. Ethylene derivatives in which four radicals are attached to the unsaturated carbon atoms (e.g., tetramethylethylene) do not react. Hugel and Hibou also found that the addition compounds formed have a variable composition, depending upon the relative proportions of hydrocarbon and mercuric salt taken.

A method for the quantitative estimation of unsaturated hydrocarbons based on their behavior with mercuric salts has been proposed by Tausz.[41] The sample of oil to be analyzed is first shaken with a saturated solution of mercuric acetate and then refluxed with the same reagent to attack the more resistant hydrocarbons. When the reaction is complete the oil is washed with sodium hydroxide and sodium bisulphite solutions and the loss in volume is taken as the unsaturated hydrocarbon content. A correction is applied for evaporation loss.

Brame and Hunter[42] attempted to use the reaction with mercuric salts for the identification and separation of olefins in cracked gasolines. They abandoned the method in favor of one involving bromination because they were unable to obtain quantitative yields of the addition compounds. It was also observed that when the mercury compounds were decomposed with acid, large quantities of hydrocarbons were destroyed and lost. Manning and Shepherd[43] found that a saturated aqueous solution of mercuric acetate only absorbed about 70 per cent of the unsaturated hydrocarbons in light oils obtained from the low-temperature carbonization of coal. With the lowest-boiling fractions, however, absorption of unsaturated hydrocarbons was almost complete. The solution of mercuric acetate absorbed and retained about 1 per cent of aromatic hydrocarbons.

OTHER METHODS FOR THE ESTIMATION OF UNSATURATED HYDROCARBONS

Numerous other methods have been suggested for the determination of unsaturated hydrocarbons in mixtures containing other hydrocarbons. Faragher, Morrell and Levine[44] proposed a two-stage procedure in which the combined olefin and aromatic content is first determined. The aromatic content is then estimated by nitration. The difference between these two values is taken as the olefin content.

The combined olefin and aromatic content is determined by treating first with 91 per cent sulphuric acid, then distilling to remove any polymers, and finally by treating with 98 per cent acid.[45] The total loss sustained in these three steps is taken as the combined percentage of olefins and aromatics.

The aromatic content of the sample is then determined with a new sample from which the olefins are removed by treatment with sulphur monochloride.[46] The sample is subsequently distilled, first at atmospheric pressure, and then under reduced pressure. The products of the reaction between olefins and sulphur monochloride are probably dichlorosulphides or disulphides, which remain as a residue in the distillation flask provided the temperature of distillation is low. The distillate thus obtained contains 1 per cent or less of olefins, which can be estimated by titration with bromine. After determining the small quantity of olefins in the distillate the aromatic content is estimated by treating the sample with a nitrating mixture. The nitro-compounds thus formed are dissolved in either 95 or 91 per cent sulphuric acid, leaving a residue of unchanged hydrocarbons. The corrected loss in volume represents the aromatic content. With 95 per cent acid, a correction factor of 0.62 per cent is applied for the solution of non-aromatic constituents, whereas with 91 per cent acid the factor is 0.22 per cent. This method was later modified by Morrell and Levine[47] so that the olefin concentration could be calculated from the weight of residue remaining after distillation of the oil obtained upon treatment with 91 per cent acid by means of empirical formulas, as follows:

If U represents the actual olefin percentage; P, the weight of distillation residue; and D, the density of the oil remaining after the 98 per cent acid treatment; the following apply:

(1) For gasolines with a $\frac{P}{D}$ factor of 10 to 25 (15 to 25 per cent olefins)

$$U = 1.3\frac{P}{D} \quad \text{or} \quad U = \frac{P}{D} + 6$$

(2) For gasolines with a $\frac{P}{D}$ factor of 25 to 35 (35 to 50 per cent olefins)

$$U = 1.4\frac{P}{D} \quad \text{or} \quad U = \frac{P}{D} + 13$$

(3) For gasolines with a $\frac{P}{D}$ factor of 35 to 40 (50 to 60 per cent olefins)

$$U = 1.5\frac{P}{D} \quad \text{or} \quad U = \frac{P}{D} + L + 15$$

[45] *Cf.* method described by Towne, *J. Inst. Pet. Tech.*, 1931, 17, 134; *Brit. Chem. Abs.* B, 1931, 469.

[46] Under the conditions prescribed by Faragher, Morrell and Levine, reactions between sulphur monochloride and both aromatics and paraffins are avoided. Lorand (*Ind. Eng. Chem.*, 1927, 19, 733) showed that sulphur monochloride reacts with the unsaturated hydrocarbons in petroleum distillates, and that this reaction formed the basis of a method for determining the comparative unsaturation of distillates.

[47] *Ind. Eng. Chem., Anal. Ed.*, 1932, 4, 321.

in which L = loss in volume per cent resulting after treatment with 98 per cent sulphuric acid subsequent to distillation.

Other methods proposed for the estimation of unsaturated hydrocarbons include the following: (1) Formation of addition compounds with perbenzoic acid[48] or camphoric acid peracid;[49] (2) reaction with liquid nitric oxide[50] at —15° to —20° C.; (3) reaction with ozone;[51] (4) reactions with hydrogen.[52]

ESTIMATION OF AROMATIC HYDROCARBONS BY ABSORPTION IN SULPHURIC ACID

The difficulties attending the use of sulphuric acid as a reagent for the separation and determination of unsaturated hydrocarbons have already been emphasized. With gasolines and light oils containing no unsaturated hydrocarbons, the determination of aromatics by absorption in sulphuric acid is a relatively simple matter. The only precaution to be observed is to make sure that the acid used does not attack any saturated hydrocarbons. As hydrocarbon analysis is usually conducted in such a way that unsaturated hydrocarbons are estimated and removed from the oil under test in the first step, it is convenient to limit this discussion to oils free from unsaturated hydrocarbons.

The aromatic hydrocarbons are readily attacked by concentrated sulphuric acid to form sulphonic acids, which remain dissolved in the acid. An approximate value of the aromatic content can be obtained by measuring the loss in volume of the gasoline or oil after this treatment. Kraemer and Böttcher[53] proposed shaking the gasoline with an equal volume of sulphuric acid containing 80 per cent by volume of concentrated acid and 20 per cent by volume of fuming acid. After allowing to stand for a short time, the decrease in volume of the gasoline is measured.

The quantity and concentration of sulphuric acid necessary to remove aromatic hydrocarbons completely and yet be without action on paraffin and naphthene hydrocarbons is controversial, although 98 per cent sulphuric acid has been used for this purpose by many investigators.[54] Sulphuric acid of strength 98 ± 1 per cent is used in the standard English procedure,[55] but other workers[56] state that 100 per cent sulphuric acid is necessary for the complete removal of aromatic hydrocarbons. Ormandy and Craven,[57] however, found that even 98 per cent sulphuric acid attacks hydrocarbons other than the aromatics, hence it is unsatisfactory for this separation.

To outline this controversy a little further, the results of Manning,[58] Manning and Shepherd [59] and Kattwinkel [60] may be mentioned. Manning and Shepherd state that appreciable errors can arise from the solubility of the saturated hydrocarbons in the saturated solution of the sulphonated aromatic hydrocarbons. This is a point often ignored by other investigators. A mixture of aromatic-free petroleum ether and 20.0 per cent of benzene, for example, when shaken for ½ hour with 2 volumes of 98 per cent sulphuric acid, lost 17.0 per cent in volume, but the residual oil, on analysis, still contained 6.5 per cent of benzene. The acid therefore had dissolved 3.5 per cent of the petroleum ether. On shaking the same mixture for ½ hour with 3 volumes of 98 per cent acid, the loss in volume was 20 per cent but the residual oil still contained between 3 and 4 per cent of benzene. To effect complete removal of aromatic hydrocarbons, Manning and Shepherd proposed the use of 98 per cent sulphuric acid containing 2 to 3 per cent of silver sulphate. They assert that this substance greatly accelerates the sulphonation of benzene and its homologues but does not affect the action of the acid on saturated hydrocarbons. Kattwinkel,[61] on the other hand, recommended either sulphoacetic acid or the use of sulphuric acid (specific gravity, 1.84) containing 30 grams of phosphoric acid per 100 cc.

ESTIMATION OF AROMATIC HYDROCARBONS BASED ON SPECIFIC GRAVITY AND REFRACTION INDEX MEASUREMENTS

Because of the difficulties which exist in separating oils and sulphuric acid completely after acid treatment; numerous methods have been proposed in which the change in some physical property of the oil is used as an indication of the proportion of aromatic hydrocarbons absorbed by the acid. Such characteristics include the specific gravity, refractive index, and especially the critical solution temperatures of the oils in various solvents. The methods depend upon the fact that the aromatic hydrocarbons have higher specific gravities and refractive indices but lower critical solution temperatures than hydrocarbons of the other three classes.

Since aromatic hydrocarbons have higher specific gravities and refractive indices than other hydrocarbons, both these values decrease when aromatics are removed from a petroleum oil. A relationship exists between the aromatic content removed and the change in the physical property. Thus, the specific gravity and composition are related in the following way:

$$n = \frac{100\,D(d_1 - d_2)}{(D - d_2)\,d_1}$$

in which
n = Percentage of aromatics by weight
D = Specific gravity of aromatics only
d_1 = Specific gravity of oil under test
d_2 = Specific gravity of oil after extraction of aromatics

$$y = \frac{100\,(d_1 - d_2)}{D - d_2}$$

in which
y = Percentage of aromatics by volume, the other symbols having the same significance as above.

[61] *Loc. cit.*

The estimation of aromatic hydrocarbons based on specific gravity measurements has been described by Thole.[62] In this method the light oil to be examined is divided into three fractions boiling at (1) 40° to 95° C., (2) 95° to 122° C., and (3) 122° to 150° C., it being assumed that these three fractions contain all the benzene, toluene and xylenes, respectively. Each fraction is sulphonated separately and the specific gravities of the oils remaining are determined. The aromatic content is calculated from this, assuming that the aromatic hydrocarbons in each fraction have the same specific gravity as benzene, toluene and xylene, respectively. The formulas given above are, however, only approximately correct, since some contraction in volume takes place when aromatic and non-aromatic hydrocarbons are mixed. Thole proposed corrections to compensate for the errors resulting from this phenomenon, but Tilitsheyev and Dumskaya[63] pointed out that these were not completely effective, because the errors depend to a considerable extent upon the chemical composition of the non-aromatic portion. Thus, when benzene is mixed with cyclohexane a greater reduction in volume occurs than when benzene is mixed with hexane. Tilitsheyev and Dumskaya compiled a series of tables showing the relationship between the specific gravity of the non-aromatic portion and the so-called aromatic coefficients, i.e., the variation in specific gravity produced by 1 per cent of aromatics. When corrections are made with these tables, the method is said to give accurate results for oils boiling below 150° C. Because the specific gravities of higher-boiling aromatics vary widely, the procedure is unreliable for oils boiling above 150° C.

A similar method in which the change in refractive index is observed has been proposed by Hoyte,[64] but this has been shown to be subject to the same limitations as the specific gravity method.[65] Determinations of refractive index have also been suggested by Lob[66] to give indications of the nature of the constituents of hydrocarbon mixtures.

ESTIMATION OF AROMATIC HYDROCARBONS BY MEASUREMENTS OF CRITICAL SOLUTION TEMPERATURES

Measurements of the temperature at which an oil and a liquid (solvent) become completely miscible afford a method for the analysis and examination of petroleum distillates. Such temperatures are known as critical solution temperatures (C.S.T.) and the methods based on their determination owe their significance to the fact that, of the various hydrocarbon classes, the aromatics have the lowest, and the paraffins the highest critical solution temperatures. The solvents used are chiefly aniline and nitrobenzene, although benzyl alcohol has also been suggested. In aniline, the critical solution temperature of normal heptane[67] is 70° C., that of cyclohexane[68] is 31° C., and that of trimethylethylene is 11° C. Benzene is completely miscible in aniline at —10° C. The critical solution temperature of a material furnishes, therefore, some information with regard to its chemical composition.

Chavanne and Simon[69] observed that the presence of aromatic hydrocarbons decreased the critical solution temperature of a hydrocarbon mixture in aniline and that the lowering was directly proportional to the weight of aromatics present. They suggested such measurements as a method of hydrocarbon analysis. Tizard and Marshall[70] established the proposed method on a sound experimental basis. The somewhat elaborate and time-consuming critical solution temperature measurements were replaced by the determinations of "Aniline Points," which may be defined as temperatures at which equal volumes of the hydrocarbon mixture and aniline become completely miscible. By this modification, the method was adapted to rapid manipulation without the loss of any of its accuracy. Tizard and Marshall found that benzene, toluene and ortho-xylene, in equal proportions by weight, produced the same depressions of the aniline point, within the limits of experimental error, but that meta- and para-xylenes lowered the aniline points rather less than the same weight of benzene and toluene. As an analytical procedure they proposed that the difference in aniline points of a gasoline be determined before and after sulphonation with 98 to 100 per cent sulphuric acid. The aromatic content corresponding to this difference is then read from a standard chart showing the relation between aromatic content and lowering of the aniline point.

[69] *Loc. cit.*

The general utility of aniline points in the examination of hydrocarbon oils was discussed by Brame and Hunter,[71] by Carpenter,[72] Minchin and Nixon,[73] and Robinzon.[74] Mizuta[75] observed that the aniline-point lowering for each per cent of aromatic hydrocarbon increases with the content of aromatic hydrocarbon, and shows a sudden change at 35 per cent. Thiophene had about 60 per cent of the aniline-point lowering of benzene.[76] Its influence on the determination of aromatics in straight-run gasoline is negligible. Tilitsheyev and Dumskaya[77] examined the method critically for mixtures of pure hydrocarbons and mixtures of pure hydrocarbons with light petroleum distillates. In attempting to apply the general equation,[78]

$$x = Kd$$

(in which x represents the percentage of aromatic hydrocarbons by weight, d is the difference in the aniline points before and after removal of the aromatics, and k is a coefficient), these investigators showed that the value of K is generally dependent upon the following factors:

(1) The nature of the aromatic hydrocarbons.
(2) Fractional composition of the gasoline.
(3) Chemical composition of the non-aromatic portion of the sample under investigation.
(4) Concentration of the aromatic hydrocarbons.

As a result of this, the aniline point method of analysis is best adapted to the examination of narrow fractions of hydrocarbon oils. This is especially true for oils boiling between 150° and 200° C., which give inaccurate results by the specific gravity and refractive index methods.

The value to be given to the coefficient K must be carefully ascertained by trial experiments with the particular aromatic hydrocarbons which are to be estimated. If the nature of these hydrocarbons is unknown, the value of K may be assumed to be 1.2, but it must be realized that in some cases, depending upon the nature of the aromatic hydrocarbons and also of the non-aromatic components, the true value may be as high as 2.0 or as low as 1.0.

[78] This equation is applicable to other methods, such as those depending upon the difference in specific gravity or refractive index of the sample before and after removal of aromatics. The numerical value of K, of course, depends upon the particular method employed.

It is essential, in order to obtain accurate results, that the aniline used be absolutely dry and pure, and for this reason it should be freshly distilled. The presence of 1 per cent of water raises the aniline point of normal heptane[79] by 6.2° C. It is best to standardize the aniline against a hydrocarbon of known purity—normal heptane appears to be the most convenient hydrocarbon for this purpose, as it may easily be obtained of 99.9 per cent purity from the oil of *Pinus sabiniana.*[80] Table 161, mainly from data collected by Howes,[81] gives the aniline points of certain pure hydrocarbons and shows that

(1) The aniline points of hydrocarbons of a homologous series increase as the boiling points of the hydrocarbons increase.
(2) The aniline points of isoparaffins and iso-olefins are higher than those of their normal homologues.
(3) The aniline points of the naphthenes are lower than those of the paraffins, ranging from 20° to 60° C.

The measurement of aniline points has been proposed by Ormandy and Craven[82] and by Tizard and Marshall[83] as the basis of a method for the estimation of naphthene hydrocarbons in naphthene-paraffin mixtures, in which the following assumptions are made:

(1) That all paraffin hydrocarbons have an aniline point of 70° C.
(2) That all naphthene hydrocarbons boiling up to 95° C. lower the aniline points of paraffins by 0.4° C.; all naphthenes boiling between 95° and 120° C., by 0.3° C.; and all naphthenes boiling above 120° C., by 0.2° C. for each per cent of naphthene. In practice the average figure of 0.3° C. is used. If N = per cent naphthenes, and T = aniline point of the paraffin-naphthene mixture, the value of N may be calculated, therefore, as follows:

$$N = \frac{70 - T}{0.3}$$

This method gives inaccurate results because of the assumptions on which it is founded. Garner[84] described a somewhat similar method of estimating naphthene hydrocarbons in such mixtures, in which allowance is made for the rise of aniline point with increase in boiling point. The Garner method gives more accurate results than that of Ormandy and Craven.

Schaarschmidt, Hofmeier and Leist[85] used aniline points for the determination of the naphthene and paraffin content of mixtures. The naphthene content (N) can be calculated from the formula:

$$N = \frac{A - A_m}{A - a}$$

in which A = aniline point of component having the higher aniline point; A_m = aniline point of the mixture; a = aniline point of other component.

Nitrobenzene has also been suggested as a liquid to employ in critical solution temperature determinations. It is said to have certain advantages over aniline when used for this purpose. As with the latter solvent, the presence of aromatics lowers the critical solution temperature of mixtures of hydrocarbons and nitrobenzene. A sufficiently linear relationship exists between the C.S.T. depression and the amount of aromatics added to allow nitrobenzene to be used in this way. Erskine[86] found that the values of K in the general equation: $x = KT$ are 0.845 for benzene, 0.890 for toluene, and 0.938 for xylene, when equal weights of hydrocarbon mixtures and nitrobenzene are employed. Compared with those obtained with mixtures of hydrocarbons and aniline, the C.S.T.'s of mixtures of hydrocarbons and nitrobenzene are much lower, and the C.S.T.'s of mixtures of normal paraffin hydrocarbons and nitrobenzene decrease with increasing molecular weight and boiling point. See Table 162.

TABLE 162.—*Critical Solution Temperature of Paraffins in Nitrobenzene.*

	° C.
n-Pentane	24.5
Isopentane	31.25
n-Hexane	14.8
Isohexane	24.05
n-Heptane	11.5
Isoheptane	18.05

The use of the critical solution temperature in nitrobenzene for the estimation of aromatics has been examined by Dobryanskii and Khesin,[87] who found that the value of the coefficient K falls off rather rapidly with increase in concentration of the aromatics but that it has practically the same value for all aromatic hydrocarbons with short side-chains. Tilitsheyev and Dumskaya[88] compared the aniline and nitrobenzene methods and found that the latter has the following advantages:

1. Lower critical solution temperatures and therefore more rapid determination.
2. Smaller fluctuations of nitrobenzene coefficient as a result of variation of the chemical composition of the non-aromatic portion.
3. Greater stability of nitrobenzene.

The nitrobenzene method is especially adapted to the examination of very light and volatile hydrocarbons, because the lower critical solution temperatures minimize the danger of loss by evaporation.

All methods for estimating aromatic hydrocarbons by C.S.T. measurements before and after the removal of aromatics are dependent for their accuracy upon the efficiency of the reagent used to extract the aromatics. If the reagent removes these hydrocarbons incompletely, the estimated aromatic content will be too low and the estimated naphthene content (if this, too, is determined by C.S.T. measurements) will be too high. To overcome this difficulty, Aubert and Aubrée[89] developed a procedure in which the removal of aromatic hydrocarbons is unnecessary. The method is applicable only to ternary mixtures and was suggested particularly for the analysis of aviation gasoline. It was tested with mixtures of pure hexane, heptane, octane, decane, cyclohexane, methylcyclopentane, benzene and toluene.

The basis of this method is as follows:

If $T =$ C.S.T. of original mixture
$T_1 =$ C.S.T. of mixture after removal of aromatics
$\theta_n =$ C.S.T. of naphthenes
$\theta_p =$ C.S.T. of paraffins
$A =$ per cent aromatics
$N =$ per cent naphthenes
$P =$ per cent paraffins

---

[86] *Ind. Eng. Chem.*, 1926, 18, 694.

[88] *J. Inst. Pet. Tech.*, 1929, 15, 465; *Brit. Chem. Abs.* B, 1929, 879; *Chem. Abs.*, 1929, 23, 5566.
[89] *Compt. rend.*, 1926, 182, 577; *Chem. Abs.*, 1926, 20, 1712.

Then

$$A = K(T_1 - T)$$

and

$$N = \frac{\theta_p - T_1}{\theta_p - \theta_n}(100 - A)$$

and by eliminating T_1 between the two equations

$$\frac{N(\theta_p - \theta_n)}{100 - A} = \theta_p - \left(\frac{A}{K} + T\right)$$

a relationship which does not involve T_1.

It is necessary to use two solvents for both of which the general values of K, θ_n and θ_p are known. The critical solution temperature of the mixture in each of these solvents is then determined, and after substituting the appropriate values in the above formula, two equations with two unknown quantities (A and N) are obtained. From these equations the values of A and N can be determined. Aniline is used as one solvent for the C.S.T. determinations and benzyl alcohol, because of its high boiling point (206° C.), was suggested as the other solvent.

Aromatics are soluble in all proportions in benzyl alcohol at ordinary temperatures, and the critical solution temperatures of hydrocarbons in benzyl alcohol are lower than in aniline, which is especially favorable for the examination of volatile fractions. For the two saturated series of hydrocarbons, namely, naphthenes and paraffins, the variation in C.S.T. from one member to another of the same series is more accentuated than with aniline.[90] This makes the use of benzyl alcohol not as well adapted to approximate analyses of gasolines and light oils as to the precise analyses of narrow fractions. In view of the fact that unsaturated hydrocarbons also have low aniline points, their presence will materially affect the accuracy of any results obtained in the determination of aromatics. It is therefore necessary to remove unsaturated hydrocarbons completely before an estimation of aromatics is conducted in this way. According to Garner,[91] a given weight of unsaturated hydrocarbons depresses the aniline point of a hydrocarbon mixture to two-fifths the extent produced by the same weight of aromatics. This, however, is to be considered only as an approximate figure. Dietrich[92] suggested the determination of aromatics by critical solution temperatures of 7 parts of the oil with 3 parts of 96 per cent ethyl alcohol. The critical solution temperatures of hydrocarbon mixtures containing over 50 per cent aromatics cannot be determined with aniline because of the low temperature. Liquid ammonia has been suggested as the solvent for such mixtures by Tropsch and Simek.[93]

ESTIMATION OF AROMATIC HYDROCARBONS WITH NITRIC ACID AND NITRIC-SULPHURIC ACID MIXTURES

The ease with which aromatic hydrocarbons may be nitrated has led to the development of other methods for the estimation of these substances. In a procedure of this kind, the aromatics are treated with fuming nitric acid. The nitrated products are then dissolved in a known volume of sulphuric acid. From the increase in volume of the acid layer,[94] the content of aromatic hydrocarbons may be calculated. This method, however, is not accurate because a change in volume occurs when nitrated products are dissolved in sulphuric acid, and each nitrated hydrocarbon not only gives a different volume change but also a different volume of nitrated products. For similar reasons, methods based on the weight of nitro-compounds produced are also inaccurate. Such methods have been proposed by Florentin and Vandenberghe,[95] and Heyn and Dunkel.[96] A more accurate procedure is to measure the volume of unchanged saturated hydrocarbons after treatment. This is recommended by Hess.[97] Egloff and Morrell[98] proposed a method depending upon the use of a concentration of nitric-sulphuric acid (25% nitric acid, 58% sulphuric acid, 17% water) in which nitro-aromatic bodies are not soluble, but separate out as a distinct layer whose volume can be measured. The volume of this layer is multiplied by a constant (4.3) to convert it directly to percentage aromatics. According to Riesenfeld and Bandte,[99] the method recommended by Hess gives good results, but those obtained by the Egloff and Morrell method are too low for mixtures of low aromatic content and too high for mixtures of high aromatic content. The latter observation was confirmed by Faragher, Morrell and Levine.[100] Garner[101] used fuming nitric acid at temperatures of —10° to —15° C. to remove both aromatic and unsaturated hydrocarbons. Accordingly, the gasoline is shaken with fuming acid at the temperature mentioned and the nitro-bodies which dissolve in the residual gasoline are washed out with additional fuming nitric acid. From the difference in the aniline points of the gasoline before and after treatment, is obtained the "aromatic equivalent", i.e., the percentage of aromatic hydrocarbons which correspond to such a lowering.[102] The percentage loss in volume resulting after the nitric acid treatment is also determined. From these two values (assuming that unsaturated hydrocarbons depress aniline points to two-fifths the same extent as aromatic hydrocarbons, as previously mentioned), the percentage of each type of hydrocarbon can be calculated in the following manner:

---

[90] Aubrée, *Chimie et industrie*, Spec. No., Sept. 1926, 336; *Chem. Abs.*, 1927, 21, 644.
[91] *J. Inst. Pet. Tech.*, 1928, 14, 695; *Brit. Chem. Abs.* **B**, 1929, 84.
[92] *Autotechnik*, 1927, 16, 7; *Brit. Chem. Abs.* **B**, 1928, 882.
[93] *Mitt. Kohlenforschungsinst. Prag*, 1931, 62; *Brit. Chem. Abs.* **B**, 1933, 497.
[94] Halphen, *Mat. grasses*, 1911, 3, 1987; *Chem. Abs.*, 1911, 5, 1676.

If $A =$ per cent aromatics
$B =$ per cent unsaturates
$a =$ aromatic equivalent
$b =$ percentage loss in volume after nitric acid treatment

then

$$A + \frac{2}{5}B = a$$

$$A + B = b$$

or

$$B = \frac{5}{3}(b - a) \quad \text{and} \quad A = b - B.$$

Another method for the determination of aromatics has been described by Manning.[103] A small sample of the oil is weighed into a small U-tube and vaporized by drawing through it a current of nitrogen or carbon dioxide-free air. If unsaturated hydrocarbons are absent, the oil vapors are absorbed in 98 per cent sulphuric acid (also in a U-tube) containing 2 to 3 per cent silver sulphate. The gain in weight of the tube represents the aromatic content of the sample.

[102] This value is actually calculated from the data previously given by Tizard and Marshall.

[103] *J.C.S.*, 1929, 1014.

When the sample contains unsaturated hydrocarbons, the oil vapors are absorbed in a nitrating mixture (10 per cent concentrated nitric acid, or 16 per cent potassium nitrate in concentrated sulphuric acid) contained in small potash bulbs. The increase in weight of the bulbs corresponds to the aromatic and unsaturated content of the oil, after a small correction has been applied for the retention of saturated hydrocarbon vapors. The nitration of the aromatics is completed by adding a little more nitric acid and heating for 2 to 3 hours on a water bath. The unsaturated hydrocarbons are at the same time oxidized to carbon dioxide, acids and other compounds soluble in water and aqueous alkali solution. The nitration mixture is poured into water, the nitrated products are extracted with benzene and, after washing, the benzene is evaporated. From the weight of products obtained, the percentage of aromatics is calculated by multiplying by the factor 0.452.

DETERMINATION OF AROMATIC HYDROCARBONS BY THE USE OF PREFERENTIAL SOLVENTS

As mentioned in Chapter 1, the most widely used solvent for the extraction of aromatics from petroleum distillates is liquid sulphur dioxide, which was originally suggested by Edeleanu[104] and which is used in the commercial refining of lubricating oils and for the removal of aromatics from kerosene. Laboratory tests on the extraction of aromatics with liquid sulphur dioxide have been carried out by Moore, Morrell and Egloff.[105] Another well-known solvent for aromatic hydrocarbons is dimethyl sulphate, proposed by Valenta,[106] who stated that it has no solvent action on paraffins or naphthenes. This assertion has been refuted by others.[107]

Various other solvents have been suggested, including aniline,[108] diethyl sulphate,[109] levulic acid, phenylhydrazine, glycol monoacetate, and furfuraldehyde,[110] and sulphoacetic acid[111] in acetic anhydride. However, none of these give accurate results because the solubility of the different classes of hydrocarbons in each other is far greater than the solubility in any solvent.

ESTIMATION OF PARAFFIN AND NAPHTHENE HYDROCARBONS

In the analysis of a light mineral oil, after unsaturated and aromatic hydrocarbons have been removed, a mixture of paraffins and naphthenes remains. The estimation of these two classes of hydrocarbons in the presence of each other is a difficult task. The only methods which give even approximately accurate results are those described by Tizard and Marshall,[112] Ormandy and Craven,[113] Garner,[114] and Schaarschmidt, Hofmeier, and Leist.[115]

Other procedures, however, have been suggested. Danaila, Andrei and Melinescu[116] proposed that the cyclohexane series of naphthenes be estimated by dehydrogenation over a nickel catalyst at an appropriate temperature. In this way, the naphthene hydrocarbons are converted into aromatics, which may be estimated by sulphonation in the manner already described. Obviously the cyclopentanes cannot be estimated in this manner. A similar dehydrogenation, in which palladium black was the catalyst, has been used by Manning and Shepherd.[117] At a temperature of 350° C. in a current of nitrogen, a 94 per cent conversion of cyclohexane into benzene resulted, but attempts to dehydrogenate cyclohexane mixed with petroleum ether (boiling point, 40° to 60° C.) failed. The results were low and could not be duplicated. Moreover, no further dehydrogenation was effected by recirculation of the vapor over the catalyst. Not only were the paraffin hydrocarbons decomposed to some extent but the unsaturated residues appeared to have coupled with the partly dehydrogenated cyclohexane to form higher homologues of the latter, which were not completely dehydrogenated under the conditions employed. These difficulties were overcome by working at a slightly lower temperature (320° to 335° C.), at which the higher homologues of cyclohexane were not as readily dehydrogenated as cyclohexane itself. In nitrogen at 350° to 360° C., not more than 70 per cent of methylcyclohexane was converted, whereas in hydrogen only 38 per cent was dehydrogenated. The equilibrium point of the reaction, which for cyclohexane corresponds to almost complete dehydrogenation under the experimental conditions employed, corresponds to only a partial dehydrogenation for methylcyclohexane. By working at 330° C. and removing the toluene as formed, 93 to 96 per cent conversion was obtained.

SEPARATION OF UNSATURATED HYDROCARBONS FROM PETROLEUM

The analytical methods already described in this chapter for the estimation of the classes of hydrocarbons in the lighter distillates of petroleum are of little value for the isolation of these substances. Other means must be employed for this purpose. In work of this character, the use of distillation columns similar to those described by investigators at the U. S. Bureau of Standards[118] offer many advantages. These columns are of the bubble-plate variety and give extremely efficient fractionation.

Hydrocarbons of the olefin series may be separated conveniently from other hydrocarbons as dibromides. The bromine addition products are of high boiling point and may be fractionated from unchanged hydrocarbons. Subsequently, they may be decomposed by the action of a zinc-copper couple and alcohol (Gladstone and Tribe's method[119]) to give the parent olefins. In the bromination of olefins, the temperature should not rise above —5° C., otherwise substitution may occur. A convenient method to adopt for the decomposition of the dibromides is to cover a freshly prepared zinc-copper couple with 90 per cent ethyl alcohol, gently boil the alcohol and gradually add to it the dibromide. The heat of reaction is generally sufficient (in the case of the lower hydrocarbons) to distil the olefin as liberated, but with higher olefins, heat from an outside source may be necessary. The alcohol-olefin distillate may be diluted with water, the olefins separated, dried and fractionated. On the other hand, it may be found convenient to fractionate the dibromides before decomposition, usually under reduced pressure. This method of isolating olefin hydrocarbons has been used successfully by Brame and Hunter,[120] and by Wilkinson.[121]

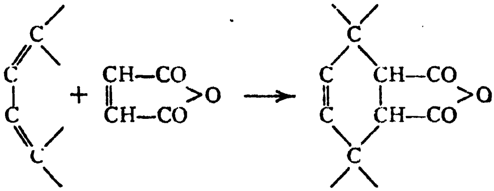
The same general procedure may be used for the isolation of diolefins. The diolefin tetrabromides which form can be separated from the dibromides resulting from monolefins, by fractionation. Butadiene and piperylene give solid tetrabromides, whereas isoprene, cyclopentadiene and the dimethyl butadienes yield liquid tetrabromides (see Chapter 27).

Cyclopentadiene has been isolated from oil-gas condensate by Etard and Lambert[122] and from lignite-tar and coal-tar oils by Krämer and Spilker[123] as the dimer, which readily forms on standing and can be decomposed by distillation. This method, involving polymerization and subsequent depolymerization, is only of use with certain cyclic diolefins. For the identification of diolefins, the typical reaction (described in Chapter 27) between diolefins and maleic anhydride may be used. This reaction proceeds as follows:



and the products formed are characteristic crystalline derivatives.[124]

As already mentioned, attempts have been made by Brame and Hunter[125] to use the reaction between olefins and mercuric acetate for the isolation of unsaturated hydrocarbons. Unfortunately, large amounts of hydrocarbons were destroyed and lost when the resulting complexes were decomposed with acids.

Separation of Aromatic Hydrocarbons from Petroleum

Because aromatic hydrocarbons have lower critical solution temperatures in aniline than other hydrocarbons, it has been found convenient to use methods of preferential extraction with such solvents to obtain oil fractions rich in aromatics. In this way a partial concentration of aromatic hydrocarbons can be effected. From such a concentrate the individual hydrocarbons can be separated by chemical methods. Solvents commonly used for such fractional extractions are aniline and liquid sulphur dioxide and the operations are usually conducted at a temperature of 0° C. or lower.

Such procedures have been used by Bruun and Hicks-Bruun[126] for the isolation of benzene from an Oklahoma crude oil and proved valuable in the separation of benzene from constant-boiling mixtures of benzene and hexanes which could not be resolved readily by other means. Thus 1600 volumes of a 68°-69° C. fraction (n^{20}_{D} 1.395) was extracted once with aniline in a special apparatus designed for this purpose. As a result two fractions were obtained, one of 200 volumes with n^{20}_{D} 1.419 and the other of 1300 volumes with n^{20}_{D} 1.391. By subjecting the 200-volume fraction to fractional crystallization a sample of purified benzene (n^{20}_{D} 1.501) was obtained.[127] An apparatus used by Bruun and Hicks-Bruun[128] permits the solvent extraction to be made conveniently more than once, the extent of the separation increasing, of course, with each extraction.

Carpenter[129] pointed out that aniline containing a small proportion of water has a more selective action on hydrocarbons than dry aniline. Low temperatures were also found to be of advantage. Such methods of preferential extraction with solvents may be employed for the partial separation of naphthene hydrocarbons from paraffins.

Another method used for the extraction and isolation of aromatic hydrocarbons from light petroleum distillates is that of Armstrong and Miller,[130] in which aromatic sulphonic acids are decomposed to the original hydrocarbons with superheated steam. When this procedure is employed, the oil can be sulphonated with 98 per cent sulphuric acid. The sulphuric acid containing the sulphonated products can then be treated as mentioned. This method has been used by Mulany and Watson[131] in a study of the aromatic content of Burmah light oils and by Iimori and Kikuchi.[132] Carpenter,[133] however, obtained only a yield of 60 per cent of the aromatics originally present in a Burmah crude.

SEPARATION OF PARAFFIN HYDROCARBONS FROM PETROLEUM

Paraffin hydrocarbons, because they are more stable than other hydrocarbons, can be separated from aromatics, olefins and naphthenes by treating mixtures containing them with reagents which react with the other three classes of hydrocarbons. Such processes, however, only yield the normal paraffins, because the branched-chain isomers are also attacked. A reagent suggested for this purpose is chlorosulphonic acid, which has been used by Shepard and Henne,[134] Shepard, Henne and Midgley,[135] Leslie and Schicktanz,[136] and by Bruun and Hicks-Bruun.[137] According to Shepard and Henne, paraffin and naphthene hydrocarbons containing secondary and tertiary carbon atoms are rapidly attacked by this reagent, whereas the normal paraffin hydrocarbons and cyclohexane and cyclopentane are only slowly affected. The latter hydrocarbons may be separated by fractional distillation. Unfortunately, the reaction takes a long time to reach completion. Shepard and Henne found it necessary to subject a decane fraction to this treatment for a period of 37 days to purify it.

Another reagent which has been used for the separation of branched-chain hydrocarbons from hydrocarbon mixtures is antimony pentachloride. Schaarschmidt[138] found that treatment with this substance caused the separation of tertiary compounds as an oily or crystalline mass which assumed an intense violet color when shaken with alcohol. One molecule of the hydrocarbon appears to react with two of antimony pentachloride. Normal and quaternary compounds also react but heat is required.

The formation of constant-boiling mixtures with methyl alcohol has been used by Bruun and Hicks-Bruun[139] in the isolation of isomeric hexanes from an Oklahoma crude oil and in the isolation of cyclohexane[140] and methylcyclopentane.[141] Fractional crystallization has been used in the isolation of pure paraffins and other hydrocarbons,[142] for example, in the separation of n-octane from an Oklahoma crude oil.[143] It was shown to be a good method for the resolution of azeotropic mixtures which cannot be separated conveniently by other means.

DISTILLATION TESTS

For routine testing of petroleum and its fractions various methods have been standardized by the American Society of Testing Materials (A.S.T.M.) and The Institution of Petroleum Technologists (I.P.T.). These methods are, for the most part, concerned with the determination of characteristics which decide the market values of the oils. These methods have been in general use in the petroleum industry for extensive periods and considerable information has been obtained with regard to their significance.[144] The following account is intended only as a brief description of the methods employed, and for complete details, reference should be made to:

(1) "Standard Methods of Testing Petroleum and its Products, 2nd Edition," **1929** —Published by The Institution of Petroleum Technologists.
(2) "United States Government Master Specification for Lubricants and Liquid Fuels and Methods of Sampling and Testing," *U. S. Bureau of Mines Technical Paper* **323B**, 1927; and
(3) Index to "American Society for Testing Materials Standards and Tentative Standards," September, **1931**, American Society for Testing Materials, 260 South Broad St., Philadelphia, Pa.

A distillation test for routine examinations must necessarily be simple and at the same time be capable of complete standardization in every detail likely to affect the results, so that substantial agreement may be obtained between different workers and different laboratories. The distillation tests of the A.S.T.M. and the I.P.T. meet these requirements. In each case, distillation is conducted in a small round-bottomed flask with side-arm, of definite dimensions, supported on an asbestos plate within a draught-proof cabinet. The condenser is a straight piece of brass tube resting in a cooling bath, and this, as well as every other part of the apparatus, is rigidly standardized.

The test, in the case of gasolines, naphthas and kerosenes, is carried out by distilling in the apparatus 100 ml. of material at a distillation rate of between 4 and 5 ml. per minute and recording either the volume of distillate obtained at temperatures that are even multiples of 25° C. (50°, 75°, 100° C., etc.) (I.P.T. procedure) or the temperatures registered on the thermometer when each successive 10 ml. of distillate is collected[145] (A.S.T.M. procedure). Observations of the temperature at which the first drop of liquid falls from the condenser tube, i.e., the "initial boiling point", the highest temperature recorded on the thermometer, i.e., the "end point", the amount of distillate collected in the receiver, i.e., the "recovery" or "total distillate" and the amount of undistilled residue, are also made. The difference between 100 ml. and the sum of the recovery and the "residue" is recorded as "distillation loss". With proper care and attention to the details prescribed, duplicate results obtained for initial boiling point and end point, respectively, should not differ from each other by more than 3° C. Duplicate readings of the volume of distillate collected in the receiver at different prescribed temperatures should not vary by more than 2 ml. The barometric pressure is also recorded, but no correction is applied except in cases of dispute, when the Sydney Young[146] equation is used.

[144] Physical properties and their significance are also discussed in: Gruse, "Petroleum and Its Products," McGraw-Hill Book Co., Inc., New York, **1928**, 67; Gurwitsch-Moore, "Scientific Principles of Petroleum Technology," D. Van Nostrand Co., Inc., New York, **1932**, 180; Hicks-Cox, "Mineral Oil Testing," Charles Griffin and Co., Ltd., London, **1925**; Hamor and Padgett, "The Technical Examination of Crude Petroleum, Petroleum Products and Natural Gas," McGraw-Hill Book Co., Inc., New York, **1920**.

$$C = 0.00012\ (760 - P)\ (273 + t)$$

in which C = correction to be added (° C.) to the observed temperature (t); P = actual barometric pressure.

With gasoline, the asbestos plate supporting the distillation flasks has cut in it a circular hole, 1¼ inches in diameter, but when kerosenes are distilled, an asbestos plate with a 1½ inch hole is used. Similarly, the cooling bath is filled with ice when gasolines are distilled, but with water at a temperature not higher than 21° C. when kerosene or similar distillates are examined. According to I.P.T. methods, gas oils and Diesel oils are examined for distillation characteristics by distilling from a 500 ml. side-arm flask supported on a sand bath.

The distillation test is of especial importance in the examination of motor fuels because the boiling range of a gasoline and its content of volatile constituents have been shown to be intimately related to its general performance in an engine.[147]

Color Tests

Color tests are used to determine the extent of refining of gasolines, kerosenes and lubricating oils. Three kinds of instruments are used for this purpose: (1) The Lovibond Tintometer, which is specified in I.P.T. tests for gasolines, naphthas and paraffin waxes; (2) the Saybolt Chromometer, which is used in A.S.T.M. tests for gasolines, kerosenes and naphthas; and (3) the Union Colorimeter for standard A.S.T.M. lubricating oil tests. In each of these instruments a beam of white light is passed through a color glass and another is passed through the oil. The colors of both beams are compared. The color of the oil sample may then be matched with that of the standard glass either by varying the depth of the oil—as in the Saybolt Chromometer—or by changing the standard color glasses—as in the Union Colorimeter and the Lovibond Tintometer. A photoelectric colorimeter, which removes some of the difficulties in matching colors, has been described by Story and Kalichevsky.[148]

---

[145] This procedure is sometimes varied in that the volume of distillate is recorded at temperatures which are even multiples of 10° (e.g., 40°, 50°, etc.). This permits an easy and rapid comparison of Centigrade and corresponding Fahrenheit temperatures.

TESTS FOR SULPHUR AND SULPHUR COMPOUNDS

Various sulphur compounds occur in motor fuels and other petroleum fractions, their type and proportion depending upon the source of the crude from which they are derived and the refining to which they have been subjected. In motor fuels and kerosenes, certain sulphur compounds must be removed, because of their offensive smell and corrosive action. Petroleum fractions intended for use as fuels must not contain more than a small amount of sulphur compounds because of the corrosive combustion products (principally sulphur dioxide) formed (see Chapter 19). Consequently, tests for sulphur compounds in petroleum distillates are performed in such a way as to differentiate between the offending sulphur bodies and those which can be tolerated. Thus, separate tests are employed for elemental sulphur, hydrogen sulphide, sulphur dioxide and mercaptans, the other sulphur compounds being classed as "residual" sulphur. The total sulphur content of fuels is generally limited to about 0.10 per cent as an extra precaution.

The I.P.T. method for testing for *elemental sulphur* in light oils makes use of the reaction between sulphur and mercury, with the addition of a small amount of dilute hydrochloric acid to the reaction mixture to coagulate the sulphide produced.[149] The precipitated sulphide is digested with hydrochloric acid, to which a small quantity of potassium chlorate is added, and subsequently diluted and filtered. The sulphur is precipitated as barium sulphate and estimated in the usual way. This method is, however, criticized by Hoffert[150] on the ground that loss of hydrogen sulphide, when the mercuric sulphide is dissolved in acid, produces low results with high sulphur concentrations.

Garner and Evans[151] described a method for estimating elemental sulphur in light oils by refluxing with copper-bronze powder. The bronze is then separated from oil by filtration and dissolved in bromine, together with the sulphide produced. A little hydrochloric acid is added and the excess bromine boiled off and the sulphur precipitated as barium sulphate in the usual way.

A modification of the Halphen[152] method of estimating cottonseed oil has been proposed by Thornton and Latta[153] for the colorimetric determination of free sulphur in petroleum distillates. The oil is treated with a mixture of 80 cc. of refined, unbleached cottonseed oil, 80 cc. of carbon disulphide and 8 cc. of pyridine at 100° C. for 30 minutes. The color developed is compared with standards.

Mercaptans are objectionable constituents of motor fuels and kerosenes because of their offensive odor and corrosive action. The common method of removing mercaptans in refining practice is with the so-called "doctor" solution. which consists of a solution of litharge (PbO) in caustic soda. The doctor test, which uses the same reagent, is the common method of test for mercaptans in light oils. The chemistry of the reaction has been discussed in Chapter 19.

The doctor test is briefly as follows: A small quantity of both the petroleum distillate and doctor solution are placed in a test tube and thoroughly agitated. The tube is then allowed to stand until the mixture has separated into two layers. A pinch of sulphur is next added to the oil (upper) layer, and the contents of the tube are again thoroughly agitated. The test tube is again allowed to stand to allow the mixture to separate into two layers. The appearance of black lead sulphide at the junction of the two layers indicates the presence of mercaptans in the distillate. If a large quantity of mercaptans is present, the distillate becomes yellow after shaking with the doctor solution as a result of the formation of soluble lead mercaptides. This also furnishes an indication of the presence of mercaptans. The doctor test for mercaptans is specified by both the A.S.T.M. and the I.P.T.

If a black precipitate of lead sulphide is formed almost immediately when the distillate and the doctor solution come in contact before agitation, this is usually taken as an indication of the presence of hydrogen sulphide in the distillate.

2,4-Dinitrochlorobenzene has been suggested for the identification of mercaptans by Bost, Turner and Norton.[154] The mercaptans combine with this reagent, yielding solids that are easily purified and have sharp melting points and definite crystalline structure. The iodometric method for the estimation of mercaptans and its various modifications are mentioned in Chapter 19.

Various tests are used to indicate the presence of elemental sulphur, or of *corrosive sulphur compounds* in light oils.[155] Copper is generally the metal used for the manifestation of the corrosive action. In the well-known copper dish test, 100 ml. of light naphtha (e.g., aviation gasoline) are evaporated from a hemispherical copper dish placed upon a water bath. If the inside of the dish becomes colored or corroded the presence of objectionable sulphur compounds is indicated, whereas if the naphtha contains undesirable gum-forming constituents a weighable amount of gum is deposited on the dish.[156] In another method a strip of freshly polished copper is allowed to stand in the sample to be tested for 3 hours[157] at a temperature of 50° C. (122° F.).

Two general methods are employed for the *total sulphur determination:* one is the "lamp" method, applicable particularly to the determination of the sulphur content of lighter distillates such as gasoline or kerosene, and the other is the bomb calorimeter method, used with heavier oils.

In the lamp method a weighed quantity of the distillate is burned in a current of air and the products of combustion, together with the excess air, are passed through a dilute, standard solution of sodium carbonate.[158] Any sulphur compounds in the sample are burned to sulphur dioxide, which is absorbed by the carbonate solution with the formation of sodium sulphite. The oxygen present in the excess air in the combustion mixture oxidizes the sodium sulphite to sodium sulphate. Titration of the carbonate solution, with a standard solution of acid, before and after absorption, indicates the quantity of sulphur dioxide formed and from this can be calculated the quantity of sulphur in the oil.

If *chlorine* is present with the sulphur, it can be estimated, according to Wirth and Stross,[159] in a similar way. The gasoline is burned in a lamp in the usual way, the combustion products being absorbed in standard sodium carbonate solution. The excess sodium carbonate is then titrated with standard sulphuric acid, and the chlorine is subsequently titrated with silver nitrate solution by Mohr's method. The first titration gives the acidity due to the formation of hydrochloric and sulphuric acids. After the chlorine has been determined, the acidity resulting from the sulphuric acid alone can be calculated.

[154] *J.A.C.S.*, 1932. 54, 1985.

[155] Numerous tests for indicating corrosive sulphur compounds were investigated by Garner and Evans, *J. Inst. Pet. Tech.*, 1931, 17, 451.

[156] Methods for the determination of gum-forming constituents are described in Chapter 40.

[157] Sometimes 30 minutes at 100° C. (212° F.) is used instead of the longer period.

[158] An improved lamp for this combustion is described by Plonskier, *Ann. chim. analyt.*, 1932, (2) 14, 154; *Brit. Chem. Abs.* B, 1932, 968.

[159] *Ind. Eng. Chem., Anal. Ed.*, 1933, 5, 85.

In the bomb method the sample is burned in the presence of a large excess of oxygen. The sulphur is converted to sulphuric acid, and the quantity of acid produced can be determined in the usual manner by precipitating as barium sulphate and weighing. An adaptation of this bomb method has been described by Woodward.[160]

Electrolytic oxidation of the sulphur in mineral oils to sulphones, in the presence of nitric acid, has been described by Boisselet and Kryloff.[161]

A method of determining sulphur in oils by fusion with calcium hydride, which converts the sulphur to calcium sulphide, has been developed by Caldwell and Krauskopf.[162] The sulphide can be estimated by titration of the acidified solution of the fusion residue with iodine.

Sulphur may also be detected by boiling with metallic sodium and testing with sodium nitroprusside.[163] Grote[164] dissolved the compound to be tested in water and added an excess of sodium bicarbonate, followed by a reagent consisting of sodium nitroprusside, hydrazine hydrochloride and bromine. Characteristic colors were observed with various sulphur compounds.

OTHER METHODS FOR THE ESTIMATION OF SULPHUR COMPOUNDS

The amounts of the various general types of sulphur compounds in petroleum distillates can be estimated by the method of Faragher, Morrell and Monroe[165] which follows:

A small quantity of the oil is shaken with a slightly acidified solution of cadmium chloride. The percentage of *hydrogen sulphide* is calculated from the weight of cadmium sulphide precipitated. Caustic soda solution cannot be used in this test because it dissolves some of the mercaptans in addition to hydrogen sulphide.

According to Trusty,[166] hydrogen sulphide in natural gas can be determined by absorption in iodine solution. In refinery gases containing unsaturated hydrocarbons which react with iodine, the hydrogen sulphide can be precipitated as lead sulphide from lead nitrate solution, the excess of the latter being titrated with ammonium molybdate. Givaudin[167] removed hydrogen sulphide from petroleum with nitrogen and passed the resulting gas mixture into zinc acetate solution. The precipitated zinc sulphide was determined iodometrically.

After removal of sulphuretted hydrogen, *elemental sulphur* is estimated by the mercury treatment already described.

After removal of hydrogen sulphide and elemental sulphur, the *mercaptans* may be removed by treatment with alcoholic plumbite solution—an alcoholic solution being used to give better contact between the oil and the plumbite. Total sulphur estimation before and after this treatment gives the mercaptan sulphur content.[168]

[168] An alternate method for the estimation of mercaptans consists in agitating the sample with an aqueous suspension of basic lead acetate, separating the oil and water layers, and determining the

Alkyl disulphides may be determined, after removal of mercaptans, by reducing them to mercaptans with glacial acetic acid and zinc dust. The resulting mercaptans may be estimated in the manner described above.

After the above successive treatments, the oil should contain no sulphur compounds other than alkyl sulphides and thiophenes. *Alkyl sulphides* can be estimated by treating the oil with an aqueous solution of mercurous nitrate—with which alkyl sulphides form addition compounds of the general type $R_2S.HgNO_3$. Total sulphur determinations before and after this treatment reveal the amounts of *alkyl sulphides* and *thiophenes* present. A method for the determination of alkyl sulphides in the absence of unsaturated hydrocarbons has been described by Sampey, Slagle and Reid.[169]

FLASH POINTS

The flash point of an oil may be defined as the temperature at which an oil evaporates so intensively that its vapor, in an open space of specified dimensions or in any other specified container, forms an ignitible mixture with air. This temperature must not be confused with the "burning point", that temperature at which the intensity of the evaporation is such that the vapors not only flash on the approach of a flame, but continue to burn. Both these values, particularly the first one, are of aid in indicating fire risks. The lower the flash point of an oil, the more likely is it to evaporate and form an explosive vapor, and consequently greater precautions against fire in storage and distribution are necessary.

For the determination of the flash points of petroleum oils, many types of apparatus are used, depending upon the kind of oil to be tested. The better-known are: (1) the Abel apparatus used in the I.P.T. standard tests for kerosenes and all oils having a flash point below 90° F. (32.2° C.); (2) the Pensky-Mortens apparatus used in I.P.T. standard tests for all oils having a flash point of above 90° F.; and (3) the Cleveland open cup tester which is used in the testing of heavy oils. Each of these types are similar in mode of operation. The oil to be tested is heated in a small container at a specified rate and at certain intervals of temperature a small test flame is applied to the vapor space above the liquid. The lowest temperature at which the oil vapor or mixture gives a momentary flash is taken as the flash point. Further details concerning the determination of flash points are given in the standard publications mentioned at the end of this chapter.

VISCOSITIES OF PETROLEUM OILS

As in the case of flash points, the viscosities of petroleum oils are usually measured in an apparatus specially designed for this purpose. Arbitrary scales of viscosity units have been in general use in the petroleum industry ever since its inception. Measurements are usually made, as in the well-known Redwood, Saybolt, and Furol viscometers, by determining the rate of efflux of oils through calibrated orifices under rigidly specified conditions. The time taken for the efflux of a specified volume of oil is usually taken as the index of viscosity. Thus, when the viscosity of an oil is given as 50 seconds Saybolt at some tem-

quantity of sulphuric acid required to react with the mercaptides. The equations given for the reactions taking place are:

$$Pb(OH)(C_2H_3O_2) + 2RSH \rightarrow (RS)_2Pb + HC_2H_3O_2 + H_2O$$
$$Pb(SR)_2 + H_2SO_4 \rightarrow PbSO_4 + 2RSH$$

Borgstrom and Reid (*Ind. Eng. Chem., Anal. Ed.,* 1929, 1, 186) suggested agitating the sample with a given volume of standard silver nitrate solution, removing excess silver nitrate with standard ammonium thiocyanate solution, and titrating excess thiocyanate with standard silver nitrate solution.

[169] *J.A.C.S.,* 1932, 54, 3401.

perature, it means that it has an efflux time of 50 seconds at that temperature from a Saybolt viscometer. Further details concerning these measurements are given in the standard publications of the Institution of Petroleum Technologists and The American Society for Testing Materials. Convenient methods for the determination of the viscosities of oils in absolute units are described by The British Engineering Standards Association in their Specification No. 188 (1929).

OTHER TESTS USED IN THE EXAMINATION OF PETROLEUM PRODUCTS

Other tests used by the petroleum industry in the examination of mineral oils include burning tests for kerosene, tests for acidity and alkalinity, determination of calorific values (i.e., heats of combustion), ash contents, and oxidation tests for lubricating oils.[170] Most of these tests are outside the scope of the present volume and the reader is referred to the previously mentioned publications for further particulars. Abietic acid, solubility in thioether, 452
Absolute alcohol, dehydration by trichlorethylene, 674
Absorption, analysis of gases by, 1093-1095
Absorption coefficients, butenes in sulphuric acid, 377
Absorption methods, hydrocarbon analysis, 1103
Absorption, of cracking gas by oil, 140
—, of ethylene by sulphuric acid, 333, 347, 349, 354
—, of gases under pressure by sulphuric acid, 355
—, of hydrogen sulphide from gases, 423, 424, 425
—, of olefins, by salt solutions, 142
—, of olefins by sulphuric acid, 333, 347, 349, 353-355, 1118-1120
—, of propylene by sulphuric acid, 347, 348, 349, 354, 355, 1118
—, of unsaturated hydrocarbons, by lead acetate, 1095
—, of water, by diethylene glycol, 527
—, separation of olefins by, 137, 139
Absorption towers, for separation of olefins, 142
—, washing cracking gas in, 350
Acenaphthene, by pyrolysis of ethane-propane mixtures, 44
—, from pitch, 227
—, naphthalic anhydride from, 929
Acenaphthenequinone, from acenaphthene, 929, 930
Acenaphthylene, acenaphthenequinone from, 929
—, from methane, electric arc, 256
Acetal of diethylene glycol monoethyl ether, 528
Acetaldehyde, aldol from, 634, 635
—, butadiene from, 634, 635
—, by dehydrogenation of glycol, 512, 513, 533
—, by ethane oxidation, 834, 867
—, by hydrocarbon oxidation, 838, 840
—, by hydrolysis of ethylene chlorohydrin, 496
—, by isomerization of ethylene oxide, 546
—, by methane-carbon dioxide reaction, 867, 932
—, by oxidation of paraffin wax, 857
—, carbon monoxide from, 885, 886, 887
—, catalytic dehydrogenation of, 413
—, crotonaldehyde from, 637, 676
—, decomposition to methane, 885
—, effect on combustion of ethane, 850
—, ethanol from, 676
—, from acetylene, 664, 666, 667, 870, 885-888
—, from butylene, 883, 884
—, from cyclohexane, 197
—, from ethyl alcohol, 345, 869
—, from ethylene, 305, 338, 874-878
—, from ethylidene diacetate, 682
—, from propylene, 879, 883
—, intermediate, in combustion of ethane, 850, 851
—, —, preparation of isoprene from acetylene, 159
—, modifying odor of isopropanol with, 365
—, oxidation to acetic acid, 675, 870, 932
—, oxidation to formaldehyde, 870
—, reaction with transformer oils, 910
—, reactivity of, 676
—, reduction, with hydrogen, 675
—, vapor-phase production of, 676
—, uses of, 675
Acetaldehydedisulphonic acid, from acetylene, 679
Acetaldehyde-glycol mixture, acetal from, 513
Acetals, butadiene from, 157
—, from acetylene, 678
Acetals, from aldehydes, 371
—, from vinyl ethers, 679
—, occurrence in oxidized hydrocarbons, 992
—, use as lubricants, 996
o-Acetamidophenol, antioxidant, for lubricating oils, 908
Acetanilide, purified with isopropyl alcohol, 364
—, stabilization of gasoline with, 897
Acetate of dimethylethylcarbinol, from trimethylethylene, 331
Acetates, from acetylene, 677
—, from alkylene oxides, 519
—, from alkyl sulphates, 325, 327
—, from chlorinated gasoline fractions, 727
—, metallic, catalysts for oxidation of alkylbenzenes, 926
—, —, dehydrogenation catalysts for alcohols, 405
—, of ethylene glycol, 518-520
—, of glycol monoethers, 524
—, of secondary alcohols, 349, 401, 402
Acethydroxamic acid, 414
Acetic acid, action on decanaphthene monochloride, 752
—, adsorptive capacity of carbon black by, 248
—, by ethane combustion, 851
—, by ethane oxidation, 834
—, by gasoline oxidation, 836
—, by nitration of naphthenes, 1047
—, by oxidation of cracked kerosene, 837
—, by oxidation of gas oil, 840
—, by oxidation of 1,3-dimethylcyclopentane, 856
—, by oxidation of hydrocarbons, 855, 856, 866
—, by oxidation of nitrogen bases, 820
—, by oxidation of propylene glycol, 530
—, carbon dioxide from 407
—, catalyst, amyl acetate from chloropentane, 797
—, —, autoxidation of olefins, 881
—, —, hydration of olefins, 300, 312, 315
—, —, partial oxidation of wax, 943
—, —, polymerization of isoprene, 626
—, dehydration by dichloroethylene, 675
—, dehydration by propylene dichloride, 480
—, emulsifying agent, for ethylene absorption in sulphuric acid, 343
—, esterification of amyl alcohol by, 795, 796
—, — sec.-butyl alcohol by, 395
—, — olefins by, 327, 330, 331
—, ethylidene diacetate from, 682, 683
—, extraction with isopropyl ether, 370
—, extraction from gasoline, 902
—, from acetylene, 667, 677, 886, 887, 888, 933
—, from butylene ozonides, 883, 884
—, from p-cymene, 926
—, from 1,3-dimethylcyclopentane, 856
—, from ethylene, 814, 876, 877, 932
—, from ethylene glycol, 513
—, from hexadecane, 959
—, from ketene, 414
—, from methane and carbon oxides, 932
—, from naphthenic acids, 1085
—, from paraffin wax, 944, 946
—, from petroleum distillates, 937
—, from propylene, 883
—, from saponification of nitriles, 684
—, from stearic acid, 959
—, glacial, polymerization of styrene by, 612
—, —, reaction with ketene, 414
—, —, reaction with olefin oxides, 540
—, oxidation of acetaldehyde to, 675, 870, 932
—, oxidation of ethyl alcohol to, 932
—, production of acetone from 406, 407
—, reaction with acetylene, 681, 683

Acetic acid, reaction with olefin oxides, 538
—, — α-pinene, 890
—, — sulphur trioxide, 683
—, — transformer oils, 910
—, — vinyl acetate, 682
—, separation of wax acids by distillation with, 954
—, solvent for ozonides, 882
—, solvent, in bromination of olefins, 321
—, use, in oxidation of mineral oils, 936
—, —, — paraffins, 990
—, —, plastics formation, 628, 629
—, vinyl acetate from, 681
Acetic acid-boron fluoride compound, 596
Acetic anhydride, catalyst, for polymerization of isoprene, 626
—, —, oxidation of alkylbenzenes, 926
—, —, oxidation of ethyl benzene, 856
—, from ethylidene diacetate, 682
—, from ketene, 414
—, from vinyl acetate, 682
—, oxidation of α-pinene in, 891
—, production of ketene from, 413
—, reaction with boron fluoride 596
—, reaction with dioxan 556
—, reaction with ethylene oxide, 540
—, and sulphoacetic acid, selective solvent for aromatics, 34
—, vinyl acetate by, 681
Acetins from trichloropropane, 799
Acetone, allylene from, 411
—, as a fuel, 412
—, azeotropic mixtures with organic liquids, 409
—, by butane oxidation, 835
—, by decomposition of ter-butyl hypochlorite, 399
—, by dehydrogenation of isopropyl alcohol, 374
—, by fermentation of carbohydrates, 404
—, by oxidation of ter-butyl alcohol, 397
—, — gas oil, 840
—, — isopropyl alcohol, 349
—, — isopropyl ether, 371
—, — paraffins, 857
—, condensation with olefins, 411, 574
—, determination of, 368, 369
—, dienes from, 633, 637
—, diisobutylene from, 410
—, effect on oxidation of benzaldehyde, 980
—, electrolysis of, 413
—, extraction of carbon blacks, 253
—, extraction of sulphonic acid, 1014, 1015
—, for airplane dopes, 349
—, from acetic acid, 407, 667, 677
—, from acetylene, 408, 677
—, from allene, 301
—, from 1-chloro-2-hydroxypropane, 500
—, from diisobutylene ozonide, 884
—, from ethyl alcohol, 406, 407
—, from ethyl alcohol, acetylene and steam, 677
—, from isopropyl alcohol, 349, 362, 363, 367, 405
—, from methane and carbon oxides, 932
—, from naphthenic acids, 1084, 1085
—, from propylene glycol, 529
—, from propylene oxide, 546, 547
—, from secondary alcohols, 408
—, hydrogenation of, 412, 413
—, ionone from, 412
—, ketene from, 414
—, methylacetylene from, 411
—, oxidation of cyclohexene in, 892
—, pinacol from, 411, 637
—, production of, 404-408
—, properties of, 408, 409
—, reaction with amalgams, 411, 637
—, — boron fluoride, 596
—, — cyclopentadiene, 658
—, — mercaptans, 433
—, — olefins, 411, 419
—, resin precipitant, 624
—, solvent in electro-chemical oxidation of toluene, 927
—, solvent for acetylene, 151, 260, 665
—, solvent for ethylene, 141
—, sulphonal from, 412
—, synthesis of indigo from, 412
Acetone, thermal decomposition, 413
—, use in plastic formation, 628
—, use in prevention of emulsions, 1026
—, use in purifying hydrogen, 230
—, utilization of, 411
Acetone-air, inflammability limits, 963
Acetone-aluminum chloride complexes, 600
Acetone peroxide, from isobutylene ozonide, 884
Acetone-sulphur dioxide, separation of diolefins by, 142, 160
Acetonitrile, from acetylene, 683, 684, 685, 886, 887
—, from ethylene and ammonia, 571, 572
—, reaction with boron fluoride, 596
Acetophenone, acetylene from, 152, 262
—, from cumene, 756
—, from ethyl benzene, 856, 926, 1056
—, reaction with cyclopentadiene, 658
Acetoxime, determination of isopropyl alcohol or acetone, 368
2-Acetoxycyclohexene, 587
Acetylacetonates, catalyst in cracking, 107
—, oxidation catalyst, 936
Acetyl chloride, condensation with olefins, 415, 503, 568, 569
—, esterification of chlorohydrins with, 497
—, reaction with ter-butyl alcohol, 392, 399
—, — 1,4-diphenylbutadiene, 654
—, — naphthenes, 197, 417, 568, 1056, 1057, 1058
Acetyl chloride, sulphuric acid mixture, sulphation of olefins with, 1034
2-Acetyl-1-methylcyclopentane, 197
Acetyl value, effect of oxidation on, 936
—, oxidized white oil, 859
Acetylation of dioxan, 556
Acetylene, 147-153
—, absorption of, 664, 1034, 1122
—, acetaldehyde from, 664, 666, 667, 870, 885-888
—, acetaldehydedisulphonic acid from, 679
—, acetals from, 678
—, acetates from, 677
—, acetic acid from, 667, 677, 886-888, 933
—, acetone from, 677
—, acetonitrile from, 683, 684, 685, 886, 887
—, action of nitric oxide on, 299
—, action of silent discharge on, 265, 267, 268
—, action on copper, 665
—, addition reactions of, 666-667
—, aliphatic ketones from, 678
—, bases from, 683, 684, 685
—, sym-bromoiodoethylene from, 672
—, burned for carbon black, 242
—, butadiene from, 155
—, by hydrolysis of carbides, 662-664, 667
—, by oxidation of hydrocarbons, 235, 663
—, by pyrolysis of hydrocarbons, 81, 125, 135, 184, 186, 187, 225, 663
—, — isobutylene, 73
—, — octenes, 76
—, — propylene, 71
—, by submerged combustion, 843, 1000
—, carbon from, 220, 221, 223
—, carbon oxides from, 885, 886, 887
—, charcoal adsorption, 143, 263
—, chemical properties, 666-667
—, chlorination of, 476, 672
—, chlorine derivatives, physical properties, 467
—, condensation from gases, 664
—, condensation with carbon monoxide, 267
—, — halides, 679-681
—, — hydroxy-compounds, 678-679
—, — organic acids, 679-681
—, conversion to acetaldehyde, 664, 666, 667, 870, 885-888
—, — acetone, 408, 677
—, — aromatics, 165
—, cuprene from, 671, 672
—, cyanides from, 293, 295
—, decomposition of, 220, 221, 223, 234
—, determination of, by absorption, 1094
—, trans-1,2-dichloroethylene from, 672
—, dichloroacetaldehyde from, 683
—, diethyl acetal from, 678
—, divinylacetylene from, 670

Acetylene, effect on pyrolysis of propane, 128
—, endothermic nature of, 665
—, ethyl alcohol from, 676, 679, 887
—, ethylamine from, 684
—, ethylene bromide from, 675
—, ethylidene diacetate from, 682, 683
—, ethyl mercaptan from, 685
—, explosive nature of, 665, 666
—, formaldehyde from, 885, 886, 887
—, formation of sulphur dyes, 430, 431
—, formic acid from, 885, 886, 887
—, from aliphatic hydrocarbons, 152
—, from amylene-hydrogen, silent discharge, 266
—, from anthracene, 219
—, from anthracene oil, electric arc, 258
—, from aromatic hydrocarbons, 149
—, from asphalts, electric arc, 262
—, from benzene, electric arc, 259
—, —, silent discharge, 269
—, from calcium carbide, 221
—, from coal, electric arc, 262
—, from coal-gas, electric arc, 258, 260
—, from coal-tar, electric arc, 258
—, from coke-oven gas, electric arc, 258
—, from copper acetylide, 663
—, from ethane pyrolysis, 43, 44, 147, 149
—, —, electric arc, 257
—, —, silent discharge, 264
—, from ethylene, cathode-ray, 274
—, —, electric arc, 257, 260, 262
—, —, pyrolysis, 66, 68, 147, 149, 187
—, —, silent discharge, 264, 265, 269
—, from ethylene dichloride, 473, 680, 816
—, from ethylene-methane-hydrogen-nitrogen mixture, 153
—, from fuel oil, electric arc, 259
—, from gasoline, 872
—, from halogenated hydrocarbons, 663
—, from hexane, electric arc, 257
—, from hydrocarbon mixture, glow discharge, 274
—, from hydrocarbon-nitrogen reaction, 295
—, from hydrocarbons, electric arc, 256, 257, 259, 260, 261, 262, 663
—, from hydrogen in carbon arc, 663
—, from kerosene, 872
—, from methane, electric arc, 256, 257, 259, 260
—, —, glow discharge, 275
—, — pyrolysis, 38, 40-42, 121, 136, 147-151, 166-169, 176, 186, 219, 296, 871, 872
—, — silent discharge, 264, 268
—, from methane-carbon dioxide reaction, 283
—, from methane-ethane-hydrogen mixture, 151
—, from methane-ethylene, electric arc, 260
—, from methane-hydrogen, 260, 263
—, from methane-oxygen mixture, 151
—, from natural gas, electric arc, 258
—, from natural gas pyrolysis, 167
—, from propylene pyrolysis, 188
—, from tars and resins, electric arc, 262
—, from unsaturated carboxylic acids, 663
—, glyoxal from, 885, 886, 887, 888
—, hydration, catalysts for, 676
—, hydration, to acetaldehyde, 675-678, 870
—, hydrocyanic acid from 296
—, hydrogen from, 220, 221, 223, 887
—, hydrogen halide addition, 471, 472, 477, 478
—, hydrogenated, silent discharge, 266, 267, 269
—, in cracking gas, 115
—, industrial utilization, 667
—, intermediate, formation of aromatics by pyrolysis, 66, 81, 148, 162, 169
—, —, formation of hydrogen cyanide, 296, 299
—, isoprene from, 159
—, liquid condensation products, 684, 685
—, manufacture of, 662, 664
—, mechanical separation of, 262
—, metal acetylides from, 678
—, methionic acid from, 1034
—, methods of production, 150-152
—, monoethylamine from, 684
—, mustard oils from, 685
—, nitriles from, 684, 685
—, oxidation of, 220, 221, 223, 857, 885-887
—, photochemical polymerization of, 667
—, physical properties, 664
Acetylene, polymerization of, 81, 82, 106, 667-672
—, —, by α-radiation, 273, 595
—, —, by cathode-ray, 274
—, —, by electric discharge 610, 668
—, —, by mercury light, 272
—, —, by silent discharge, 264, 267, 268
—, —, by ultraviolet light, 667
—, —, effect of copper, 82
—, production of carbon black from, 234
—, purification and separation from gas mixtures, 664
—, pyrolysis of, 38, 81, 82, 176, 180, 181
—, reaction with acetic acid, 681
—, — acetylene tetrachloride, 673
—, — amines, 683, 684
—, — ammonia, 299, 683-685
—, — ethanol, 678
—, — ethylene, 585
—, — fuming sulphuric acid, 679
—, — halogens, 672, 675
—, — hydrogen cyanide, 684
—, — hydrogen sulphide, 426, 684
—, — hypochlorous acid, 683
—, — methane, 684
—, — nitric acid, 683
—, — oxides of nitrogen, 298, 887, 888
—, — ozone, 887
—, — phosphorus pentachloride, 685
—, — sodium hydroxide, 677, 678
—, — sulphur, 684
—, reactions in silent discharge, 267
—, removal from mixtures by fractional distillation, 1116
—, separation by freezing, 153
—, separation from gas mixtures, by solid absorbents, 152, 153
—, —, by solvents, 150-152, 260, 262, 664
—, sodium acetate from, 678
—, solubility in various solvents, 665
—, storage of, 664
— sulphur compounds from, 685
—, tetrahydroquinoline from, 684
—, thermal stability of, 81, 82
—, thermodynamic effect of temperature on production of, 162
—, thermodynamic stability of, 92, 94, 147, 256, 663
—, thiophene from, 684, 887
—, titration of, by bromine, 1121
—, 1,1,2-trichloroethane from, 680
—, use in purifying hydrogen, 230
—, vinyl chloride from, 680
—, vinylsulphuric acid from, 679
—, yield from methane, 872
Acetylene-air, inflammability limits, 961, 962
Acetylene-benzene equilibrium, 148
Acetylene black, 221, 222, 242
—, properties of, 250
Acetylene dichloride, 674, 675
Acetylene halides, 667
Acetylene hydrocarbons, action of ozone on, 930
—, from amylene, silent discharge, 267
—, from natural gas, electric arc, 258
—, in petroleum, 11
—, isomeric, from allenes, 616
Acetylene-olefin mixture, pyrolysis of, 158, 187
Acetylene ozonide, 887
Acetylene polymers, bromides of, 267
—, distillation of, 669
—, nitro derivatives, 267
—, oxygen derivatives, 267, 268
—, reaction with silver nitrate, 268
Acetylene-propylene mixture, isoprene from, 158, 159
Acetylene-sulphur dioxide, condensation in silent discharge, 267
Acetylene tetramer, by polymerization of acetylene, 669
Acetylene trimer, by silent discharge, 268
Acetylene tetrabromide, 659
—, conversion to acetylene, 663
Acetylene tetrachloride, acetylene dichlorides from, 674
—, chlorination of, 715

Acetylene tetrachloride, conversion to acetylene, 663
—, formation of, 666, 690
—, reaction with acetylene, 673
—, reaction with xylene, 674
—, solvent for wax, 948
Acetylenylamine, polymerized, from methane, 264
Acetylides, from acetylene, 678
—, stability of, 666
2-Acetylpentane, from n-pentane and acetyl chloride, 417, 1057
ω-Acetylstyrene-p-carboxylic acid, 928
Acheson graphite, heats of combustion, 249
Acid absorption of olefins, 354
Acid anhydrides, as antidetonants, 835
—, effect on properties of wetting agents, 1024
—, from oxidation of paraffins, 943, 987
—, production of, 412
—, reaction with alcohols, 943
—, — boron fluoride, 596
—, — olefin oxides, 540
Acid bismuth orthophosphate, catalyst, butadiene formation, 159
Acid cadmium phosphate, polymerization catalyst, 144
Acid chlorides, action on ter-butyl alcohol, 397
—, conversion to aldehydes, 197, 198
—, condensation with hydrocarbons, 417
—, condensation with olefins, 419
—, esterification of chlorohydrins, 497
—, esterification of wax alcohols, 998
—, reaction with tertiary alcohols, 392, 399, 403
—, use in Friedel-Crafts reactions, 1056, 1057
Acid concentration, effect on rate of absorption of olefins, 347
—, effect on hydration of olefins, 300, 301, 312
Acid extract, alcohols from, 355
—, definition of, 485
—, from cracking gas, 350
—, halogenation of, 485
—, hydrolysis of, 349, 354
—, isolation of nitrogen compounds from, 822
—, production of, 350
Acidic polyesters, from glycols, 521
Acidity, of Russian petroleum, effect of boiling points, 1062, 1063
Acidity tests, for petroleum products, 1153
Acid number, voltolized oils, 271
—, determined with isopropyl alcohol, 365
—, naphthenic acids, 1063, 1082
Acid refining of distillates, 1005, 1006, 1007
—, of petroleum, sulphonation of acids in, 1065
Acid resins, in acid sludge, 353
Acid sludges, alcohols from, 353
—, as pickling inhibitors, 434
—, from lubricating oils, 1012
—, separation of, from tars, 353
—, sulphonated compounds from, 1023
—, sulphonic acids from, 1013, 1014, 1015, 1016
—, use in varnishes, 1030
Acid sulphates, of nitrogen bases, 826
—, use in condensation of phenols and alcohols, 399
Acids, by air-oxidation of crude distillates, 1017
—, by alcohol oxidation, 843
—, by hydrocarbon oxidation, 834, 835, 836, 837, 838, 840, 843, 931-939, 987, 990
—, by hydrolysis of ozonides, 844
—, by oxidation of aldehydes, 870
—, — halogenated paraffins, 931
—, — hexane, 868
—, — methane, 864
—, — olefins, 871
—, — paraffin wax, 931, 997
—, — petroleum distillates, 830, 868
—, by vapor-phase oxidation, 1001
—, carboxylic, in crude petroleum, 30
—, —, production from hydrocarbons, 935
—, —, synthesis of, from aromatic hydrocarbons, 932
—, catalysts, for hydration of olefins, 300, 301, 303, 318, 348
—, —, isomerization olefin oxides, 546
—, —, isomerization styrene oxide, 558
—, —, polymerization of diolefins, 618, 619
Acids, combination of olefins with, 320
—, esterifying action on olefins, 303, 320
—, final extraction of olefins from hydrocarbon mixtures by, 349

—, nitration of naphthenes, 1048, 1051, 1052
—, oxidation to acids, 870
—, reaction with cyclopentadiene, 658
—, — ethylene oxide, 556
—, — mercaptans, 433
—, removal from oxidation products, 992
—, separation from acids, 837, 937
—, sulphur dyes from, 431
Aldol, from acetaldehyde, 634, 635
—, intermediate in preparation of isoprene, 159
Algae, as source of petroleum, 36
Alginic acid, 999
Alicyclic hydrocarbons, pyrolysis of, 158
Aliphatic acids, by oxidation of nitrogen base fractions, 820
—, catalysts for oxidation of mineral oils, 936
—, dehydration of, 480
—, esterifying olefins with, 328
—, extraction with isopropyl ether, 370
—, from naphthenic acids, 1072
—, oxidation of paraffin wax, 950
—, production of, 940
—, synthesis from nitriles, 810
Aliphatic chlorides, effect on properties of wetting agents, 1024
Aliphatic diamines, preparation of, 818
Aliphatic ethers by dehydration of alcohols, 370
Aliphatic hydrocarbons, acetylene from, 152
—, aromatic hydrocarbons from, 152, 165-177
—, fluorinated hydrocarbons from, 709
—, ignition temperatures, 968
—, oxidation of, 937
—, pyrolysis of, 188
Aliphatic ketones, from acetylene, 678
Aliphatic mercaptans, pyrolysis of, 457
Aliphatic nitriles, hydrolysis of, 811
Aliphatic olefins, effect on gasoline, 901
Aliphatic oxygenated compounds, iodoform from, 707
Alizarine, from anthraquinone, 924
Alkylated aromatics, production of, 562-565
Alkali borates, aromatization catalysts, 183
—, catalysts, condensation of alkyl chlorides, with carbon monoxide, 815
Alkali carbonates, action on monochloroparaffin, 740
—, aromatization catalysts, 182
—, removal of carbon monoxide from hydrogen, 233
Alkali-cellulose, treatment with ethylene chlorohydrin, 742
Alkali cyanamides, formation of, 297
Alkali fluorides, fluorinating chlorinated hydrocarbons with, 708
Alkali formates, hydrolysis ethylene dichloride with, 506
Alkali fusion, of chlorinated petroleum, 740
Alkali hydrolysis, of acid extract, 352, 353
Alkali hydroxides, catalysts, hydration of ethylene, 312
—, use in hydrolysis of methyl chloride, 783, 785
Alkali hypochlorites, use in sweetening, 444
Alkali metals, catalyst activators, decomposition of hydrocarbons, 223
—, catalysts, chlorination of hydrocarbons, 714
—, —, production of synthetic rubber, 629
—, —, reaction of diolefins with nitrogen bases, 656
Alkali naphthenates, as antidetonants, 983
—, isolation of acids from, 1070-1072
Alkali oleates, as antidetonants, 983
—, oxidation catalysts, 936
Alkali oxides, catalyst activators, decomposition of hydrocarbons, 223
—, catalysts, polymerization of diolefins, 618, 619
—, —, oxidation of methyl alcohol to formaldehyde, 868
Alkali phenolates, ethers from ethylene chlorohydrin with, 497
Alkali phenoxides, reaction with alkyl chlorides, 809
Alkali phosphates, aromatization catalysts, 183
—, catalysts, reaction of alkyl halides with carbon monoxide, 815
Alkali polysulphides, plastics from, 474, 475
Alkali resinates, oxidation catalysts, 936
Alkali salts, stabilizers, oxidation of hydrocarbons, 915
Alkali silicates, aromatization catalysts, 183
Alkali sludges, 1066, 1068
Alkali solutions, removal of peroxides from gasoline, 901
Alkali sulphonates, as antidetonants, 983
—, as detergents, 1022, 1023, 1024
Alkalies, absorbents for hydrogen cyanide, 298
—, carbon dioxide from gases by, 289, 290
—, catalysts, oxidation of paraffins, 951
—, —, oxidation of paraffin wax, 960

Alkalies, effect on hydrolysis of olefin dihalides, 508
—, for separating diolefins, 160
—, reaction with chlorine, 490
—, — ethylene chlorohydrin, 496
—, — halogenated paraffins, 742, 818
—, refining of oxidized wax with, 953, 954, 955
—, refining petrolatum with, 934, 1026, 1027
—, use in hydrolysis of amyl chlorides, 790, 791
—, — tanning composition, 1031
Alkaline-earth alkyls, catalysts, polymerization of diolefins, 619
— borates, aromatization catalysts, 183
— chlorides, catalysts, chlorination of hydrocarbons, 701, 702, 713
— cyanamides, catalysts, carbon monoxide-ammonia reaction, 298
— —, production of, 571
— cyanides, formation of, 297
— fluorides, fluorinating chlorinated hydrocarbons with, 708
— hydroxides, use in hydrolysis of methyl chloride, 781, 782, 783, 784, 785
— oleates, oxidation catalysts, 936
— oxides, catalyst activators, 289, 290
— —, catalysts, oxidation of methyl alcohol, 868
— —, —, polymerization of diolefins, 618, 619
— phosphates, aromatization catalysts, 183
— polysulphides, plastics from, 474, 475
— resinates, oxidation catalysts, 936
— salts, catalysts, pyrolysis methane, 150
— silicates, aromatization catalysts, 183
Alkaline-earths, catalyst activators, 223
—, catalysts, chlorination of benzene, 766
—, —, dipropyl ketone from butyraldehyde, 416
—, removal of carbon dioxide from hydrogen, 232
—, saponification of wax acids with, 953
—, stabilizers for oxidation of hydrocarbons, 915
Alkaline solutions, absorption of hydrogen cyanide in, 298
—, of olefins, electrolysis of, 511
Alkalinity tests, for petroleum products, 1153
Alkaloids, purified with isopropyl alcohol, 364
—, relation to hydroaromatic bases, 819
Alkylacetylenes, from oil gas, 116
Alkyl acid thiosulphates, from mercaptans, 437
Alkyl amino alcohols, 543
Alkylallenes, from acrolein, 632, 633
Alkylamines, stabilizing chlorinated hydrocarbons, 704
—, production of, 571, 572, 806
Alkylated compounds, of aromatic hydrocarbons, 559-564
Alkylation, of ammonia, 806, 807
—, of aromatic hydrocarbons, isomerization reaction, 809, 810
—, —, use of ter.-butyl alcohol, 398, 399
—, of aromatic substances, 374, 375, 810
—, of ketones with olefins, 574
—, phenols by alkyl halides, 810
Alkylbenzene-benzene mixture, pyrolysis of, 147
Alkylbenzenes, oxidation, 859, 925, 926
—, reaction with chromyl chloride, 1055
Alkyl bisulphites, from sulphite-olefin reaction, 575
Alkyl bromides, from alkyl sulphates, 325
—, from olefins, 323
—, hydrolysis of, 787, 788
Alkyl 2-bromoethyl ethers, alkyl vinyl ethers from, 682
Alkyl chlorides, alcohols from, 686
—, alkylation of phenols with, 810
—, carboxylic acids from, 814, 815
—, condensation with carbon monoxide, 815
—, from alcohols, 371, 392
—, from alkyl sulphates, 325
—, from olefins, 323, 330
—, hydrolysis with steam, 782, 783, 784, 785, 787
—, importance, in chemical synthesis, 800
—, mercaptans from, 811
—, nitration, 814
—, primary amines from, 807
—, pyrolysis of, 802
—, reaction with alkali phenoxides, 809
—, reaction with magnesium, 812-813
Alkyl chlorides, tendency of decomposition, 804
—, use in synthetic lubricating oils, 810
Alkyl disulphides, determination of, 1152
—, reduction to mercaptans, 1152
Alkyl dithiosulphates, from mercaptans, 437, 438
Alkylene cyanohydrins, preparation of, 545
Alkylene oxides, with carboxylic acids, 519, 541
—, condensation with hydrocarbons, 1059, 1060
—, — polyhydroxy compounds, 522
—, reaction with oxidized montan wax, 541
—, *see also* Olefin oxides.
Alkyl esters, from olefins, 313, 318
—, from orthosulphuric acid, 313
—, hydrolysis of, 300
Alkyl halides, alkylation of phenols by, 810
—, by esterification of alcohols, 371
—, carbohydrate ethers from, 809
—, catalysts, condensation of olefins with phenols, 566, 567
—, reactions with ammonia, 806
—, — phenols, 399, 400
—, decomposition into olefins, 801-805
—, from alkylsulphuric acids, 714
—, from ethylene, 318
—, from halogen acids, 306
—, Grignard compounds from, 812, 813
—, hydrolysis of, 319, 781, 782, 783, 784, 785, 786, 792, 793
—, interchange of halogens, 800
—, isomerization phenomena, 805, 806
—, nuclear alkylation of aromatics by, 809-810
—, olefins from, 564
—, order of chemical reactivities, 800

—, reactions with ammonia, 806
—, — inorganic salts, 810-812
—, — mercaptans, 449
—, — metallic cyanides, 810
—, — thioethers, 451
Alkyl hypochlorites, formation of, 392, 399
Alkyl iodides, catalysts, tetraethyl lead production, 813
—, hydrolysis of, 787, 788
—, reactions with mercaptans, 449
—, — thioethers, 451
Alkylnapthalenes, from napthalene, 810
Alkylnaphthalenesulphonic acids, as detergents, 1022
Alkylolamines, use in breaking emulsions, 1026
Alkyl phenyl ethers, rearrangement by boron fluoride, 596
Alkyl sulphates, corrosion by, 422
—, organic acid esters from, 324
Alkyl sulphides, action of sodium hypochlorite on, 459
—, adsorption by nickel oxide, 462
—, corrosion by, 422
—, determination of, 1152
—, from olefins and hydrogen sulphide, 585
—, to sulphones, 459
Alkylsulphonic acids, 1005, 1011
—, from sulphite-olefin reaction, 575
Alkylsulphuric acids, alkyl esters from, 325, 327
—, intermediate formation of, 590
Alkylsulphuric esters, from amylenes, 313
—, from hexylenes, 313, 384
—, from olefins, 320, 325, 329, 347, 350, 354, 376, 383, 804, 1126
—, hydrolysis of, 319, 352, 353, 356, 1005
Alkyl trisulphides, corrosion by, 438
Alkyl vinyl ethers, preparation of, 682
Alkyl vinyl ketones, production of, 419
Alkynes, 662
Alleman process, naphthenic acids from, 1082, 1089, 1091
Allene, acetone from, 301
—, by dehalogenation of allene dibromides, 632, 633
—, from propylene dibromide, 481
—, in cracking of hydrocarbons, 153
—, in pyrolysis of acetylene, 668
—, methylacetylene from, 632
—, polymerization of, 272, 273, 614-616
—, properties of, 632
—, pyrolysis of, 614, 615
—, removal from acetylene, 664

Allene dibromides, dehalogenation to allene, 633
Allene homologues, from olefin dihalides, 483, 485
Allene tetrabromide, properties of, 632
Alloys, catalysts, pyrolysis of hydrocarbons, 224
—, for cracking tubes, 175
Allyl alcohol, from propylene oxide, 547
—, hydration to propylene glycol, 300, 529
—, to glycerol, 494, 505, 506, 510
Allyl bromide, bromination of, 633
—, from propylene dibromide, 480
—, hydrogen bromide addition, 480, 481
Allyl chloride, from propylene dichloride, 480
—, glycerol dichlorohydrin from, 799
—, hydration by sulphuric acid, 500
—, 2-hydroxy-1-chloropropane from, 500
Allylcyclohexane, pyrolysis of, 75, 85, 86
Allyl iodide, hydrogen iodide addition, 481
Allylene, by pyrolysis of paraffins, 135
—, from acetone, 411
—, from amylene-hydrogen, silent discharge, 266
—, from hydrocarbons, 152
—, reaction with sulphuric acid, 1128
Alpha particles, 255, 268, 269
Alpha radiation, action on cyclopropane, 273, 599
—, action on olefins, 272, 273, 595, 599, 602
—, action on paraffins, 272-274
—, effect similar to semi-corona discharge, 269
—, influence in origin of petroleum, 36
—, polymerization of olefins, 589
Alpha-rays, refining hydrocarbons with, 274
Alum, ammonium manganic, oxidation catalyst, 920
Alumina, action on ethylene, 305
—, catalyst, condensation of olefins with phenols, 566, 567
—, —, conversion of isopropylethylene to trimethylethylene, 74
—, —, conversion of 2-pentene-4-ol to piperylene, 637
—, —, conversion of propylene glycol to propionaldehyde, 530
—, —, cracking naphthenic acids, 1085
—, —, dehydration of amyl alcohol, 636
—, —, dehydration n-butanol, 481
—, —, dehydration of pinacone, 637
—, —, for butadiene from ethanol, 635
—, —, for diolefin-ammonia reaction, 656
—, —, for replacement of alcohol radical, 395
—, —, hydration of olefins, 310, 314
—, —, hydrolysis of phenyl halides, 767
—, —, isomerization of amylenes, 603
—, —, isomerization of olefin oxides, 419, 546
—, —, isoprene from unsymmetrical-dimethylallene, 632
—, —, methane-steam reaction, 289, 290
—, —, nitric oxide-hydrocarbon reaction, 299
—, —, olefin-chlorine addition, 469
—, —, polymerization of olefins, 599, 603
—, —, preparation of isopropyl alcohol, 370
—, —, pyrolysis of chlorinated hydrocarbons, 802, 803
—, catalyst activator, methane-steam reaction, 280
—, —, production of acetone, 408
—, catalytic effect, on hydration reactions, 303, 304, 305
—, effect on pyrolysis of methane, 39
Alumina gel, catalyst, for acetylene-ammonia reaction, 684
Aluminates, catalysts, diphenyl production, 189
Alumino-silicate refractories, catalysts, pyrolytic formation of naphthalene, 184
Aluminum, activation of, 106
—, catalyst, condensation of olefins and aromatics, 565
—, —, isomerization of olefin oxides, 547
—, —, methane-carbon monoxide reaction, 932
—, —, oxidation of aromatics, 917, 921, 925, 929
—, —, oxidation of methane, 863
—, —, oxidation of mineral oils, 936
—, —, oxidation of olefins, 878
—, —, reduction of olefin oxides, 549
—, cracking catalyst, 113
—, effect on catalytic action of aluminum chloride, 202
Aluminum, effect on distillation of butadiene, 641
—, — ignition temperature of hydrocarbons, 967
—, — oxidation of petroleum, 905, 951
—, — oxidation of transformer oils, 909
—, extraction of sulphur compounds by, 462
—, in hydrocarbon-sulphur reaction, 429
—, oxidation catalyst, 838
—, polymerization catalyst, 610, 629, 630
—, purification of hydrocarbons with, 188
—, pyrolysis catalyst, 47, 128, 157, 187
—, removal of gasoline gum by, 902
Aluminum alloys, catalysts, methane-steam reaction, 291
Aluminum amalgam, catalyst, halogenation of aromatics, 770
Aluminum benzoylacetone, as antidetonant, 983
Aluminum borate, catalyst activator, 291
—, oxidation catalyst, 833
Aluminum bromide, action on cyclohexane, 198
—, bromination catalyst, 749, 750, 753, 754, 778
—, catalyst, formation of ethyl bromide, 324
—, cracking American gasoline with, 190
Aluminum carbide, hydrolysis of, 662
Aluminum carbonate, catalyst activator, 291
Aluminum chloride, adsorption of ethylene by, 195
—, action on alcohols, 343
—, — aromatics, 199, 200, 202
—, — cycloparaffins, 194, 197-199
—, — olefins, 194-197
—, — paraffin hydrocarbons, 193-194
—, as alkylation catalyst, 809
—, as dehydrogenating agent, 200
—, carbonization of hydrocarbons by, 191
—, catalyst, carbon monoxide-hydrocarbon reaction, 417, 418
—, —, condensation of hydrocarbons and alkylene oxides, 545, 1059
—, —, — hydrocarbons with acetyl chloride, 417
—, —, — isoprene with diolefins, 657
—, —, — olefins and acid chlorides, 415, 419, 568, 569, 570, 654
—, —, — olefins with aromatics, 559-565
—, —, — olefins with diolefins, 624
—, —, — olefins with phenols, 566, 567
—, —, — phenols and alkyl chlorides, 399, 400, 401
—, —, esterification of olefins with hydrogen chloride, 322, 323, 329
—, —, hydrocarbon-sulphur reaction, 429
—, —, hydrolysis of methyl chloride, 782
—, —, in cracking, 106, 107
—, —, isomerization of cyclohexane, 87
—, —, polymerization of diolefins, 603, 618, 619, 624
—, —, polymerization of olefins, 80, 144, 190, 194, 200-204, 570, 589, 590, 593, 594, 597, 598, 600, 608, 609, 610, 613, 1050
—, chlorination catalyst, 690, 730, 749, 758, 759 763, 764, 765, 775, 780
—, cracking with, 64, 164, 190, 193, 194, 196, 198, 201
—, —, decomposition rate, 191
—, extraction of sulphur compounds by, 459
—, lubricating oils from olefins by, 197, 200
—, mechanism of cracking with, 190, 192
—, oxidation catalyst, 837, 840, 920, 930, 939, 940, 947
—, preparation, 192, 193
—, production of gasoline, 190-193
—, —, mechanism of reactions, 191
—, reactions with cracked petroleum distillate, 203
—, rearrangement of hydrocarbons by, 191
—, refining hydrocarbons with, 609
—, use in condensation reactions, 1056-1060
Aluminum chloride-acid chloride complex, 569
Aluminum chloride-hydrocarbon complexes, 192, 195, 198, 582, 609
Aluminum compounds, catalyst activators, for methane-steam reaction, 291
—, of acetophenone, as antidetonants, 983
—, stabilizer promoters of oxidation, 915, 917
Aluminum electrodes, use of, 263
Aluminum halides, halogenation catalysts, 746, 755, 756, 768, 780

Aluminum hydrosilicate, catalyst, glycolacetate production, 519, 520
Aluminum hydroxide, catalyst, chlorination of aromatics, 761
—, — stabilizer, 345
Aluminum-mercury couple, 760, 771
Aluminum naphthenates, 1083, 1089, 1090
Aluminum nitrate, nitration of hydrocarbons with, 1046, 1048, 1049, 1054
Aluminum nitride, formation of, 294
Aluminum oleate, oxidation catalyst, 936
Aluminum oxide, aromatization catalyst, 186
—, catalyst activator, for hydrocarbon-steam reaction, 280, 281, 289, 290
—, catalyst, ammonia-carbon monoxide reaction, 298
—, —, butyl sulphide pyrolysis, 457
—, —, esterifying alcohols by hydrogen halides, 324
—, —, higher alcohols from ethanol, 345
—, —, hydration of ethers, 783
—, —, hydration of olefins, 311
—, —, in cracking, 202
—, —, methane-steam reaction, 288, 292
—, —, pyrolysis of hydrocarbons, 83, 84, 85, 221, 223
—, —, vapor-phase hydration of acetylene, 676
—, effect on cracking with aluminum chloride, 191
—, extraction of sulphur compounds with, 459, 461
—, dehydrogenation catalyst for alcohols, 635
—, oxidation catalyst, 834, 863, 887, 893, 917, 922
Aluminum phosphate, catalyst, condensation of olefins with phenols, 566, 567
—, —, conversion of 1-butene to 2-butene, 72
—, —, hydration of ethylene, 308
—, oxidation catalyst, 833
Aluminum resinates, from acid-treated lubricants, 995
—, oxidation catalysts, 936
Aluminum salts, extraction of sulphur compounds with, 460
—, of oxidized paraffin, 995
—, separation of aldehyde-acids by, 938
Aluminum silicate, catalyst, polymerization of propylene, 599
Aluminum soaps, antioxidants for transformer oils, 909
Aluminum stearate, catalyst, oxidation of paraffin wax, 947
Aluminum sulphate, action on ethylene, 305
—, action on petroleum acid sludge, 1024
—, catalyst, chlorination of aromatics, 761
—, —, isomerization of olefins, 74, 603
—, —, polymerization of olefin oxides, 548
—, —, production of acetone, 414
—, dehydrogenation of alcohols with, 330, 370
—, recovery of sulphonic acids, 1015
Aluminum sulphonates, for breaking emulsions, 1026, 1027
—, from acid sludges, 1015
Alundum, use in pyrolysis of hydrocarbons, 207
Amalgams, reaction with acetone, 637
—, removal of sulphur from distillates, 427
American carbon black, analysis of, 246
American gasoline, cracking by aluminum chloride, 190
American kerosene, pyrolysis of, 61
American lubricating stocks, naphthenic acids, 1082
American natural-gas gasoline, analysis of, 17, 18
American oils, autoxidation of, 893
—, decomposition by aluminum chloride, 198
American oil shale, sulphur in, 462
American petroleum, butadiene from, 158
—, hydrocarbons in, 23, 24, 30
—, naphthenic acid content, 1063
—, straight-run gasoline from, 20
American straight-run gasolines, analysis of, 21
Amides, extraction with petroleum ether, 954
—, montan wax acids, 1002
—, reaction with boron fluoride, 596
—, synthesis with nitriles, 810
Amine-olefin method, determination of naphthenic acid structure, 1077
Amines, aliphatic, pyrolysis of, 617
—, alkylation of, 807
—, antioxidants for lubricating oils, 907
—, aromatic, condensation with formaldehyde, 860
—, —, pyrolysis of, 617
—, by reduction of C-chloro-N-dichloroamines, 578
—, — nitro compounds, 1042, 1043, 1050-1052,
—, catalyst for production of plastics, 630
—, condensation with alkyl halides, 806
—, — olefins, 571, 572
—, — nitrosochlorides, 580
—, — unsaturated compounds, 585
—, formation of aldehyde resins, 999
—, from ethylene chlorohydrin, 498
—, from Kimmeridge shale oil, 463
—, ignition temperatures, 968
—, inhibitors of polymerization, 630
—, reaction with acetylene, 683, 684
—, — β,β'-dichlorodiethyl ether, 498
—, — diolefins, 656
—, — ethylene chlorohydrin, 497
—, — ethylene oxide, 541, 544
—, — propylene chlorohydrins, 501
—, — propylene glycol, 557
—, secondary, condensation with olefin oxides, 543
—, separation of diolefins by, 641
—, solubility of, 808
—, stabilizer in production of sulphones, 656
—, synthesis from nitriles, 810
—, tertiary, catalyst, condensation of olefin oxides, 538
—, washing and wetting agents, 498
—, water-soluble, detergents from, 1023, 1024
Amino alcohols, 543
Aminoazo bases, stabilization of gasoline, 897
Amino-azobenzene, stabilizing chlorinated hydrocarbons, 704
p-Aminobenzoic acid, esterification with, 497
p-Aminobenzoic ester, novocain from, 496
1-Amino-2-chloroethane, 578
Amino compounds, in motor fuels, 1054
2-Aminocyclohexanol, preparation of, 543
4-Amino-3-cyclohexyl-toluene, 572
2-Aminocyclopentanol, 543
Amino derivatives, from propylene chlorohydrins, 501
Amino ethers, from β,β'-dichlorodiethyl ether, 498
Amino group, alkylation of, 573
Aminomercapto compounds, 434
p-Aminophenol, antioxidant for lubricating oils, 907
—, condensation with glycol, 817
—, production of, 767
—, stabilization of gasoline, 897
—, wetting agent from, 817
Aminophenylcyclohexane, 572
Aminotrimethylcarbinol, 542, 558
Ammonia, (aqueous) absorption of hydrogen sulphide, 424, 425
—, alkylation of, 806, 807
—, ammonolysis with, 807
—, anhydrous, selective solvent for butylene-butane mixture, 140, 141
—, — solvent for acetylene, 152
—, catalyst, chlorination of toluene, 773
—, —, reaction olefin oxides and polyhydric alcohols, 538
—, condensation of ethylene by, 571
—, condensation with alkyl halides, 806
—, — olefins, 571, 572
—, — unsaturated compounds, 585
—, effect on electric decomposition methane, 259, 260
—, ethylation of, 806
—, from nitrogen bases, 820
—, from nitric oxide-hydrocarbon reaction, 299
—, from nitrogen-methane reaction, 208
—, hydrocyanic acid from, 216
—, impurity in acetylene, 664
—, liquid, determination of aromatics with, 1141
—, —, desulphurization of petroleum oils, 458
—, —, extraction of mercaptans, 436
—, —, for purifying hydrogen, 230
—, —, solvent for acetylene, 664

Ammonia, nitrogen-hydrogen for synthesis of, 838
—, nitrogenous paraffin derivatives by, 817
—, purification of sulphonic acids, 1018
—, reaction with acetylene, 683, 684, 685, 887
—, — β,β'-dichlorodiethyl ether, 498
—, — butadiene, 656
—, — carbon monoxide, 297-298
—, — diolefins, 656
—, — ethylene, 571
—, — ethylene oxide, 541, 542, 551
—, — formaldehyde, 861
—, — hydrocarbons, 292-293, 295-297
—, — olefin oxides, 542, 543, 557, 558
—, — sulphonic acids, 1023
—, removal of carbon monoxide from hydrogen, 231, 232, 233
—, separation of wax acids with, 954
—, solvent butylene-butane separation, 143
—, stabilizer for formaldehyde, 874
—, stabilization of gasoline, 897
—, stabilizing agent for formic acid, 861, 862, 863
—, synthesis from hydrogen and nitrogen, 215
—, toxicity of, 709
—, use in cracking, 993
—, — electrolytic purification of naphthenic acids, 1069
—, — oxidation of ethylene, 882, 883
—, — oxidation of oils, 937
—, — removing sulphur oxides, 988
Ammonia-acetylene reaction, 299, 666
Ammoniacal cuprous chloride, reagent, 1094
Ammonia-carbon reaction, 295
—, equilibrium in, 296
Ammonia-ethylene reaction, 299, 571
Ammonia-ethylene dichloride polymerization, 474
Ammonia-hydrocarbon reaction, 296, 297
Ammonia synthesis, hydrogen-nitrogen mixtures for, 285, 286
Ammonium bifluoride, treatment of petroleum residues with, 598
Ammonium bisulphite, addition to olefins, 575
—, reaction with 2,3-dimethylbutadiene, 655
Ammonium carbonate, catalyst, chlorination of hydrocarbons, 730
—, saponification of wax acids by, 953
Ammonium chloride, catalyst, preparation of 2-chlorobutadiene, 638
—, —, preparation of vinyl chloride, 680
—, reaction with ethylene ozonide, 883
—, removal of gum from gasoline, 903
—, use in polymerization of acetylene, 669
Ammonium cyanide, from ammonia-methane, electric arc, 259
—, recovery of hydrogen cyanide as, 298
Ammonium formate, from ethylene ozonide, 883
Ammonium lead tetrachloride, reaction with benzene, 764
Ammonium mercaptides, 436
Ammonium molybdate, catalyst, reaction of ethylene and ammonia, 571
—, dehydrogenation catalyst, 186
—, reduction by hydrogen, 571
—, titration of lead nitrate by, 1151
Ammonium naphthenate, plant spray, 1090
Ammonium persulphate, oxidation catalyst, 920
Ammonium salts, catalysts, divinylacetylene from acetylene by, 670
—, from nitriles, 684
Ammonium sulphate, from ammonia, hydrolysis of ethylsulphuric acid, 343
—, from petroleum oils, 458, 459
Ammonium sulphide, from petroleum oils, 458
Ammonium tetrathionate, absorption of hydrogen sulphide, 424
Ammonium thiosulphate, absorption of hydrogen sulphide, 424
Ammonium vanadate, oxidation catalyst, 929, 930
Ammonolysis, with anhydrous ammonia, 807
Amorphous carbon, carbon black, 247, 250
Amyl acetate, from amyl chloride, 782, 792, 793, 794
—, from amylene, 330
—, from monochloropentane, 726, 727
—, properties, 797, 798
Amyl acetate, stabilization of gasoline, 897
sec.-Amyl acetate, 402, 403
sec.-Amyl alcohol, by hydration of olefins, 129, 387, 401
—, dehydration of, 394
—, esterification of, 395
—, properties of, 401, 402
ter.-Amyl alcohol, by hydration of methylethylethylene, 381, 387
—, by hydrolysis of tertiary amyl chloride, 387
—, dehydrogenation of, 405
—, from olefins, 129
—, esterification of, 798
—, properties and uses, 403
—, stability to bromine, 392
Amyl alcohols, by hydration of pentenes, 380, 381, 382, 387
—, composition of synthetic mixture, 797
—, effect on pyrolysis of amyl chlorides, 803
—, from monochloropentanes, 789, 790, 791, 792
—, from pentane, 726, 727, 729
—, impurities in, 351, 352
—, number of isomers, 797
—, production, 790, 791, 792, 793
—, properties, 797
—, purification of, 796, 1018
—, stabilization of gasoline, 898
sec.-Amyl-p-aminophenol, stabilization of gasoline, 897
Amylbenzene, production of, 562
—, reaction with bromine, 1131
Amyl benzoate, from amylene, 330
Amylbenzoyl-o-benzoic acid, 565
ter.-Amyl bromide, 806
Amyl bromides, isomerization of, 806
sec.-Amyl chloride, from pentane, 721
ter-Amyl chloride, by trimethylethylene chlorination, 483, 484
—, from amylenes, 387
—, esterification with potassium acetate, 793
—, properties of, 403
—, rate of esterification, 793
Amyl chlorides, by chlorination of pentanes, 731, 788
—, conversion to amyl acetate, 782, 792, 793
—, decomposition to amylenes, 789, 794, 803
—, decomposition in liquid phase, 803
—, from amylene, 330
—, from fatty acids, 721
—, from pentanes, 723, 724, 726, 729, 730
—, hydrolysis of, 789, 790, 791, 792, 794, 795
—, properties of, 721
—, rate of hydrolysis, 789, 790, 791, 793
—, reaction with sodium cyanide, 811
—, secondary, 647
Amylcresols, production of, 567
n-Amyl cuprous mercaptide, 445
n-Amyl cyanide, 811
Amylcyclohexanes, decomposition by aluminum chloride, 199
Amyl dichloracetate, from amylene, 330
Amylenes, absorption of oxygen, 889
—, acid absorption of, 345, 380
—, addition of organic acids, 330
—, addition to nitrosyl chloride, 579
—, alcohols from, 313
—, aldehydes from, 879
—, alkylsulphuric esters from, 313
—, amyltoluene from, 561
—, by oxidation of n-hexane, 867
—, by pyrolysis of ethylene, 67
—, — hexadecene, 76
—, — n-hexane, 60
—, — isoprene, 79
—, — mineral oils, 133
—, — wax, 60
—, from amyl alcohol, 636
—, carbon oxides from, 879
—, chlorination of, 483-485
—, condensation with isoprene, 657
—, — cresol, 567, 568
—, critical inflexion temperature, 967
—, decomposition by silent discharge, 267
—, decomposition in electric arc, 257
—, double compound with mercuric acetate, 583

Amylenes, formation in hydrolysis of amyl chloride, 796
—, formation of, 599, 852
—, formic acid addition, 330
—, from amyl chlorides, 803
—, from butyl chlorides, 722, 723
—, from cracking gas, 139, 140, 144, 355
—, from ethylene, 594
—, from monochloropentanes, 789, 790, 791, 792, 793, 794
—, from propyl chlorides, 722, 723
—, from propylene, 879
—, hydration, by acids, 300, 318
—, hydrogen chloride addition, 330
—, lubricants from, 202
—, methylethylethylene from, 881
—, minimum ignition temperature, 967
—, oxidation of, 836, 879
—, peroxides from, 879
—, polymerization of, 598, 602-604
—, polymerization by aluminum chloride, 195, 202, 1050
—, — sulphuric acid, 380, 382
—, — zinc chloride, 330
—, polymerization products of, 589
—, pyrolysis of, 77, 80
—, reaction with ammonium bisulphite, 575
—, — boron fluoride, 596
—, — hydrogen persulphide, 585
—, — hydrogen sulphide, 584
—, — hypobromites, 503
—, — methyl alcohol and aluminum chloride, 196
—, — ozone, 885
—, — selenium oxychloride, 577
—, — sulphur dioxide, 575
—, rearrangement by silent discharge, 267
—, separation of, 142, 144, 380
—, stabilizing chlorinated hydrocarbons, 704
—, trimethylethylene from, 881
Amylene bromohydrins, 503
Amylene chlorohydrins, 502
Amylene dichloride, by trimethylethylene chlorination, 483, 484
Amylene fraction, absorption in sulphuric acid, 608
Amylene hydrate, from amylene, 380
Amylene-hydrogen, action of silent discharge, 266
Amylene ozonide, 885
Amylene-succinic acid, 568
Amyl esters, toluol tolerance of nitrocellulose solutions, 798
—, uses of, 797, 798
Amyl formate, from amylene, 330
—, properties of, 798
—, purification, 796
ter.-Amyl hypochlorite, 403
ter-Amyl iodide, from methylethylethylene, 329
Amyl ketol, 416
Amyl mercaptan from distillates, 448
—, effect of metallic salts on, 446
—, pyrolysis of, 457
—, treatment with sulphuric acid, 437
Amyl nitrite, as knock inducer, 986
—, reaction with nitric acid, 580
p-ter.-Amylphenol, formation of, 399, 566
—, properties of, 400
Amyl phthalate, 794, 795
Amyl propionate, properties of, 798
Amyl salicylate, from amylene, 330
Amylsulphonic acid, properties of, 1011
Amyltoluene, reaction with bromine, 1131
—, production of, 561
Amyl trichloracetate, from amylene, 330
Amylxylene, reaction with bromine, 1131
Anaerobic fermentation, as a mechanism of petroleum formation, 36
Anaesthetics, 705, 710, 715
Analytical fractionating columns, 1110
Analysis, applicability of methods, 1126
—, of air, 1095
—, of carbon blacks, 214
—, of coal gas, 1101, 1116
—, of cracked gasolines, 117
—, of cracked natural gas, 212
—, of cracking gas, 1092
Analysis, of cokes, 227
—, of gaseous unsaturated hydrocarbons, 1120-1122
—, of gases by absorption, 1093-1095
—, of hydrocarbons, 1095-1104, 1113, 1116
—, of isomeric butenes, 1122
—, of natural gas, 1092, 1116
—, of refined petroleum oils, 1125
—, of ternary mixtures of hydrocarbons, 1113
—, of unsaturated gases, 1122-1124
—, Podbielniak apparatus, 1108, 1109
—, with iodine chloride, 574
Anethol, reaction with boron fluoride, 596
Anhydrides of montan wax acids, 1002
Aniline, as an antiknock, 966, 983
—, as oxidation inhibitor, 909, 980, 984
—, condensation with ethylene, 571, 572
—, — 1,4 dihydronaphthalene, 572
—, critical solution temperature determinations in, 1136
—, determination of aromatics with, 1137, 1138, 1141
—, effect on active oxygen, combustion of fuels, 978
—, — gas-phase oxidation, 980
—, — ignition temperatures, 969
—, — oxidation hydrocarbons, 853
—, from chlorobenzene, 767
—, precipitation of sulphonic acids, 1018
—, purification of naphthenic acids with, 1067
—, reaction with acetylene, 684
—, — bisnitrosates, 580
—, — trimethylethylene chlorohydrin, 503
—, selective solvent for hydrocarbons, 160, 597, 640, 1143, 1145, 1146
—, separation of ichthyolsulphonic acids with, 1037
—, stabilization of gasoline by, 897, 898
—, sulphur dyes from, 431
—, treatment of naphtha, 455
—, use in oxidation of paraffins, 945
Aniline-cobalt complexes, 572
Aniline equivalent, 985
Aniline hydrobromide, reaction with isoprene alcohol, 636
Aniline hydrochloride, condensation with cyclohexene, 572
Aniline points, 1137-1139, 1142
Aniline salts, effect on pyrolysis of alkylbenzenes, 147
4-Anilinobiphenyl, stabilization of gasoline by, 897
Anilinoethanol, from ethylene chlorohydrin, 498
Animal charcoal, catalyst, methane chlorination, 690, 696, 697, 698
Animal oils, solubility in isopropyl ether, 370
Anisaldehyde test for isopropyl alcohol with, 368
Anisol, carboxylation of, 930
Ansolvo acids, decolorization of wax acids by, 952
—, polymerization of olefins with, 594
Anthracene, acetylene from, 219
—, anthraquinone from, 924, 925, 930
—, as antidetonant, 983
—, as oxidation inhibitor, 984
—, as a tanning compound, 1031
—, by acetylene pyrolysis, 82, 180
—, by butadiene pyrolysis, 79
—, by 2-butene polymerization, 602
—, by 2-butene pyrolysis, 73, 180
—, by cumene pyrolysis, 88
—, by ethane pyrolysis, 46
—, by ethylene pyrolysis, 66, 69, 177
—, by isobutene pyrolysis, 73, 179
—, by isoprene pyrolysis, 79
—, by methane pryolysis, 168, 169
—, by natural gas pyrolysis, 167
—, by propylene pyrolysis, 179
—, by pyrolysis of aromatics, 88
—, by pyrolysis of petroleum distillates, 86, 162, 176
—, condensation with olefins, 565
—, from 9.10-dihydroanthracene, 200
—, from pitch, 227
—, hydrogen from, 219

Anthracene, oxidation of, 916, 924, 925, 928
—, phthalic anhydride from, 925
—, pyrolysis of, 89
—, reaction with monochlorinated wax, 741
—, stabilization of gasoline by, 897
Anthracene oil, decomposition, electric arc, 257
Anthracite, catalyst, pyrolysis of aromatics, 146
Anthraquinone, from aromatics, 924, 925
—, from phthalic anhydride, 922
—, oxidation catalyst, 926, 936
—, production of, 653, 924-925
—, stabilization of gasoline by, 897
Anthraquinone dyes, 434, 924
Antidetonants, 979, 984
Antifreeze liquids, 367, 515, 786
Antiknock materials, 966, 983
—, aromatic hydrocarbons, 161, 166
—, by pyrolysis of gaseous olefins, 186
—, effect on rate of oxidation, 981
—, tetraethyl lead-ethylene dibromide, 478
Antiknock value, increased by oxidation, 991, 993
—, of cracked gasoline, 92, 110
—, of polymerized ethylene, 593
Antimonates, aromatization catalysts, 186
—, dehydrogenation catalysts, 405
Antimonides, dehydrogenation catalysts, 405
Antimony, chlorination catalyst, 475, 698
—, hydration catalyst, 536
—, oxidation catalyst, 511, 876
—, pyrolysis catalyst, 135, 136, 189
—, reaction with vinyl compounds, 680
—, removal of gasoline gum by, 902
Antimony chloride, catalyst, condensation of olefins with aromatics, 569
—, chlorination catalyst, 569, 471, 699, 749, 775
—, cracking with, 193
—, polymerization catalyst, 618, 619, 623
—, pyrolysis catalyst, 189
—, reaction with hydrocarbons, 1061
—, stabilization of gasoline by, 898
Antimony halides, bromination catalyst, 768
—, polymerization catalyst, 594
Antimony oxide, catalyst, for carbon monoxide-hydrogen reaction, 232
Antimony pentachloride, by chlorination of antimony trichloride, 701
—, catalyst, preparation of fluorinated hydrocarbons, 707, 710
—, chlorination catalyst, 673, 690, 691, 764, 770, 778
—, chlorinating agent, 687, 701, 717, 735, 738, 756, 764
—, separation of paraffin hydrocarbons with, 1146
Antimony pentoxide, oxidation catalyst, 943
Antimony salts, catalysts, methane chlorination, 698
Antimony sulphide, adsorption of mercaptans, 446
Antimony tribromide as catalyst, esterifying propylene by hydrogen bromide, 327
—, preparation fluorinated hydrocarbons, 707
Antimony trifluoride, fluorinating carbon tetrachloride, 707, 710
Antimony vapor, effect on ignition temperatures, 979
Antioxidants, effect of, esterifying propylene by hydrogen bromide, 327
—, in textile oils, 1029
—, prevention of gum formation in gasolines, 896, 897, 898, 903
—, use in polymerization of diolefins, 628
Antiseptic properties, of isopropyl alcohol, 363 365
—, of naphthenic acids, 1082
—, of thymol, 375
Aposafranine, stabilization of gasoline by, 897
Appalachian oil, n-hexane from, 24
Arachidic acid, from petroleum distillates, 1063, 1076
—, from paraffin wax, 944
Aralkyl mercaptans, 437
Argon, analysis and separation of, 1099
Arkansas cokes, analyses of, 227
Aromatic alcohols, oxidation of, 926
Aromatic amines, antidetonating properties, 977
—, condensation with formaldehyde, 860
Aromatic bases, separation of, 825
Aromatic content, of cracked gasolines, 117, 118, 119
Aromatic equivalent, of gasoline, 1142
Aromatic ethers, musk-like odor of, 400
Aromatic sulphonic acids, from naphthene, 1009, 1010
—, decomposition of, 1146
Aromatic tars, by pyrolysis of trimethylethylene, 75
Aromatic vinyl ethers, preparation of, 682
Aromatics, absorption of, 1095
—, action of aluminum chloride on, 199-200
—, alkylation of, 573, 810
—, antiknock properties of, 977, 980
—, as antiknock materials, 161, 166
—, bacterial oxidation of, 1004
—, bicyclic derivatives in petroleum, 33
—, breaking emulsions with, 1027
—, by acetylene polymerization, 667, 668
—, by acetylene pyrolysis, 82, 176, 180, 181
—, by benzene-ethylene pyrolysis, 177
—, by butadiene pyrolysis, 176
—, by butane pyrolysis, 171-174, 185
—, by butene pyrolysis, 179, 180
—, by cracking, 103, 162, 163, 164, 837
—, by crude oil pyrolysis, 188
—, by cyclohexene pyrolysis, 85, 155
—, by dehydrogenation of cycloparaffins, 33, 97, 163, 164, 176, 181, 182, 187, 1144
—, by ethane pyrolysis, 46, 47, 65-69, 170-173-183, 185
—, by ethane-propane pyrolysis, 44, 49, 163, 170
—, by ethylene-acetylene pyrolysis, 180
—, by ethylene pyrolysis, 66-69, 171, 177, 178
—, by gasoline oxidation, 635, 836
—, by heptane-octane pyrolysis, 61
—, by hexadecane pyrolysis, 63, 76
—, by n-hexane pyrolysis, 60, 172
—, by isobutene pyrolysis, 73, 179, 180
—, by isopentane pyrolysis, 175
—, by methane pyrolysis, 40, 147, 161, 166-172, 176, 182-189
—, by naphthene oxidation, 838
—, by natural gas pyrolysis, 91, 161, 167, 172, 182, 184
—, by olefin pyrolysis, 97, 99, 173, 176-180, 182 184-187, 188
—, by paraffin wax pyrolysis, 175, 176
—, by pentane pyrolysis, 58, 171, 172
—, by propane pyrolysis, 49, 171-173, 185
—, by propane-butane pyrolysis, 163 170
—, by propylene pyrolysis, 70, 71, 178, 179, 18
—, by pyrolysis of diolefins, 79
—, by pyrolysis of paraffins, 64, 97, 152, 161, 165-177, 182-186, 188
—, by pyrolysis of petroleum distillates, 86, 91, 133, 161-165
— by oxidation of petroleum, 842
—, by secondary pyrolytic reactions of olefins, 81
—, by water gas-gaseous olefins pyrolysis, 187
—, catalysts in pyrolytic formation of, 162, 163
—, concentration of, 1145
—, condensation of, 97
—, condensation with aluminum chloride, 202
—, — alkylene oxides, 1059
—, cracking of, 96
—, determination of, 1126, 1134-1143
—, from coal gas, 166
—, from coal-tar, 87, 161
—, from coke-oven gas, 166
—, from cracking tar, 88
—, from gaseous hydrocarbons, 172, 173
—, from methane-propane-butanes, 173
—, from oil gas manufacture, 161
—, from olefins and hydrogen sulphide, 425
—, from petroleum, 11, 20, 30, 33, 34, 36, 1146
—, gum formation in, 902
—, ignition temperatures, 968
—, in acid sludge, 27, 28
—, in cracked gasoline, 116, 117, 118, 119, 1126
—, in gasoline produced by aluminum chloride, 191
—, in kerosene, 26, 27, 28

Aromatics, in natural-gas gasoline, 18
—, in straight-run gasoline, 20, 21, 22, 25, 27
—, isopropylation of, 374, 375
—, mechanism of chlorination, 756
—, nitration of, 353, 1040, 1053, 1054, 1143
—, nitration of side chains, 1046
—, oxidation of, 914-930
—, polynuclear hydrocarbons from, 199
—, production of, 106, 124, 182-188
—, pyrolysis of, 87-90, 147, 188
—, reactions in formation of, 162
—, reaction with mercuric acetate, 1132
—, — sulphuric acid, 1134
—, reactivity with halogens, 755
—, refining by oxidation, 987
—, removal from kerosene, 1143
—, removal of, by fuming sulfuric acid, 164
—, separation from naphthenes, 33
—, — paraffins, 33, 1146
—, — petroleum, 1145-1146
—, solubility in aniline, 1145
—, — benzyl alcohol, 1141
—, — sec.-butyl alcohol, 394
—, solvents for 1143
—, sulphonation of, 1006, 1035-1036, 1136
—, thermal stability of, 87, 89, 95, 97
Aromatization, of olefins, 89
Aromatization catalysts, 182, 183, 186, 187
Arsenates, catalysts, condensation of olefins with aromatics, 564, 571
—, dehydrogenation catalysts, 405
Arsenic, catalyst, diphenyl production, 189
—, —, glycol production, 511
—, —, hydrocarbon pyrolysis, 135, 136
—, chlorination catalyst, 758, 775
—, hydration catalyst, 536
—, oxidation catalyst, 432, 833, 876
—, polymerization catalyst, 623
—, removal of gasoline gum by, 902
Arsenic oxide, oxidation catalyst, 922
Arsenic salts, reaction with acetylene, 667
Arsenic sulphide, adsorption of mercaptans, 445
—, catalyst, diphenyl production, 189
Arsenides, dehydrogenation catalyst, 405
—, oxidation catalyst, 834
Artificial asphalt, by oxidation of hydrocarbons, 940
Artificial musk, 400
Artificial silk, use of acetone, 370
Arylalkylated aromatic compounds, 564
Arylalkyl ethers, production of, 740, 808
Arylamines, alkylated, production of, 573
Arylamino alcohols, 543
Arylamino derivatives, of naphthenic acids, 1019
Aryl chlorides, hydrolysis to phenols, 767, 785
Aryldiazonium fluoborates, 597, 611
Arylethanols, 545
Aryl-substituted alkylenes, glycols from, 510
Aryl-substituted olefin oxides, isomerization, 547
Aryl-substituted olefins, ease of polymerization, 610
Asbestos, catalyst, esterification of olefins, 326, 327
—, —, ethylene bromide from vinyl bromide, 478
Asbestos fiber, treatment with turpentine, 890
—, oxidation catalyst, 917, 919
Ash content, carbon black, 212, 244, 246
—, of petroleum products, 1153
Ash, petroleum, analysis of, 31
Asphalt, artificial, by oxidation of petroleum residues, 830, 831, 841, 842
—, coke from, 228, 229
—, cracked by submerged combustion, 1000
—, decomposition, electric arc, 262
—, emulsified with petroleum sulphonic acids, 1026
—, from acid sludges, 1015
—, from lignite tar, 949
—, from olefin-sulphur reaction, 429
—, from oxidation of lubricating oils, 903
—, from tars, 1013
—, in petroleum, 11
—, insulating materials from, 740
—, oxidation of, 993
—, purification of, 16
Asphalt, pyrolysis of, 133
—, solubility in sec.-hexyl acetate, 402
Asphalt content, of oils, 229
—, voltolized oils, 271
Asphalt distillates, nitration of, 1053
Asphalt emulsions, stabilizers for, 994
Asphalt oils, use as color coats, 1030
Asphaltic material, from oxidation of lubricating oils, 903
—, in naphthenic acids, 1067
—, in sludges, 1013
—, removal by sulphuric acid, 1012, 1064
Asphaltenes, from crude oils, 950
—, in lubricating oils, 904
—, removal from transformer oils, 910
Astringents, use of isopropyl alcohol in, 362
Atomized oil, thermal decomposition, 234
Auramine dyes, 860
Auric chloride, action on monovinylacetylene, 669
—, chlorination catalyst, 775
Austrian oils, decomposition by aluminum chloride, 198
Autoxidation, catalysts for, 890
—, definition of, 889
—, effect on polymerization, 619, 893
—, of olefins, 654, 881
—, of pinene, 889
—, of petroleum distillates, 831, 987
—, reduction of rate of, 890
Aviation gasoline, analysis of, 1140
Avirols, detergents, 1022
Azeotropic mixtures, of acetone, 409
—, ethylene chlorohydrin, 495
—, isopropyl alcohol-benzene, 394
—, isopropyl alcohol-isopropyl acetate, 373
—, isopropyl alcohol-water, 359, 360, 361, 362, 364
—, resolution, by fractional crystallization, 1147

B

Bacterial oxidation, of crude oils, 1004
Bakelite, 860
Baku gas oil, oxidizability of, 934
Baku gasoline, treatment with acetyl chloride, 1056
Baku naphtha, cyclohexane from, 23
Baku naphthenic acids, paraffin carboxylic acids in, 1076
Baku oils, oxidation of, 950
—, treatment with sulphur, 950
Baku petroleum, diisopropyl from, 735, 736
—, naphthenic acids in, 1081
—, nitration of, 1043
—, pyrolysis of, 162
—, sulphur content of, 421
Balakhani oils, oxidation of, 950
Barbituric acid, from bromides of naphthenic acids, 1072
Barium, catalyst, desulphurization of petroleum oils, 458
Barium acetate, action on mercaptans, 447
Barium acetylacetonate, catalyst, oxidation of paraffin wax, 947
Barium carbide, hydrolysis of, 662
Barium carbonate, promoter, production of acetone, 408
—, reaction with trimethylethylene chlorohydrin, 503
Barium chloride, catalyst for diolefin-ammonia reaction, 656
—, catalyst for pyrolysis of chloro-compounds, 635, 673, 802, 803
—, catalyst in preparation of chloroethanesulphonates, 474
—, chlorination catalyst, 691
—, molten, in hydrocarbon pyrolysis, 135
—, oxidation catalyst, 866
Barium cinnamate, oxidation catalyst, 947, 1001
Barium cyanide, catalyst for acetylene-hydrogen cyanide reaction, 684
Barium hexanesulphonate, 1008
Barium hydroxide, adsorption of mercaptans, 446
—, production of diacetone alcohol with, 410

Barium menthanedisulphonate, 575
Barium naphthenate, 1089
Barium nitrate, chlorination catalyst, 691
Barium oxide, action on tertiary alcohols, 392
—, hydration catalyst, 677
—, oxidation catalyst, 944
Barium peroxide, isoprene polymerized by, 625
—, oxidation catalyst, 406, 843
Barium phosphate, catalyst in formation of acrylic acid esters, 571
Barium salts, absorption of hydrogen sulphide, 424
Barium stearate, oxidation catalyst, 945, 947
Barium sulphate, as a "preventative catalyst," 414
—, catalyst for oxidation of mercaptans, 441
Barium sulphonates, 575
Bars, metallic, ignition of gases by, 968
Baryta, effect on methane pyrolysis, 39
Batchite, 691, 797
Batwing flame, for carbon black production, 236
Bauxite, absorption of hydrogen sulphide, 425
—, catalyst, conversion of 1-butene to 2-butene, 72
—, —, for acetylene-hydrogen sulphide reaction, 426, 684
—, —, for preparation of thiophene from acetylene, 684
—, —, for reaction of vinyl acetate and alkylamines, 656
—, preparation of aluminum chloride from, 193
—, purification of phthalic acid with, 923
Beeswax, condensation with carbyl sulphate, 1033
—, hydrogen from, 209
—, oxidation, with sodium hydroxide, 950
—, pyrolysis of, 209
—, substitutes, by chlorination of montan wax, 740
— —, by paraffin oxidation, 952, 972
—, wetting agents from, 1033
Belgium, sources of carbon dioxide in, 236
Bentonite, treatment of petroleum with, 460, 609
Benzal chloride, 755
—, by chlorination of toluene, 769-773
—, uses of, 776
Benzaldehyde, autoxidation of, 851, 853, 920, 921
—, from benzal chloride, 776
—, benzoic acid from, 921
—, by oxidation of toluene, 39, 838, 914-916, 918-922, 927, 928, 930
—, from benzene, 920
—, from ethyl benzene, 1056
—, oxidation of, 858, 979, 980
—, purification of, 364, 920
—, reaction with boron fluoride, 596
—, reduction of benzoyl chloride, 1057
—, selective solvent for separation of paraffins and naphthenes, 35
Benzanthrone, phenyl-α-ketonaphthalene from, 200
Benzene, 423, 659, 1136
—, acetylene from, 149
—, action of ozone on, 930
—, addition products with nitrogen dioxide, 832
—, adhesion tension, carbon blacks, 249
—, adsorption by charcoal, 261
—, alkyl derivatives from, 560-562
—, as antidetonant, 964, 983
—, azeotrope with isopropyl alcohol, 351, 394
—, bacterial oxidation, 1004
—, bromination of, 767, 768
—, by condensation of ethylene with butadiene, 44
—, by decomposition of trichlorocyclohexane, 817
—, by dehydrogenation of cyclohexane, 83
—, by oxidation of petroleum, 842
—, by polymerization of butenes, 602
—, by pyrolysis of allylcyclohexane, 86
—, — butadiene, 79, 177
—, — butane, 53, 171, 174, 185
—, — n-butane-isobutane, 57
—, — 1-butene, 72, 180
—, — 2-butene, 73, 180
—, — coal gas, 166
Benzene, by pyrolysis of coke-oven gas, 166
—, — cumene, 88
—, — cyclohexane, 84, 85, 181
—, — cyclohexene, 67, 85
—, — ethane, 170, 171, 185
—, — ethane-propane, 44, 170
—, — ethylene, 45, 46, 47, 66, 69, 169, 177, 180
—, — gaseous paraffins, 175
—, — hexane, 59
—, — hexatriene, 177
—, — hydrocarbons, effect of carbon-hydrogen ratio, 174
—, — isobutylene, 73, 179, 180
—, — isoprene, 79
—, — methane, 38, 40, 41, 42, 166, 167, 168, 171, 184
—, — methane-propane-butane, 173
—, — natural gas, 167, 172, 184
—, — olefins, 187
—, — paraffin wax, 176
—, — pentane, 171
—, — petroleum distillates, 86, 162, 163, 165, 176
—, — 4-phenyl-1-butene, 89
—, — propane, 171, 177, 185
—, — propane-butane, 170
—, — propylene, 70, 71, 179
—, — toluene, 88, 89
—, — xylene, 88, 89
—, chlorination of, 702, 713, 755, 756, 758, 761-765
—, —, hydrogen chloride from, 767
—, compression strength, 978
—, condensation with alkylene oxides, 1059
—, — cyclohexanol, 564
—, — hexene, 1128
—, — monochloroacetone, 777
—, critical solution temperature, 1136
—, decomposition in electric arc, 257, 259
—, decylbenzene from, 562
—, determination of, with bromine, 1122
—, diluent in polymerization of cyclopentadiene, 623
—, diphenyl from, 199
—, distillation of chlorohydrin with, 494
—, ditolyl from, 199
—, effect on active oxygen, combustion of fuels, 978
—, — aniline point, 1137
—, — on butyl sulphide pyrolysis, 457
—, — chlorohydrin-formation velocity, 489
—, — oxidation of benzaldehyde, 980
—, ethylated compounds from, 560
—, evaluation of transformer oils, 911
—, extraction of thiophene from, 460
—, — sulphonates, 1017
—, formation of emulsions, 1026
—, from acetylene, 81, 82, 180, 181, 261, 667, 668
—, — coal gas, 161
—, — coke-oven gas, 161
—, — p-cymene, 200
—, — gasoline, 914, 915
—, — hydrocarbons and hydrogen sulphide, 425
—, — naphthenic sludge, 1035
—, — oil gas, 116
—, — petroleum distillates, 33
—, — petroleum tars, 873
—, — toluene, silent discharge, 267
—, — 1,3,5-trichlorocyclohexane, 749
—, — xylene and aluminum chloride, 200
—, hydrogenated in silent discharge, 264
—, hydrogenation of, 181, 460
—, in compression product, blau gas, 119
—, in straight-run gasoline, 22, 25, 26, 27
—, isolation of, 1145
—, isopropylation of, 374
—, lacquer diluent, 1030
—, miscibility with ethylene chlorohydrin, 495
—, nuclear polychloro-derivatives, 764
—, oxidation of, 927
—, — cyclohexene in, 893
—, paraffin derivatives, 562
—, photochemical chlorination of, 757
—, polymerized by silent discharge, 269

Benzene, purification of, 188, 653
—, pyrolysis of, 88, 89, 188, 189, 227
—, reaction with ammonium lead tetrachloride, 764
—, — antimony chloride, 764
—, — bromine, 1131
—, — chlorides, 764
—, — chlorine, velocity of, 757
—, — crotonylene, 1128
—, — cuprene, 672
—, — cyclohexene, 561
—, — diolefins, 204
—, — ethylene, 560
—, — ethylene oxide, 545
—, — ferric chloride, 764

—, — isoprene, 204
—, — manganese dioxide, 764
—, — monochlorinated wax, 741
—, — nitrogen pentoxide, 1044
—, — propylene, 560, 561
—, — sulphur monochloride, 764
—, — sulphuryl chloride, 764
—, refining by oxidation, 987
—, removal of, from mixtures, 1116
—, secondary standard for knock rating, 985
—, separation of ichthyolsulphonic acids by, 1036
—, — wax acids with, 954
—, solvent in chlorohydrin formation, 493
—, sulphur dyes from, 431
—, thermal chlorination of, 762, 763
—, thermal stability of, 90
—, used in purifying hydrogen, 230
Benzene-acetylene equilibrium, 148
Benzene-air, ignition of, 973
—, inflammability limits, 961
Benzene content, of cracked gasoline, 118
Benzene-1,3-disulphonyl chloride, 1009
Benzene-ethylene reaction, conditions affecting, 560
Benzene homologues, dehydrogenation of, 146
—, from Persian petroleum, 34
—, reaction with bromine, 1131
Benzene nucleus, effect, preparation resins, 204
Benzene ring, existence in nitrogen bases, 820
Benzenestearosulphonic acid, fat-hydrolyzing agent, 1025
Benzenesulphonic acid, catalyst for formation of acetic anhydride, 682
—,— hydration of olefins, 348, 385
—, esterification of ethylene by, 322
—, formation of, 1006
—, from cycloparaffins, 1010
—, properties of, 1011
—, purification of isopropyl alcohol, 360
—, separation of higher alcohols from oils with, 389
Benzenetricarboxylic acid, from lignin, 949
Benzenoid hydrocarbons, action of ozone on, 930
Benzerythrene, by benzene pyrolysis, 227
Benzidine, purified with isopropyl alcohol, 364
—, stabilization of gasoline with, 898
Benzine, as an extracting agent, 953, 954, 955
—, autoxidation of, 893
—, by acetylene pyrolysis, 668
—, by action of aluminum chloride on petroleum, 193
—, gum formation of, 902
—, hydrogen from, 209
—, oxidation of, 938
—, pyrolysis of, 149, 209
Benzoic acid, 1082
—, adsorptive capacity of carbon blacks for, 248
—, addition to amylene, 330
—, as antidetonant, 983
—, by hydrocarbon oxidation, 35, 838
—, by oxidation of hydrocarbons with benzoyl peroxide, 1061
—, effect on oxidation of benzaldehyde, 980
—, from acetylene polymers, 268
—, from benzene, 930
—, from benzyl alcohol, 921
—, from cuprene, 671
—, from ethylbenzene, 921, 926
—, from lignin, 949
Benzoic acid, from naphthalenes, 922
—, from toluene, 915, 916, 918, 919, 921, 922, 928, 929
—, manufacture, 776
—, oxidation catalyst, 943
—, purified with isopropyl alcohol, 364
—, reaction with ethylene oxide, 541
—, reaction with nitrogen pentoxide, 1044
Benzoic esters, from alkyl sulphates, 325
Benzoic phthalic glyceride, 996
Benzoin, distributing agent made from, 367
Benzonaphthol, purified with isopropyl alcohol, 364
Benzonitrile, selective solvent for separation of paraffins and naphthenes, 35
Benzophenone-aluminum chloride complex, 600
Benzoquinone, condensation with diolefins, 650, 651, 653
—, from benzene, 917, 925, 927
Benzotrichloride, formation of, 769, 770, 776
Benzoyl choride, from benzaldehyde, 197
—, reaction with cyclopentane derivatives, 197
—, — 1,4-diphenylbutadiene, 654
—, — naphthenes, 1056, 1057, 1058
—, — olefins, 569, 570
—, separation of paraffins from naphthenes with, 35
Benzoyl nitrate, use in nitration, 1046
Benzoyl peroxide, catalyst, polymerization of butadiene, 626, 629, 630
—, —, polymerization of divinyl ether, 682
—, —, polymerization of vinylacetylene, 670
—, effect on oxidation of benzaldehyde, 980
—, effect on propylene-hydrogen bromide reaction, 327
—, reaction with hydrocarbons, 1061
Benzyl abietate, 395
Benzyl alcohol, as antidetonant, 983
—, determination of aromatics with, 1141
—, effect on oxidation of benzaldehyde, 980
—, from benzyl chloride, 920
—, — toluene, 922
—, oxidation of, 915, 919, 921
—, solvent for determining critical solution temperatures, 1136, 1141
—, toxicity of, 362
Benzylamine, reaction with propylene oxide, 557
1-Benzylamino-2-propanol, 557
Benzyl bromide, production of, 777, 778
Benzyl chloride, from toluene, 755
—, oxidation of, 919, 920
—, production of, 769, 770, 771, 772, 773, 774, 776
—, uses of, 776
Benzyl disulphide, in adhesives, 456
Benzyl mercaptan, pickling inhibitor, 434
—, pyrolysis of, 457
—, stability of, 457
Benzylmorphine salts of alkylsulphonic acids, 1011
Benzyl nitrate, oxidation of hydroaromatics with, 930
Benzyl sulphide, in adhesives, 456
Berberonic acid, preparation of, 824, 825
Beryllia, catalyst, oxidation of alcohols, 406
—, effect on pyrolysis of methane, 40
Beryllium carbide, hydrolysis of, 663
Beryllium carbonate, aromatization catalyst, 182
Beryllium, catalyst activator, 280, 288
—, catalyst, for production of ethylene, 125
—, —, pyrolysis of benzene homologues, 146
Beryllium compounds, catalyst, production of diphenyl, 189
Beryllium halides, refining oils with, 597
Beryllium oxide, as catalyst, carbon monoxide-hydrogen reaction, 232
—, pyrolysis of methane, 150
Beryllium phosphate, catalyst, hydration of ethylene, 308
Beta-rays, action on gaseous hydrocarbons, 274
—, refining hydrocarbons with, 274
Bicyclic hydrocarbons, in kerosene, 28
Bicyclic monocarboxylic acids, in petroleum, 1073
Bicyclo-(0,3,3)-octane, 86
5,5'-Bipyrazoline, 652
ββ'-Bisiodomercuridiethyl ether, 583

Bismarck brown, 1029
Bismuth, absorption of hydrogen sulphide, 425
—, catalyst, chlorination of benzene, 758
—, —, formation of butadiene from vinyl compounds, 680
—, —, glycol production, 511
—, —, methane-steam reaction, 285
—, —, preparation of olefin oxides, 536
—, —, vapor-phase hydration of acetylene, 676
Bismuthates, dehydrogenation catalyst for alcohols, 405
Bismuth bromide as catalyst, esterification of olefins, 323, 324, 327
—, ethylidene bromide from vinyl bromide, 478
Bismuth chloride as catalyst, chlorination of toluene, 775
—, esterification of olefins with hydrogen chloride, 322, 323, 326, 715
—, hydration of propylene, 314
Bismuth compounds, catalysts for absorption of propylene, 355
—, formation of nitrites, 684
—, hydration of ethylene, 355
Bismuth-copper, catalyst, oxidation of alcohols, 869, 870
Bismuth halides, catalyst, polymerization of cyclopentadiene, 623
—, refining oils with, 597
Bismuth nitrate, action on mercaptans, 447
—, nitration of hydrocarbons, 1046
Bismuth oxychloride, catalyst, hydration of propylene, 314
Bismuth vanadate, oxidation catalyst, 919, 921, 922
Bismuth vapor, effect on ignition temperatures, 979
Bisnitrosates, 580
Bisulphates, catalysts, hydration of ethylene, 312
Bisulphite compounds of ketones, 1084
Bisulphites, reaction with styrene, 575
Bitumen, hydrogen from, 209
—, pyrolysis of, 209
—, solvents for, 614
Bituminous coal, pyrolysis of, 129, 133
Bituminous products, source of petroleum, 36
Bivalent lead compounds, as antidetonants, 984
Blast-furnace stove, use of, 216
Blast gas, use in pyrolysis, 210
Blau gas, butadiene from, 156
Bleaching montan wax, 997
Bleaching powder, hypochlorous acid from, 488
—, oxidation of ethylene, 991
—, oxidation of hydrocarbons with, 933
—, — phosphine, 664
—, reaction with toluene, 776
Blowing, of liquid hydrocarbons, 933
—, petroleum distillate, 937
Blown asphalts, 999
Blown wax, 994
Blue light, activating methane chlorination, 694
Blue-oxide, as oxidation catalyst, 938
Bomb calorimeter test, total sulphur, 1150, 1151
Bone black, analysis of, 246
—, catalyst, hydrocarbon decomposition, 222
Bone charcoal, catalyst, preparation of tetrachloroethane from acetylene, 673
Borates, aromatization catalysts, 186
—, catalysts, condensation of olefins with aniline, 571
—, —, — olefins with aromatics, 564
—, —, dehydrogenation of alcohols, 405
—, oxidation catalyst, 834
Borax, oxidation catalyst, 990
—, removal of gum in gasoline with, 902
Boric acid, absorption of hydrogen sulphide, 424
—, catalyst, condensations of alkyl chlorides with carbon monoxide, 815
—, —, for preparation of amylene bromohydrins, 500, 503
—, oxidation catalyst, 876, 886, 943, 1001
Boric anhydride, effect on ethylene absorption, 339
—, oxidation catalyst, 943
Boric oxide, 595
Borneo petroleum, bicyclic naphthenes from, 25
—, fatty acids in, 1076
—, gases from, 18
—, naphthalene hydrocarbons in, 28
—, straight-run gasoline from, 21, 22
—, sulphonation of, 1017
—, toluene fraction, nitration of, 35
Borneol, from pinene, 331, 890
—, oxidation of, 331
Bornyl acetate, 331
Bornyl oxalate, 331
Boron chloride, catalyst, condensation of olefins with organic chlorides, 569
—, —, polymerization of diolefins, 618, 623
—, oxidation catalyst, 939
Boron fluoride, addition to olefins, 596
—, condensation catalyst, aromatics with alkyl chlorides, 596
—, —, hydrocarbons and alkylene oxides, 1059
—, —, olefins with aromatics, 559
—, —, olefin oxides with aromatics, 545
—, —, propylene with phenol, 566
—, —, preparation of lubricating oils, 200
—, cleavage of ethers by, 596
—, compound with dioxan, 596
—, cracking mineral oils with, 201
—, double compounds of, 597
—, in Friedel-Crafts synthesis, 596
—, polymerization of olefins by, 197, 589, 590, 593, 595-598, 600, 606, 613
—, preparation of mineral oils, 201
—, properties of, 595
—, reaction with organic compounds, 596
—, synthesis of, 595
—, synthetic rubber production, 629
Boron fluoride-acetic acid, an ansolvo-acid, 594, 597
Boron halides, catalysts, polymerization of olefins, 594
—, refining oils with, 597
Boron oxide, dehydrogenation catalyst, 223
Boron phosphate, catalyst, hydration of olefins, 310, 311
—, —, hydration of propylene, 315
Boron trioxide, catalyst, hydration of acetylene, 676
—, —, sulphonation of olefins, 1034
Boryslaw crude, oxidation of, 832
Bouncing pin method, knock rating, 984
Branched-chain alcohols, by hydration of olefins, 401, 403
Branched-chain hydrocarbons, action of chlorosulphonic acid on, 1008
—, from n-octane, 428
—, nitration of, 1040, 1044, 1045
—, reaction with sulphur chloride, 1060, 1061
—, sulphonation of, 1005, 1008, 1009
Brass, aromatization catalyst, 187
—, catalyst, pyrolysis of pentane, 129
—, dehydrogenation of isopropyl alcohol with, 349
—, oxidation catalyst, 905, 909
Brick, catalyst, olefin chlorine addition, 469
—, use in pyrolysis of hydrocarbons, 210, 213, 214
British Air Ministry test, oxidation of oils, 904
Brittolizing, 984
Bromide-bromate reagent, estimation butadiene, 658, 1120
Bromides, catalysts, esterifying olefins, 328
—, from acetylene polymers, 267
—, — naphthenic acid alcohols, 1072
Brominated hydrocarbons, hydrolysis of, 788
Bromination, analysis of hydrocarbons by, 1120-1122
—, of benzene, 767, 768
—, — butane, 720
—, — butenes, 482, 483
—, — cyclohexane, 744, 745, 746, 749, 750
—, — cyclohexane derivatives, 753, 754
—, — cyclopentane, 744
—, — cyclopropane, 746
—, — ethane, 715, 716
—, — ethylene, 465, 466, 477
—, — gaseous paraffins, catalytic, 693
—, — isobutane, 721
—, — isobutene, 483

Bromination, of isopentane, 726
—, — isopropyl alcohol, 374
—, — methane, 706, 707
—, — methylcyclohexane, 751
—, — oil gas, 480
—, — olefins, 465, 466
—, — —, rates of, 465, 466, 1124
—, — paraffins, 706
—, — pentane, 723
—, — propane, 718
—, — —, iron catalyst, 718
—, — toluene, 777
—, — —, photochemical, 778
Bromine, addition to benzene, 768
—, addition compounds with thioethers, 450, 451
—, catalyst, chlorination toluene, 775
—, —, chlorination of cycloparaffins, 744, 745
—, determination of, 1121
—, —sulphur with, 1151
—, estimation of butadiene by, 1120
—, olefin determination with, 464, 465
—, promoter, polymerization of styrene, 611
—, reaction with acetone, 409
—, — acetylene, 675
—, — benzene, 1131
—, — benzene homologues, 1131
—, — butadiene, 641, 643
—, — conjugated diolefins, 642-645
—, — cycloparaffins, 616, 1131
—, — ethylcyclohexane, 616
—, — ethylene, 321, 467, 477
—, — iodomethanes, 707
—, — isoprene, 643
—, — mercaptans, 432, 433
—, — naphthenes, 1131
—, — naphthenic acids, 1083
—, — nitrogen bases, 820, 821, 824
—, — pentane, 723
—, — polymerized olefins, 592
—, — substituted cyclopropane, 1131
—, — tertiary alcohols, 392
—, — thiophanes, 453
—, — trimethylene sulphide, 453
—, — trimethylquinoline, 824
—, reagent for absorption of hydrocarbons, 1094
—, use in synthetic rubber production, 629
Bromine hydrate, rôle in bromination, 465, 477
Bromine numbers, 1128, 1130
Bromine-sensitized oxidation of olefins, 876
Bromine water, absorption of ethylene by, 1122
—, determination of benzene by, 1122
—, ethylene bromohydrin from ethylene, 499
—, reaction with conjugated dienes, 648
—, — ethylene, 488
Bromoacetone, from isopropyl alcohol, 374
Bromobenzene, carboxylation of, 930
—, formation of, 768
—, reaction with nitrogen pentoxide, 1044
o-Bromobenzoic acid, from o-bromobenzene, 929
1-Bromobutadiene, reaction with hydrogen bromide, 647
2-Bromobutadiene, from monovinylacetylene, 669
—, polymerization of, 670
1-Bromobutanol-2, 501
Bromobutene, reaction with sodium ethoxide, 483
1-Bromo-1-butene, 482
2-Bromo-1-butene, 482
2-Bromo-2-butene, 483
—, from butane, 720
Bromocyclohexane, from cyclohexane, 750
1-Bromo-2,2-dimethylpropane, from isopentane, 726
2-Bromo-2-methylbutane, 726
3-Bromo-3-methyl-1-butene, 645
3-Bromo-2-methyl-1-propene, 637
Bromoform, by methane bromination, 706, 707
—, conversion to acetylene, 663
Bromoform, from acetone, 409
—, germicide, 706
Bromoheptane, 742
Bromohexane, 742
Bromohydrin formation, reaction velocity, 499
—, temperatures for, 499
Bromohydrins, preparation of, 540
—, separation of olefins as, 144
Bromoiodoethylene, from acetylene, 672
Bromoiodomethane, from diiodomethane, 707
Bromomaleic acids, from thiophens, 917
Bromomethylbutane, from tertiary amyl bromide, 806
Bromomethylbutene, from isoprene, 636, 645
1-Bromo-1-methylcyclopropane, from methylcyclopropane, 746
Bromomethyl ethyl ketone, 501
3-Bromopentane, from 2-pentene, 330
Bromopentanes, production of, 723
Bromopropylenes, from propylene dibromide, 481
Bromothymol blue, 550
Bromotoluene, production of, 777, 778
—, bromobenzoic acid from, 929
Bronze, aromatization catalyst, 187
Brown-coal oils, sulphonated, 1019
Brown-coal paraffin, oxidation of, 956
Brown-coal residues, oxidation with nitric acid, 1003
Brown-coal tar, burning oils from, 202
Brown-coal tar oils, sulphonated, 1061
Brown soap, bleaching, by hypochlorite, 942
Brucine, stabilization of gasoline, 898
Brucite, removal of hydrogen sulphide, 423
—, use in sweetening, 443
Burma kerosene, p-cymene from, 28
Burma oils, 1146
Burma petroleum, aromatics from, 25
—, pentaethylbenzene from, 28
Burner tips, of lava, 241
Burning oils, from brown-coal tar, 202
Burning-point, definition, 1152
Burton process, cracking, 109, 405
Bustenari petroleum, sulphonation of, 1035
Butadiene, 633-635
—, absorption by sulphuric acid, 641
—, by acetylene-olefin pyrolysis, 187
—, by catalytic dehydration of alcohols, 635
—, by coal-gas oxidation, 834
—, by condensation of ethylene, 44, 46
—, by hydrocarbon pyrolysis, 64, 158, 176
—, by oxidation of pentane, 852
—, by vapor-phase cracking, 129
—, condensation with ethylene, 44, 67
—, — olefins, 155, 156
—, — quinone, 653
—, crotyl bromide from, 645
—, cyclohexene from, 155, 156
— derivatives, polymerization of, 614
— —, reaction with sulphur dioxide, 576
—, determination of, 658, 659, 1120, 1122, 1124
—, — butylene in presence of, 1123
—, dibromides from, 641, 643
— 1,4-dibromide, 649
— dibromohydrins, 646
—, dimers of, 620
—, effect of methyl substitution on polymerization of, 627
—, from acetaldehyde, 634, 635
—, — acetals, 157
—, — acetylene, 155, 668
—, — alcohols, 155, 157, 159, 635
—, — amylene, 80
—, — butane, 156, 174

—, use for reduction of inflammability of isopropyl esters, 373
—, use in ethylene absorption, 341
—, uses as solvent, 493, 632, 644, 705, 718, 730, 882, 927, 954, 1124
Carbon tetrafluoride, from methane-fluorine reaction, 707
Carbon thiocarbonates, use in adhesives, 456
Carbonyl compounds, preparation of, 223
Carbonyl sulphide, removal from hydrogen, 230
Carbopetrocene, 226
Carborundum, catalyst, pyrolysis of methane, 39
Carborundum tubes, use of, pyrolysis of paraffins, 135, 215
Carboxylic acid chlorides, from alkyl chlorides, 814, 815
Carboxylic acids, by oxidation of hydrocarbons, 935
—, catalysts, oxidation of mineral oils, 936
—, detergency of, 935
—, from monochlorinated petroleum fractions, 814
—, from oxidation of synthetic oils, 201
—, from sulphonic acids, 1007
—, from Texas crudes, 1073
—, hydrogenated to alcohols, 990
—, oxidation of nitrogen bases to, 827
—, purification of, 935
—, reaction with olefin oxides, 519, 541
—, synthesis from aromatic hydrocarbons, 932
Carboxylic esters, from olefins, 325
Carbyl sulphate, condensation with beeswax, 1033
—, from ethylene, 335, 336, 343, 1006, 1032
Carnauba wax, acids by oxidation of, 996
—, identification of alcohols from, 960
—, rust-preventive from, 1031
Carvestrene, addition to hydrobromic acid, 331
Carvestrene dihydrochloride, 617
Caryophyllene series, 650
Casinghead gas, 16
Casinghead gasoline, pyrolysis of, 129
Casinghead naphtha (*see* Natural-gas gasoline), 17
Castor oil, as antidetonant, 983
—, dechlorination of petroleum products with, 804
—, esterification of, 539
—, oxidation of, 997
—, solubility in various materials, 394, 395, 798
Catechol, carboxylation of, 930
—, stabilization of gasoline with, 897
Cathode-rays, action on hydrocarbons, 273, 274
—, action on petroleum, 274
Caucasian petroleum, acids from, 935
—, cyclopentane from, 23
—, decomposition by aluminum chloride, 198
—, dichloromethylcyclopentane from, 817
—, methylcyclopentane from, 23
—, naphthenes from, 430
—, nitration of, 1041, 1047, 1049
—, oxidation of, 933, 934
Cellosolve, 524
Cellosolve acetate, 524, 525
Celluloid, use of nitrated distillates in, 1052
Cellulose acetate, solubility in various materials, 366, 373, 395, 402, 495, 500, 520, 524, 527, 673
Cellulose esters, coatings, 996
—, solubility in ethylene glycol monomethyl ether, 524
—, use with isopropyl alcohol, 366
Cellulose ethers, mixed, preparation, 538

Cellulose hydroxyethyl ether, 539
Cellulose nitrate, dehydration with sec.-butyl alcohol, 395
—, solubility in various materials, 373, 396, 452, 520, 524, 525, 527, 727, 797, 798
—, stabilization of, 550
Cellulose xanthate, preparation of, 742
—, reaction with halogenated paraffins, 741
Ceramic materials, oxidation catalysts, 872
Ceresin, composition of, 29, 950
—, chlorination of, 740
—, oxidation of, 950
—, solid acids from, 950
—, sulphonated oxidized products of, 1001
Cerium, catalyst activator, 288
—, catalyst, ammonia-carbon monoxide reaction, 298
—, oxidation catalyst, 942
Cerium acetylacetonate, oxidation catalyst, 936
Cerium carbide, hydrolysis of, 662
Cerium compounds, catalysts for diphenyl production, 189
—, catalysts for ethylene absorption in sulphuric acid, 340
—, oxidation catalysts, 953
Cerium metaphosphate, catalyst, condensation of olefins with aromatics, 564, 567, 571
—, —, hydration of ethylene, 303, 307
Cerium oxide, catalyst activator, 280, 288
—, catalyst, methane-steam reaction, 288, 289
—, —, for pyrolysis, 223
—, oxidation catalyst, 406, 856, 863, 920, 926
—, polymerization catalyst, 629
Cerium salts, effect on oxidation of wax, 949
Cerium stearate, oxidation catalyst, 945
Cerium sulphate, oxidation catalyst, 928, 948
Cerotic acid, from triacontane, 958
Cetene, polymerization of, 606
—, sulphonation of, 1033
Cetyl alcohol, reaction with boron fluoride, 596
Cetylbenzene, from benzene, 562
Cetyl chloride, palmitic acid from, 740, 814
Chain reactions, in oxidation, 851, 877
—, in pyrolysis of hydrocarbons, 47, 48, 52, 53, 55
Chamotte, catalyst, hydrocarbon pyrolysis, 136
Channel process, production of carbon black by, 234, 237, 242, 245, 246
Charcoal, acetylene absorbent, 263
—, aromatization catalyst, 186
—, bromination catalyst, 716
—, catalyst, carbon monoxide-ammonia reaction, 298
—, —, hydrolysis of alkyl chlorides, 787, 794
—, —, oxidation of mercaptans, 449
—, —, polymerization of acetylene, 668
—, —, polymerization of olefins, 589, 594
—, —, pyrolysis of methane, 39
—, —, reaction of sulphur and hydrocarbons, 429
—, catalyst stabilizer, 345
—, chlorination catalyst, 469, 697, 698, 701, 712, 713, 766
—, effect on ignition temperatures, 967
—, effect on pyrolysis of acetylene, 82
—, olefins absorbed by, 338
—, oxidation catalyst, 839, 840, 879, 939, 942, 949
—, purification of isopropyl alcohol with, 359
—, use in decolorization of fatty acids, 1025
—, — pyrolysis of coal gas, 210
—, — removal of olefin polymers, 608
—, — refining of oil, 609
—, *see also* Carbon
Charging stock, effect on cracking, 93, 98, 101, 107, 108
—, effect on cracked gasoline, 116, 117
Charlton carbon black, 245, 250, 253, 254
Chemical reactions during cracking, 92, 93
Chewing-gum base, chloroparaffin resin as, 740
Chinese wax, alcohols from, 960
Chlorex, *see* β.β' Dichloroethyl ether
Chlorides, anhydrous, prepared from heated oxides, 192
—, catalysts, chlorination of benzene, 766
—, —, esterifying olefins by aliphatic acids, 328
Chlorides, catalysts, methane chlorination, 699
—, —, reaction of olefins with aromatics, 559, 560
—, chlorination catalysts, 699, 722, 766
—, compounds with dioxan, 556
—, effect on pyrolysis of paraffin oils, 125
—, oxidation catalysts, 878
Chlorinated acetones, 373
Chlorinated ethanes, properties of, 467
Chlorinated hydrocarbons, condensation with naphthenes, 203
—, detergents, 1022
—, fluorinated hydrocarbons from, 708, 709
—, from cracking gas, 485
—, nomenclature and physical properties, 466, 467
—, reaction with hydrocarbons, 224, 225
—, stabilization of, 456, 704
—, stain-removing composition from, 742
—, use in insulating materials, 739, 740
Chlorinated isopentane, hydrolysis of, 788, 789
Chlorinated ketones from nitrosyl chloride reactions, 1055
Chlorinated methanes, physical properties, 467
Chlorinated oil, nitration of, 814
Chlorinated oxidized hydrocarbons, 1000, 1001
Chlorinated paraffin oil, catalyst, methane chlorination, 699
Chlorinated pentane, hydrolysis of, 788, 789
Chlorinated petroleum, cracking of, 106
—, insecticides from, 742
Chlorinated petroleum fractions, alkali fusion of, 740
—, drying oils from, 738, 741
—, use in soaps, 740
Chlorination, acetylene, 666, 672
—, acetylene tetrachloride, 715

—, — vinyl chloride, 475
—, purification of isopropyl alcohol with, 359
—, treatment of oxide ores with, 192
—, use, synthetic-rubber production, 629
Chlorine compounds, effect on pyrolysis of hydrocarbons, 224, 225
Chloroacetic acid, 674
Chloroacetic ester of ethylene glycol, 520
Chloroacetic esters, condensation with aldehydes, 534
Chloroacetones, condensation with benzene, 777
—, preparation, 373-374
Chloroacetyl chloride, 675
Chloroacetylenes, 675
Chloro-acid chlorides, production of, 570, 571
Chloroamine, use in olefin determination, 1131
2-Chloro-3-aminobutane, 578
Chloroaminophenolsulphonic acid, 767
Chloroamylene, 483, 484
Chloroanil, formation, 761
Chloroanthraquinones, oxidation catalysts, 926
Chlorobenzene, chlorination of 760
—, from benzene, 755, 758, 759, 760, 761, 763, 764, 765
—, from ethylene dichloride-ammonia reaction, 807
—, from tetrachlorocyclohexane, 749, 750
—, properties, 766
—, reaction with sodium hydrogen sulphide, 767
—, uses, 766, 1027
o-Chlorobenzoic acid, from o-chlorotoluene, 929
Chlorobenzoylbenzoic acids, 807
1-Chloro-2-bromoethane, from ethylene, 472
Chlorobromomethane, from chloriodomethane, 707
2-Chloro-1-bromopropane, from propylene dibromide, 480
4-Chloro-1,2-butadiene, from vinylacetylene, 638, 639
2-Chloro-1,3-butadiene, from vinylacetylene, 669, 670
—, properties of, 638,
—, reaction with hydrochloric acid, 648
Chlorobutanes, by chlorination, 719, 721
—, from nitrosyl chloride reactions, 1055
Chlorobutanes, pyrolysis of, 802
Chlorobutanols, 501
Chlorobutenes, 482, 484
Chlorocyclohexane, cyclohexene from, 801
—, from cyclohexane, 748, 749
—, from Galician petroleum, 728
—, properties, 748, 749
—, reaction with cyclohexane, 1058
2-Chlorocyclohexanone, 504
Chlorocyclohexyl methyl ketone, 569
2-Chlorocyclohexyl phenyl ketone, 569, 570
Chlorocyclopentane, 747
Chlorocyclopropane, 745
Chlorodecanaphthenes, 752
Chlorodecanes, 737, 738
1-Chloro-2-dichloroamino-butane, 578
Chloro derivatives of paraffins, uses of, 739-742
Chlorodimethylcyclohexanes, 751
Chloroethylbenzene production, 780
—, pyrolysis of, 147
Chloroethanes, 690, 691, 694, 695
Chloroethanesulphonic acid, 474
β-Chloroethyl ether, from ethanol, 489
β-Chloroethyl-β-hydroxy ethyl ether, 540
Chloroethylsulphuryl chloride, from ethylene dichloride, 474, 494
β-Chloroethyl vinyl ether, formation, 555
Chloroform, by chlorination of methane, 688, 689, 690, 691, 692, 694, 695, 697, 698, 699, 700, 701, 702, 703, 705
—, — methyl chloride, 688, 697, 703, 704
—, — methylene dichloride, 705
—, — of natural gas, 690, 691, 692, 694, 695, 698, 700, 703
—, effect on chlorination of toluene, 773
—, from acetone, 409
—, from carbon tetrachloride, 705, 706
—, from ethyl alcohol, 343
—, physical properties, 705
—, pyrolysis of, 692
—, use as foam-producing material, 341
—, use in dewaxing oils, 706
—, use in extraction of sludge, 911
—, uses, 705
—, uses as solvent, 493, 520, 623, 643, 644, 705, 746, 747, 920, 1035, 1036
Chloroheptane, decomposition of, 803
Chlorohexanes, by chlorination of hexanes, 734, 736
—, hydrogen chloride from, 805
—, hydrolysis of, 791, 792, 795
Chlorohexyl ketone, 832
Chlorohydrins, distillation of, 533
—, elimination of hydrogen chloride from, 504
—, esterification by acid chlorides, 497
—, esterification of rosin by, 498
—, from 2-hexene, 503
—, from olefin oxides, 540
—, from olefinic distillates, 491, 500, 502
—, from trimethylethylene, 502
—, from unsaturated hydrocarbons, 492, 493, 540, 559
—, glycols from, 487
—, olefin oxides from, 487, 533
—, purification of, 493, 494, 495
—, separating olefins from gases, 144
—, technical production, 491-494
Chlorohydrin ethers, 489
Chlorohydrin formation, effect of various factors on, 489-492
Chlorohydrocarbons, solvents from, 741
—, uses, 686
1-Chloro-2-hydroxypropane, acetone from, 500
—, ethers of, 497
—, from propylene, 499
α-Chloro-β-iodopropane, 586
Chloroisoamylene, isoprene from, 803
Chloroisobutanes, from petroleum, 720, 721
Chloroisoheptane, 728
Chloroisocotanaphthenes, 751, 752
Chloroisopentanes, 724, 725, 727
Chloroketones, production of, 568, 569, 570, 1056
Chloromethanes, by chlorination of methane, 688-703
—, by chlorination of natural gas, 712, 714

Chloromethanes, properties of, 710
—, thermal reactions with methane, 692
Chloromethylallene, 669
Chloromethylbutanes, esterification, 793
—, from isopentane, 724, 725
—, from methylethylethylene, 329
Chloromethyl β-chloroethyl ether, cyclic acetal from, 513
Chloromethylcyclohexanes, from methylcyclohexane, 750
Chloromethylcyclopentanes, 747, 748
Chloromethyl ethyl ketone, 501
Chloromethyl hexyl ketone, 504
2-Chloro-4-methylpentane, 326
Chloromethylpropanols, 502
Chloromethylpropenes, from isobutene, 482
β-Chloro-γ-methylvaleryl chloride, 570
Chloromesitylene, 779
Chloronaphthalene, as antidetonant, 983
—, condensation with olefins, 563
Chloronitroanilines, 767
Chloronitrobutane, 814
Chloronitrophenols, 767
2-Chlorooctane, 735, 737
Chloro-olefins, by chlorination of olefins, 482
—, by hydrolysis of chlorinated paraffins, 795
Chloroparaffins, alcohols from, 338
—, formation, 727, 728
—, naphthoxyparaffins from, 809
—, phenoxyparaffins from, 740
—, reaction with naphthols, 809
—, reaction with potassium hydroxide, 948
Chloroparaffin resin, as chewing-gum base, 740
Chloropentanes, amyl acetate from, 796, 797
—, esterification with potassium acetate, 793
—, from heptane, 735, 736
—, from pentanes, 721, 722, 723, 726, 730
—, hydrolysis to alcohols, 788, 789, 790, 791, 792, 793, 795
—, isomerization of, 722, 723
p-Chlorophenol, 767
4-Chloro-2-phenylanthraquinone, 807
β-Chloro-β-phenylpropionyl chloride, 570
β-Chloro-β-phenylvinylphosphinic acid, 685
Chloroplatinates of nitrogen bases, 821, 826
— thiophanes, 453
Chloroprene, polymerization of, 639, 640
—, preparation of, 638-640
Chloropropanes, formation of, 373, 716
—, uses of, 718
α-Chloropropionic acid, 496
β-Chloropropionic acid, 571
Chloropropylenes, from propylene dichloride, 480
β-Chloropropionyl chloride, 570
Chlorocosane, 740
Chlorosulphonic acid, as sulphonating agent, 1061
—, action on ethylene, 322, 324, 337, 342, 1032
—, — hydrocarbons, 1009, 1010
—, — naphthenes, 1010
—, — naphthenic acids, 1019
—, purification of hydrocarbons with, 22, 23, 33, 1146
—, reactions with olefins, 322, 324, 337, 342, 1032, 1033, 1034
—, — petroleum asphalts, 1035
—, sulphonation of waxes with, 1001
—, treatment of isopropyl alcohol with, 372
Chlorotetramethylethylene, 484
4-Chloro-1,2,5,6-tetrahydrophthalic acid, 639
o-Chlorotoluene, o-chlorobenzoic acid from, 929
Chlorotoluenes, preparation of, 770, 771, 774, 775
5-Chloro-1,2,4-trimethylbenzene, 779
Chloroundecane, 737, 738
Chloroundecanaphthenes, 752
N-Chlorourea, 502-504
Chlorous acid, oxidation of mercaptans with, 444
Chlorous anhydride, action on heptylene, 504
Chloroxylenes, 780
Cholesterol, as source of petroleum, 36
Chromates, catalysts for diphenyl production from benzene, 189
—, oxidation catalysts, 834
—, use in chlorohydrin formation, 493
Chromic acid, catalyst for hydration of acetylene, 676
Chromic acid, oxidation of alcohols with, 501, 932
—, — hydrocarbons with, 877, 928, 1026
—, — nitrogen bases with, 820
—, — phosphine with, 664
—, — propylene glycol with, 530
—, — thiophanes with, 452
—, — wax acids with, 955
—, reaction with diamylenes, 605
—, — tertiary alcohols, 393
Chromium, aromatization catalyst, 182, 185
—, catalyst, hydration of olefins, 307, 314
—, —, for methane-carbon monoxide reaction, 932
—, —, methane-steam reaction, 279, 288, 291
—, —, polymerization of olefins 610
—, —, pyrolysis of hydrocarbons, 41, 50, 127, 133, 134, 136, 150, 158, 224
—, oxidation catalyst, 833, 834, 836, 864, 870, 872, 929, 930, 1000
—, removal of gasoline gum with, 902
Chromium compounds, aromatization catalysts, 183
—, catalysts for ethylene absorption in sulphuric acid, 340
—, oxidation catalysts, 944
Chromium naphthenate, 1089, 1090, 1091
Chromium-nickel alloy, use in electrodes, 262
Chromium oxide, absorption of hydrogen sulphide by, 425
—, aromatization catalyst, 182
—, catalyst activator, 223, 280, 281, 289, 290, 345
—, catalyst, acetylene-steam reaction, 677
—, —, carbon monoxide-hydrogen reaction, 232, 989
—, —, condensation of acetone with olefins, 411, 419
—, —, hydration of olefins, 311
—, —, hydrogenation of benzene, 460
—, —, pyrolysis, 122
—, extraction of sulphur compounds with, 460
—, oxidation catalyst, 406, 834, 836, 837, 838, 840, 843, 849, 864, 891, 992
—, use in condensation of ketones with olefins, 574
Chromium phosphate, catalyst for pyrolysis, 146
Chromium resinate, catalyst for oxidation, 890
Chromium salts, effect on oxidation of lignite paraffin, 949
—, extraction of sulphur compounds with, 460
Chromium salts, of sulphonic acids, 1027
—, use in electrolytic oxidation of benzene, 927, 928
Chromium sulphate, catalyst, conversion of acetone to ketene, 414
—, oxidation catalyst, 955
Chromium sulphide, catalyst, hydrogenation of benzene, 460
Chromyl chloride, as oxidizing agent, 832, 920
—, reaction with hydrocarbons, 1055, 1056
Chrysanthemum root, extraction of, 476
Chrysene, 82, 88, 180, 227
Cineol, 650
Cinnamene, 610
Cinnamic acid, addition of sulphites, 574
—, hydroxylation of, 505
—, oxidation catalyst, 960
Citraconic acid, 838
Citraconic anhydride, reaction with diolefins, 652
Citric acid, solubility in ter.-butyl alcohol. 398
—, use as insecticide, 1027
Civetone, 83
Clay, catalyst, ammonia-hydrocarbon reaction, 296
—, —, condensation of olefins and aromatics, 564
—, —, pyrolysis, 146, 210
—, in petroleum, 11
—, oxidation catalyst, 876
Cleansing agents, by sulphonation of isopropyl alcohol, 372
—, — various compounds, 1019
—, from halogenated paraffins, 808
—, sulphonated mineral oils, 1028, 1029
—, sulphonated oxidized hydrocarbons, 1001
Coagulating agents, 1025
Coal, alcohol by distillation, 333, 355
—, analysis of gases from, 1101

Coal, aromatic acids from, 930
—, decomposition in electric arc, 262
—, hydrocarbons from, 933
—, mellitic acid from, 930
—, use in pyrolysis of hydrocarbons, 209
Coal gas, analysis of, 1092, 1116
—, aromatics from, 166
—, bromination of, 480
—, by pyrolysis, 37
—, carbon from, 208
—, carbon monoxide from, 208, 209
—, cyanides from, 297
—, decomposition of, 208, 258, 260
—, Dessau balloon gas from, 208
—, ethyl chloride from, 322
—, ethylene dichloride from, 469
—, ethylene from, 143, 333
—, formaldehyde from, 860, 864
—, hydrocarbons from, 161
—, hydrogen from, 208, 230, 874
—, methane from, 208
—, nitrogen from, 208
—, oxidation of, 834, 860, 864, 874, 875, 989
—, polymerization of, 668
Coal oils, styrene from, 146
Coal paraffins, oxidation of, 942
Coal tar, aromatic hydrocarbons from, 33, 87, 161
—, coke from, 228
—, cyclopentadiene from, 1145
—, decomposition in electric arc, 257
—, oxidation of, 839
—, use in asphalt manufacture, 841
Coal-tar distillates, resin formation with cracked distillates, 998
Coal-tar oils, use in plastic compositions, 1031
Coatings, drying oil-higher alcohol mixtures, 995
—, from divinylacetylene, 670
Cobalt, catalyst, butyraldehyde-steam reaction, 416
—, —, carbon dioxide-methane reaction, 279, 281
—, —, decomposition of carbon monoxide, 218
—, —, hydration of olefins, 307, 309, 314
—, —, methane-carbon monoxide reaction, 932
—, —, methane-steam reaction, 279, 280, 281, 287, 289, 290, 291
—, —, polymerization, 594, 668
—, —, pyrolysis, 44, 50, 106, 127, 135, 136, 163, 170, 206, 210, 218, 220, 221, 222, 223
—, dehydrogenation catalyst, 87, 182, 405
—, hydrogenation catalyst, 584, 990
—, oxidation catalyst, 833, 834, 865, 869, 870, 872, 905, 929
—, removal of gasoline gum with, 902
—, use in distillation of butadiene, 641
Cobalt acetate, action on mercaptans, 447
Cobalt acetylacetonate, oxidation catalyst, 936, 983
Cobalt borate, oxidation catalyst, 833
Cobalt carbide, by pyrolysis of methane, 39
—, catalyst in ammonia-carbon monoxide reaction, 298
Cobalt carbonate, hydrogenation catalyst, 412, 990
Cobalt chloride, catalyst for pyrolysis of alkyl chlorides, 802
—, oxidation catalyst, 938, 991
Cobalt compounds, as antidetonants, 983
—, catalysts for ethylene absorption in sulphuric acid, 340, 342
—, oxidation catalysts, 953
Cobalt naphthenate, 935, 1090, 1091
Cobalt oxalate, catalyst for hydration of ethylene, 309
Cobalt oxide, catalyst, diphenyl production from benzene, 189
—, —, hydrocarbon decomposition, 222, 223
—, —, methane-steam reaction, 276
—, extraction of sulphur compounds with, 460
—, hydrogenation catalyst, 232, 345, 460
—, oxidation catalyst, 406, 847, 848, 906, 989, 1098
Cobalt phosphate, oxidation catalyst, 833
Cobalt resinate, oxidation catalyst, 890
Cobalt salts, action with acetylene, 667
—, effect on oxidation of paraffin, 949
—, extraction of sulphur compounds with, 460
Cobalt stearate, oxidation catalyst, 881
Cobalt sulphide, catalyst for diphenyl production, 189
—, catalyst for removal of hydrogen sulphide, 423
—, catalyst for hydrogenation of benzene, 460
Cobalt sulphonates of petroleum oils, uses, 1027, 1030
Cobaltites, catalysts, methane-carbon monoxide reaction, 932
Coconut oil acids, esterification, 528
Coconut oil soap, detergent from, 1024
Coke, analyses of, 227
—, by cracking of gas oil, 132, 133
—, by pyrolysis of aromatics, 164
—, catalyst for chlorination, 469, 690, 697
—, formation during cracking, 101, 103, 104, 105, 107, 108, 110
—, oxidation catalyst, 839, 840
—, oxidation catalyst support, 988
—, petroleum, production and properties, 225-229, 234, 904
—, —, uses, 227, 228
—, production of cyanides from, 293
—, use in hydrocarbon decomposition, 208, 209, 210, 212, 213, 214, 215, 217
Coke-oven gas, cyanides and ammonia from, 295
—, decomposition in electric arc, 258
—, ethylene from, 322, 332, 338, 354, 478
—, hydrocarbons from, 161, 166
—, hydrogen from, 219, 230
—, oxidation of, 872, 989
—, purification of, 342
Coking, prevention of, 206
Coking stills, 225
Collodion, use of isopropyl alcohol in, 365, 366
Colophony mixture with paraffin oxidized, 997
Color tests of oils, 1148
Colorado oil shale, 462, 463
Colorimetric determination of acetone, 369
Columbium, catalyst for chlorination of benzene, 759
Columbium chloride, catalyst for chlorination of benzene, 759
Combustion, analysis by, 1095-1098, 1103
—, heats of, of carbon blacks, 249
—, —, of graphite, 250
—, increase of pressure during, 971
—, mechanism of, 977
Concentration of acid, effect on ethylene absorption, 335, 336, 341, 342, 343, 347, 349
Condensation, analysis by, 1098-1104
Condensation, anthracene, by aluminum chloride, 202
—, aromatic hydrocarbons, 97, 202
—, conjugated diolefins, 650
—, lower olefins to higher olefins, 159
—, naphthalene, by aluminum chloride, 202
—, nuclear, effect of aluminum chloride on, 200
—, olefins, with aromatic hydrocarbons, 559-565
—, — bases, 571-573
—, — diolefins, 624-625
—, — middle-oil hydrocarbons, 201
—, — organic chlorides, 568-670
—, — phenols, 565-568
Conradson carbon values, 904
Constant-boiling mixtures, isopropyl alcohol-isopropyl acetate, 373
—, isopropyl alcohol-water, 349, 359, 362
—, sec.-butyl acetate-water, 395
—, sec.-butyl alcohol-water, 394, 395
—, ter.-butyl alcohol-water, 397
—, water-amyl chlorides-amyl alcohols, 791
Contact, effect on ethylene absorption in sulphuric acid, 343, 344
Contact time, effect on hydrocarbon oxidation, 838, 877, 878, 879
—, — pyrolysis of Mid-Continent gas oil, 132
—, relation to yield in pyrolysis of Pennsylvania straight-run gasoline, 131
Copals, from montan wax, 740
—, solubility in various solvents, 366, 373, 500
Cosmetics, isopropyl alcohol in, 362, 363, 364, 365, 368
Copper, adsorption of mercaptans by, 446
—, aromatization catalyst, 186, 187

Copper, attack by acetylene, 665
—, attack by naphthenic acids, 1082
—, catalyst, ammonia-carbon monoxide reaction, 298
—, —, carbon dioxide-methane reaction, 281
—, — chlorobenzene-ammonia reaction, 767
—, —, dehydration of alcohols, 396, 531
—, —, ethylene dichloride-ammonia reaction, 807
—, —, ethylene dichloride-sulphite reaction, 474
—, —, for bromination, 706
—, —, for chlorination, 698, 766
—, —, for pyrolysis, 39, 46, 47, 50, 53, 57, 58, 65, 121, 122, 128, 129, 134, 135, 136, 220, 221, 222, 223, 224
—, —, hydration of olefins, 307, 314
—, —, hydrocarbon-steam reaction, 285
—, —, hydrolysis of chlorobenzene, 767
—, —, hydrolysis of ethylene dichloride, 506
—, —, methane-carbon monoxide reaction, 932
—, —, polymerization of acetylene, 82, 668, 669, 671
—, —, polymerization of butadiene, 629
—, —, preparation of ketene, 414
—, —, production of acetone from acetic acid, 407
—, —, production of butadiene, 635
—, —, production of p-chloro phenol, 767
—, dehydrogenation catalyst, 83, 87, 181, 349, 404, 405, 415
—, effect of, in cracking, 106
—, effect on ignition temperatures, 967
—, extraction of sulphur compounds with, 427, 462
—, hydrogenation catalyst, 412, 413, 584
—, molten bath of, use in pyrolysis, 220
—, oxidation catalyst, 405, 406, 833, 834, 836, 838, 847, 856, 860, 862, 863, 864, 865, 867, 868, 869, 870, 872, 873, 875, 876, 890, 891, 905, 908, 909, 930, 933, 934, 942, 987, 988, 989, 990
—, oxidation test of turbine oil, 912
—, reaction with vinyl compounds, 680
—, removal of gum with, 902
—, stabilizer in production of sulphones, 656
—, use in desulphurization of gases, 460
—, — distillation of butadiene, 641
—, — hydrocarbon-sulphur reaction, 429
—, — oxidation of mercaptans, 432, 449
—, — production of acetylene, 663
—, — production of cyanides, 294
—, — removing oxygen from gases, 289
Copper acetylide, 663, 665
Copper alloys, catalysts, methane-steam reaction, 291
—, oxidation catalysts, 397, 405, 406
Copper-bismuth, oxidation catalyst, 869, 870
Copper borates, aromatization catalysts, 183
Copper bromide, catalyst for methane bromination, 706
Copper bronze, formation of cuprene, 672
—, test for sulphur, 1149
Copper chromate, hydrogenation catalyst, 990
Copper chromite, hydrogenation catalyst, 412
Copper compounds, catalysts for ethylene absorption, 340, 341, 342, 355
Copper cyanamide, oxidation catalyst, 833
Copper-dish method for determination of gum content, 894
Copper-dish test for sulphur compounds, 1150
Copper electrodes, use of, 262, 263
Copper-gold, oxidation catalyst, 869-870
Copper halide, catalyst for polymerization of olefins, 594
Copper mercaptides, properties, 445
—, use, in sweetening, 444, 445
Copper naphthalenedisulphonate, 314
Copper naphthenates, 935, 1083, 1089, 1091
Copper-nickel, oxidation catalyst, 869, 870
Copper nitrate, catalyst for chlorination, 691
Copper oxide, absorption of hydrogen sulphide by, 425
—, action on mercaptans, 447
—, catalyst, ammonia-dichloroethane reaction, 818
—, —, carbon monoxide-hydrogen reaction, 232
—, —, ethyl alcohol to higher alcohols, 345
Copper oxide, catalyst, hydration of olefins, 307, 314
—, —, polymerization of acetylene, 671
—, —, pyrolysis, 123, 221, 222, 223
—, combustion of gas mixtures by, 1098
—, dehydration of ethyl alcohol with, 303
—, oxidation catalyst, 840, 842, 843, 848, 863, 864, 869, 905, 918, 919, 922, 925, 926, 931, 937, 951, 989, 992, 998
—, reagent in determination of hydrogen, 1095
—, removal of hydrogen by, 186
—, treatment of petroleums with, 459, 460
Copper oxychloride, removal of gum with, 903
—, use for treatment of ethylene, 492
—, use in preparation of hypochlorous acid, 488
Copper-palladium, oxidation catalyst, 869, 870
Copper phosphate, aromatization catalyst, 183
—, catalyst, formation of olefin oxides, 536
—, —, hydration of olefins, 307, 309, 314, 316
—, —, isomerization of olefin oxides, 547
—, —, production of trichloroethylene, 674
Copper phosphide, 664
Copper-platinum, oxidation catalyst, 869, 870
Copper-platinum-pumice, catalyst, for pyrolysis, 128
Copper resinate, effect on oxidation, 890
—, use as insecticide, 1027
Copper salts, absorption of carbon monoxide by, 231
—, aromatization catalysts, 182, 183
—, catalysts, esterification of amyl chlorides, 795
—, —, for bromination, 706
—, —, for chlorination, 698, 775
—, —, for pyrolysis of hydrocarbons, 135
—, effect on chlorohydrin formation, 489
—, extraction of sulphur compounds with, 460
—, of sulphonic acids, 1027
—, oxidation catalysts, 905, 949
—, separation of diolefins with, 641
—, stabilizers in production of sulphones, 656
Copper silicates, aromatization catalysts, 183
Copper-silver oxidation catalyst, 869, 870
Copper soap, anticatalyst in oxidation, 909
Copper sulphate, catalyst, ethylene dichloride-sulphite reaction, 474
—, —, hydration of propylene, 314
—, —, isomerization of olefin oxides, 419, 547
—, oxidation catalyst, 919
—, polymerization of ethylene with, 1032
—, use in dehydration of alcohols, 303, 357
Copper sulphides, catalysts for diphenyl production, 189
—, removal of mercaptans with, 440
Copper toluene-p-sulphonate, 314
Copper-zinc, oxidation catalyst, 397, 869, 870
Cork substitute, cuprene as, 672
Corona discharge, in cracking, 271, 272
—, effect on hydrocarbon oxidation, 843
Corrosion by sulphur compounds, 421, 422
Corrosive sulphur compounds, tests for, 1150
Cotton, reaction with ethylene oxide, 549
—, spontaneous ignition of, 890
Cotton fabrics, treatment with dichlorodiethyl ether, 498
Cottrell separator, for tar fog, 170
Coumarone, polymerization of, 598
Cracked distillates, action of sulphuric acid on, 352, 458, 607
—, addition of hydrogen chloride, 330
—, aromatics in, 352
—, nitrogen bases as stabilizers for, 829
—, olefins in, 352
—, oxidation of, 837
—, resins from, 998
—, sulphonation of, 1017
—, sulphur compounds in, 454-455
—, — mercuric chloride, 454
—, treatment with aluminum chloride, 201
—, velocity of thermal decomposition of, 99, 101
Cracked gasoline, alcohols from olefins in, 352, 401, 403
—, analysis of, 117, 119
—, antiknock value of, 92
—, composition of, 116-119
—, iodine values of, 145

Cracked gasoline, olefins from, 145
—, polymerization of, 78
—, production figures, 91, 92
—, pyrolysis of, 78
—, tertiary alcohols from, 352, 403
Cracked kerosene, oxidation of, 837, 838
Cracked oil gas, naphtha from, 142
Crackene, 227
Cracking, butylenes from, 631
—, by submerged combustion, 843, 1000
—, commercial processes, 108-113
—, corona discharge in, 271, 272
—, development of, 10, 91, 92
—, duration of, effect on gasoline, 116
—, effect of mercuric chloride on catalysts in, 202
—, — uranyl chloride, on catalysts in, 202
—, factors influencing, 100-105, 116, 117
—, formation of aromatics during, 162
—, growth of industry, 92
—, heat effect of, 98
—, in electric arc, 255
—, influence of temperature, 100, 101
—, initial temperature of, 96, 100
—, mechanism of, 93, 95, 96, 97
—, of aromatic hydrocarbons, 96
—, of brown-coal tar oils, 201
—, of Esthonian shale oil distillates, 164
—, of gas oils, 98, 100, 101, 457
—, of gasoline, 96, 98
—, of naphthene hydrocarbons, 97
—, of naphthenic acids, 1085
—, of olefins, 96, 202
—, of paraffin hydrocarbons, 96, 175, 194, 197, 202, 208, 212-216
—, of petrolatum, 100
—, of polymerized hydrocarbons, 97
—, of solar oil, 193
—, of spray oil, 163
—, of tars, 201
—, of various crude oils, 92, 101, 164, 190, 201, 457
—, of wax, 104, 191, 203
—, physical chemistry of, 98, 99, 100
—, pressures of, 92
—, primary reactions of, 93, 96, 106
—, reactions during, 65, 92, 93, 98
—, secondary reactions of, 96, 101
—, temperatures of, 92, 93, 95, 96, 192
—, theory of, 93
—, thermodynamic considerations of, 93-95
—, time-temperature index of, 102, 103
—, tube and tank process, 109
—, vapor-phase, 110, 111, 112, 113, 132
—, velocity of, 96, 98, 100, 101
—, with acetylacetonate catalysts, 107
—, with aluminum catalyst, 113, 193
—, with aluminum bromide catalyst, 190
—, with aluminum chloride catalyst, 106, 107, 164, 190, 191, 192, 193, 194, 201
—, with aluminum oxide catalyst, 202
—, with antimony chloride catalyst, 193
—, with boron fluoride catalyst, 201
—, with copper catalyst, 106
—, with ferric chloride catalyst, 193, 197, 202
—, with ferrous chloride as catalyst, 197
—, with iron catalyst, 113, 201
—, with mercury catalyst, 107
—, with metallic catalysts, 201
—, with molybdenum catalyst, 113
—, with nickel catalyst, 201
—, with nitrate catalysts, 107
—, with phosphate catalysts, 107
—, with porcelain catalyst, 106
—, with silica catalyst, 106
—, with silicate catalysts, 113
—, with silicon catalyst, 113
—, with silicon carbide catalyst, 107
—, with stannic chloride catalyst, 193
—, with steam, 107, 110, 112
—, with tantalum catalyst, 107
—, with tin catalyst, 107
—, with titanium catalyst, 107, 113
—, with titanium chloride catalyst, 193
—, with tungsten catalyst, 106
Cracking, with zinc catalyst, 113
—, with zinc chloride catalysts, 193, 202
Cracking gas, action of ultraviolet light on, 188
—, alcohols from olefins in, 349, 388, 401, 403
—, sec.-butyl alcohol from, 394
—, ter.-butyl alcohol from, 398
—, by pyrolysis, 37
—, chlorination of, 469, 485
—, chlorohydrins from, 491, 500
—, composition of, 113, 114, 115, 116, 1092
—, esterification with hydrogen chloride, 144
—, formaldehyde from, 860
—, fractional-distillation curve of, 1110
—, hydrocarbons from, 156, 349, 354, 355, 394, 491
—, isopropyl alcohol from, 359
—, ketones from, 416
—, oxidation to carbon monoxide and hydrogen, 989
—, purification of, 140
—, tertiary alcohols from, 403
—, utilization of, 37, 114
—, yields from various processes, 113
Cracking stills, 225
Cracking tar, source of aromatic hydrocarbons, 88
Cracking tendencies, of hydrocarbons, 95
Cracking tubes, alloys for, 175
Crankcase ventilation, avoidance of corrosion, 422
Creosote, decomposition of, 219
Creosote oil, by pyrolysis of petroleum, 165
Cresol, as antidetonant, 983
—, condensation with amylene, 566
—, from toluene, 928
—, production of cyclic ketones from, 419
—, salicylaldehyde from, 915
—, sulphonation of, 375
Cresol diisobutyl ether, 566
Cresol sulphonic acids, 375
Cresol-sulphur chloride resins, 452
Cresylic acid, selective solvent, 35
Critical inflexion temperature, 966
Critical pressure of olefins, 137, 138
Critical solution temperatures of hydrocarbons, 1135, 1136, 1137, 1140
Critical temperature of olefins, 137, 138
Crotonaldehyde, condensation with olefins, 568
—, from acetaldehyde, 637, 676
—, from ethyl alcohol-hydrogen, 345
—, from propylene oxide, 547
—, methylallene from, 632
—, methylation of, 637
Crotonic acid, addition of sulphites, 574
—, condensation with olefins, 568
—, hydroxylation of, 505
—, reaction with iodine monochloride, 586
Crotononitrile, condensation with cyclopentadiene, 658
Crotonylene, from 2-bromo-2-butene, 482
—, reaction with benzene, 1128
Crotyl bromide, butadiene from, 634
—, from butadiene, 645
Crucible method, for determination of ignition temperatures, 967
Crucibles made from petroleum coke, 223
Crystalline structure of carbon black and graphite, 247, 248
Cumarone resin, solubility in various materials, 373, 402, 525
Cumene, oxidation of, 856
—, pyrolysis of, 88
Cuminol, diisopropylbenzaldehyde from, 930
Cumulative extraction, 825, 826
Cuprene, from acetylene, 668, 671, 672
—, properties and reactions of, 671, 672
—, uses of, 671, 672
Cupric acetate, action on mercaptans, 446, 447
—, catalyst, esterification of amyl chlorides, 795
—, in sweetening, 445
Cupric carbonate, adsorption of mercaptans by, 445, 446
—, hydrogenation catalyst, 412, 990
Cupric chloride, action on ethyl alcohol, 343
—, catalyst, condensation of olefins with acid chlorides, 569

Cupric chloride, catalyst, production of ethylene chlorohydrin, 491, 492
—, —, production of trichloroethylene, 673
—, chlorination catalyst, 675, 690, 691, 693, 698, 699, 701, 702, 713, 766
—, extraction of mercaptans with, 436
—, formation of complexes with oils, 192
—, from cuprous chloride, 701
—, use in production of hypochlorous acid, 488
Cupric oxide, catalyst for production of dioxan, 555
—, oxidation catalyst, 893, 906, 946
Cupric sulphate, action on mercaptans, 446, 447
Cupric sulphide, adsorption of mercaptans by, 445, 446
—, extraction of sulphur compounds with, 459
Cuprous acetylide, addition to acetylene, 666
Cuprous chloride, action on monovinylacetylene, 669
—, catalyst, addition of hydrogen chloride, 638, 639, 648, 680
—, —, hydration of olefins, 307, 314, 316
—, —, hydrolysis of chlorobenzene, 767
—, oxidation catalyst, 848, 930
—, polymerization catalyst, 600, 669, 670
—, reaction with butadiene, 641
—, separation of diolefins with, 160
Cuprous mercaptides, 445
Cuprous oxide, catalyst for olefin absorption, 336, 337, 341, 358
Cuprous salts, absorption of ethylene by, 582
—, addition to acetylene, 666
—, catalyst for ethylene absorption, 335
—, catalyst for ethylene polymerization, 336, 594
—, double compounds of olefins with, 582
—, purification of acetylene, 664
—, use in absorption of olefins, 142, 160
Cuprous sulphate, catalyst for ethylene absorption, 339, 341
Cyanamides, alkaline-earth, production of, 571
—, catalysts, carbon monoxide-ammonia reaction, 298
—, use in production of ammonia and hydrogen cyanide, 295
Cyanates, use in ammonia-carbon monoxide reaction, 298
Cyanides, production of, 292-299
—, reaction with olefin oxides, 545
Cyanogen, combination with olefins, 585-586
Cyanogen bromide, reaction with olefins, 586
Cyanogen chloride, reaction with olefins, 586
Cyanogen compounds, catalysts for ethylene absorption, 342
—, removal from acetylene, 664
Cyanogen iodide, reaction with ethylene, 479, 586
Cyanohydrins, 501, 545, 558
Cyano hydrocarbons, selective solvents, 34
Cyclic acetals, preparation, 513, 530, 556
Cyclic bases, production, 571
Cyclic diethers, of ethylene glycol, 512
Cyclic ethers, from isoprene, 650
Cyclic hydrocarbons, by pyrolysis of octenes, 76
—, condensation with acetyl chloride, 568, 569
—, condensation with olefins, 564, 565
—, production of, 243
Cyclic ketones, acetylene solvent, 262
Cyclic nitrogen compounds, preparation, 652
Cyclic olefins, from chlorinated cycloparaffins, 805
—, from cracked gasoline, 145
—, resins from, 204
Cyclic sulphonic acids, 1007
Cyclicization, of olefins, 78, 97, 176, 188
—, of saturated hydrocarbons, 162, 854
Cycloalkyl ketone from cyclohexane, 1057
Cyclobutane, halogenation of, 744, 745, 746, 747
—, pyrolysis of, 84
—, reaction with bromine, 1131
—, reactivity of, 1039
Cyclogeraniol, 650
Cycloheptane, in straight-run gasoline, 23
—, isomerization of, 86, 87
—, pyrolysis of, 86
Cyclohexadiene, dimer of, 623, 624
—, effect of sulphuric acid on, 642
—, from butenes, 179
Cyclohexadiene, from cyclohexane and sulphur, 430
—, from dichlorocyclohexane, 749
—, polymerization of, 623, 624
—, preparation of, 638
—, reaction with hydrogen halides, 648
—, — maleic acid, 659, 660
—, — sulphur dioxide, 575
Cyclohexane, absorption of oxygen, 754
—, acetaldehyde from, 197
—, action of sulphuric acid on, 1008, 1009, 1010
—, benzene from, 33, 198
—, bromination of, 749, 753, 754, 1131
—, butadiene from, 156, 157, 158, 633
—, by pyrolysis of allylcyclohexane, 86
—, by pyrolysis of amylene, 78
—, — cyclohexene, 85
—, — olefins, 176
—, — paraffins, 176
—, by reduction of benzene, 182
—, chlorination of, 748, 749
—, condensation to higher hydrocarbons, 1057
—, condensation with acetyl chloride, 417
—, — alkylene oxides, 1059
—, — carbon monoxide, 417
—, dehydrogenation of, 85, 87, 93, 95, 181, 198, 199, 1144
—, dimethylcyclobutane from, 198
—, effect of aluminum chloride on, 199
—, effect on oxidation of benzaldehyde, 980
—, estimation of, 1144
—, from diolefins, 614
—, from hexane, 197
—, from petroleum, 33, 629, 1147
—, halogenation of, 744, 745, 748, 749
—, hydrocarbons from, 197
—, in lubricating oil, 30
—, in natural-gas gasoline, 18
—, in straight-run gasoline, 23, 27
—, isomerization of, 87, 198
—, methylcyclopentane from, 197, 198
—, molecular rearrangement, 198, 199
—, nitration of, 1040, 1046, 1048-1050
—, oxidation of, 25, 836, 880, 916
—, polymers of, 1058
—, propylene from, 158
—, pyrolysis of, 84-86, 87, 134, 158, 181, 182
—, reaction with acetyl chloride, 197, 1057
—, — aluminum chloride, 197, 1056, 1057, 1058
—, — ethylene oxide, 545, 1059
—, — phosphorus, 875
—, — sulphur, 430, 1061
—, reactivity of, 1039
—, solubility of hydrogen sulphide in, 423
—, stability to aluminum chloride, 199
—, thermal stability of, 90
—, treatment with aluminum bromide, 198
—, — carbon monoxide, 198
—, unsaturated ketones from, 198
Cyclohexane-air, ignition temperatures, 978
Cyclohexane derivatives, by pyrolysis of hydrocarbons, 176
—, decomposition by aluminum chloride, 197
—, dehydrogenation of, 33, 83, 163
—, in petroleum distillates, conversation to aromatics, 164
—, isomerization of, 199
—, nitration of, 1040, 1046, 1048-1050
—, pyrolysis of, 87
trans-1,2-Cyclohexanediol, from cyclohexene, 506
Cyclohexanol, adipic acid from, 929
—, butadiene from, 157
—, condensation with benzene, 564
—, cyclohexene from, 159
—, dehydrogenation of, 419
—, effect in transformer oils, 910
—, from cyclohexene, 389
—, from phenol, 419
—, glutaric acid from, 929
—, oxidation of, 420
—, production of, 408
—, succinic acid from, 929
Cyclohexanone, as antiknock, 980
—, as solvent, 262, 420
—, from cyclohexene oxide, 547

Cyclohexanone, from nitrocyclohexane, 1052
—, production of, 408, 415, 419, 420, 1048
—, properties, 420
—, reaction with diolefins, 652
Cyclohexene, absorption of oxygen, 854
—, aromatics from, 155
—, by condensation of ethylene and butadiene, 67
—, by pyrolysis of allylcyclohexane, 86
—, — butenes, 179
—, — cyclohexane, 85
—, — olefins, 176, 179
—, — propylene, 179
—, chlorination of, 748-749
—, condensation with acetyl chloride, 568, 569
—, — aniline hydrochloride, 572
—, — benzoyl chloride, 569, 570
—, — carbazole, 573
—, — hydrogen cyanide, 585
—, — iodine cyanate, 585
—, — phenols, 566, 567
—, — p-toluidine, 572
—, trans-1,2-cyclohexanediol from, 506
—, cyclohexene chlorohydrin from, 504
—, cyclohexene peroxide from, 982
—, cyclohexylbenzene from, 561
—, cymene derivatives of, 561
—, decomposition of, 67
—, dibenzyl derivative of, 561
—, diphenyl derivatives of, 561
—, diphenylmethane derivatives of, 561
—, double compound with mercuric acetate, 582
—, from butadiene, 155, 156
—, from chlorocyclohexane, 801
—, from cyclohexane and sulphur, 430
—, from cyclohexanol, 159
—, hydration of, 389
—, naphthalene derivative of, 561
—, oxidation of, 892, 893
—, polymerization of, 597
—, pyrolysis of, 85
—, reaction with ammonium bisulphite, 575
—, — benzene, 561
—, — lead tetra-acetate, 587
—, — nitrogen pentoxide, 581
—, — nitrogen trichloride, 578
—, — nitrosyl chloride, 579
—, — sulphur dioxide, 575
—, — sulphuric acid, 624
Cyclohexene chlorohydrin, 504
Cyclohexene dihalides, 1,3-cyclohexadiene from, 638
3-Cyclohexene-1,2-diol acetate, from oxidation of cyclopentadiene, 893
2-Cyclohexene-1-ol, 892, 893
2-Cyclohexene-1-ol acetate, 893
Cyclohexene-2-ol, 587
Cyclohexene oxide, isomerization of, 547
—, reaction with ammonia, 543
Cyclohexene peroxide, from cyclohexene, 892
—, reaction with stannous chloride, 899
Cyclohexene phosphorite, 875
Cyclohexenesulphonic acid, 575
Cyclohexenyl methyl ketone, 569
Cyclohexylamine, precipitation of sulphonic acids, 1018
—, reaction with ethylene oxide, 551
Cyclohexylaniline, 572
Cyclohexylbenzene, production of, 561, 564
—, properties, 651
Cyclohexylcyclopentane, pyrolysis of, 84
Cyclohexyl chloride, production, 566
β-Cyclohexylethanol, 545
Cyclohexylethanolamine, 543, 551
Cyclohexylphenol, 566, 567
Cyclohexyl-p-toluidine, 572
1,5-Cyclooctadiene, 616
Cyclooctane, pyrolysis of, 86
Cycloparaffin ring, in naphthenic acids, 1072
Cycloparaffins, action of aluminum chloride on, 197-199
—, by polymerization of olefins, 80, 593, 595, 602, 603
—, by pyrolysis of olefins, 67, 77, 78, 178, 180, 195, 196, 595
Cycloparaffins, chlorinated, cyclic olefins from, 805
—, condensation with alkylene oxides, 1059
—, dehydrogenation of, 181, 182
—, Friedel-Crafts reactions, 1056-1059
—, from kerosene, 28
—, halogenation of, 686, 744-753
—, in petroleum, 11
—, nitration of, 1046-1050
—, production in silent electric discharge, 595
—, pyrolysis of, 48, 83-87, 181, 182
—, reaction with sulphur, 429
—, — sulphur chloride, 1060
—, reactivity of, 1039
—, sulphonation of, 1006, 1007, 1009, 1010, 1012
—, thermal stability of, 87
—, *see also* Naphthenes
Cyclopentadiene, by carbonization of coal, 153
—, by pyrolysis of hydrocarbons, 57 69, 174, 177, 638
—, chlorination of, 747
—, condensation of, 657, 658
—, condensation with crotononitrile, 658
—, — ketones, 891
—, — quinone, 650
—, fulvenes from, 891
—, identification of, 660
—, in cracked gasoline, 119
—, isolation of, 1145
—, oxidation of, 893
—, polymerization of, 598, 619-623, 891
—, reactions of, 648, 652, 658-660
—, reaction with hydrogen chloride, 648
—, tetrabromide from, 1145
Cyclopentadiene chloranil quinone, 650
Cyclopentadiene isomers, 643
Cyclopentadiene naphthoquinone, 650
Cyclopentadiene quinone, 650
Cyclopentadiene rubber, 623
Cyclopentadiene tetrabromide, 659
Cyclopentane, action of aluminum chloride on, 194
—, butadiene from, 157
—, chlorination of, 747
—, cyclopentanone from, 420, 892
—, from crude petroleum, 33
—, from pentene, 194
—, halogenation of, 744, 745, 753
—, in natural-gas gasoline, 18
—, in straight-run gasoline, 22, 23, 27
—, nitration of, 1040, 1046, 1047
—, pyrolysis of, 84
—, reaction with bromine, 1131
—, — aluminum chloride, 197, 199, 1056, 1057
—, — antimony chloride, 1061
—, — benzoyl chloride, 179
Cyclopentane derivatives, decomposition by aluminum chloride, 197
Cyclopentane-1,3-dicarboxylic acid, 622
Cyclopentane ring, basis of naphthenic acid molecule, 1071, 1072
Cyclopentanes, dehydrogenation of, 87, 197
—, nitration of, 1040, 1046, 1047
—, reactivity of, 1039
Cyclopentanol, chlorination of, 747
Cyclopentanone, 420, 892
1-Cyclopentene-1-aldehyde, from cyclohexene, 892
Cyclopentene oxide, reaction with ammonia, 543
Cyclopentyl rings, antiseptic properties, 1082
Cyclopropane, action of sulphuric acid on, 1009
—, bromination of, 746
—, chlorination of, 745
—, determination of, 1122
—, halogenation of, 744, 745
—, polymerization of, 273, 599
—, pyrolysis of, 83
—, reaction with bromine, 1131
Cyclopropane homologues, chlorination of, 745, 747
Cyclopropanes, reactivity of, 1039
—, substituted, reaction with bromine, 1131
Cycloran, use as detergent, 1022
p-Cymene, acetic acid from, 926
—, benzene from, 200
—, by dehydrogenation of menthane, 181
—, by pyrolysis of hexahydrocymene, 85

p-Cymene, by pyrolysis of methylenecyclobutane, 84
—, cyclohexane derivative of, 561
—, effect of aluminum chloride on, 200
—, formaldehyde from, 926
—, from kerosene, 28
—, from toluene and propylene, 561
—, from turpentine, 891
—, reaction with butyl alcohol, 563
—, — chromyl chloride, 1056
—, terephthalic acid, from, 926
—, toluene from, 200
—, p-toluic acid from, 926
—, xylene from, 200
Cystamin, 860

D

Dammar, solvents for, 366, 395, 402, 798
Decahydro-3,8-dimethyl-5,7-methano-4,8-ethanopyrindacine, from petroleum, 823, 824
Decahydronaphthalene, condensation with olefins, 563, 564
—, decomposition of, silent discharge, 270
—, in straight-run gasoline, 25
—, phthalic and maleic acids from, 922, 923
Decahydronaphthol, 929, 930
Decalin, solvent, 598
β-Decanaphthene, 754
Decanaphthenes, by pyrolysis of amylene, 78
—, chlorinated, properties, 752, 753
—, in straight-run gasoline, 25
—, nitration of, 1050
—, unsaturated hydrocarbons from, 752
Decanaphthenic acid, 1071
Decanaphthylene from monochloro derivatives, 752
Decane, action of aluminum chloride on, 194
—, chlorination of, 737, 738
—, nitration of, 1045
—, oxidation of, 855, 856
—, pyrolysis of, 60
n-Decane, in straight-run gasoline, 22, 27
Decanoic acid, from paraffin wax, 944
Dechlorinated oil products, uses of, 804
Dechclorination, olefins by, 801
—, of polychlorinated paraffin hydrocarbons, 804-805
Decolorization, naphthenic acids, 1069
—, of distillates, by oxidation, 987
Decomposition, alkyl halides to olefins, 801-805
—, coal gas, 208, 209
—, asym.-dichloroethylene, 815
—, dihalogen derivatives, 815, 816
—, diisopropyl sulphate, 348
—, ethane, 235
—, ethylene, 235
—, ethylene glycol, 513
—, ethylsulphuric acid, 333
—, hydrocarbons, 208-210
—, —, by catalysts, 222
—, —, during cracking, 93
—, —, effect of chlorine, 224
—, —, in electric arc, 218
—, —, with molten metal baths, 220
—, natural gas, 221, 213, 214, 215
—, oils, 208, 209
—, olefins, 135
—, organic materials, 235
—, propylene, 348
—, tars, 208, 209
Decomposition rate, cracking by aluminum chloride, 191
—, methane, 205
Decylbenzene, production, 562
Decyl chlorides, from petroleum, 738
Decylene, from ethylene, 594
—, sulphonation of, 1033
Decylene oxide, preparation, 534
Decylsulphonic acid, properties, 1011
De-ethylenation, of n-hexane, 60
—, of n-pentane, 58
Degradation method, naphthenic acids, 1078
Degumming silk, 1028, 1029
Dehydration, alcohols, 159, 303, 304, 337, 359, 360, 370, 379, 391, 481
—, aliphatic acids, 480
Dehydration, n-butanol, 379, 481
—, ter.-butyl alcohol, 397
—, ethyl alcohol, 159, 303, 304, 337
—, ethylene glycol, 512, 527
—, gases, 355
—, ter.-hexyl alcohol, 392
—, isobutyl alcohol, 378
—, isopropyl alcohol, 359, 360, 370
—, isopropyl ether, 370
—, ketones from glycols, 531
—, methyl alcohol, 159
—, olefins, effect of metallic salts on, 304
—, primary alcohols, 391
—, propyl alcohol, 159
Dehydrogenating agent, aluminum chloride as, 200
Dehydrogenation of alcohols, catalysts for, 405
— n-butane, 53, 129
—, butylene, 74
—, cyclohexanes, 33, 85, 87, 93, 95, 163, 181
—, —, initial temperature of, 83
—, cycloparaffins, 181, 182
—, cyclopentanes, 87, 197
—, diolefins, 223
—, ethane, 342
—, gasoline, 836
—, hexahydrocymene, 85
—, hexahydroxylene, 85
—, n-hexane, 60
—, hydroaromatic compounds, 164
—, hydrocarbons, 839, 842
—, in cracking, 96, 97
—, isopropyl alcohol, 349, 374
—, liquid hydrocarbons, 186
—, methylcyclohexane, 85
—, naphthenes, 87, 97, 187, 430
—, —, by sulphuric acid, 1010
—, olefins, 223, 584
—, paraffin hydrocarbons, 45, 93, 96, 871
—, n-pentane, 58
—, 2-pentene, 74
—, petroleum distillates, 1017
—, petroleum fractions, 993
—, propane, 49, 50, 52, 53, 127
—, pyrolysis of propane, 127
—, pyrolytic formation of aromatics, 162
—, silent discharge, 255, 264, 268, 269
—, use of metals, 349
Dehydrogenation catalysis, theory of, 87
Dehydrogenation catalysts, pyrolysis of ethane, 122
Demethanation, n-butane, 53
—, n-hexane, 60
—, paraffin hydrocarbons, 45
—, n-pentane, 58
—, 2-pentene, 74
—, propane, 49, 50, 52, 127, 128
—, trimethylethylene, 75
Denaturants for alcohol, 367
Density, of carbon blacks, 254
— gas, effect on thermal conductivity, 977
— gasoline fractions, 985
Dentifrices, use of thymol in, 375
Deodorants, use of isopropyl alcohol in, 366
Deodorization, isopropyl alcohol, 359
—, naphthenic acids, 1069
—, oxidation of distillates, 987, 988
—, petroleum oils by sulphonation, 1018
Depolymerization, hydrocarbons, during cracking, 93
—, olefins, 93, 95, 97
Deposition of carbon from hydrocarbon flames, 236, 239, 242
Desichthyol, 1036
Dessau balloon gas, 208
Destructive distillation, as mechanism of petroleum formation, 36
—, production of charcoal, 234
—, production of petroleum coke, 234
Desulphurization of oils, with ozone, 988
Desulphydration of mercaptans, 437
Detection of isopropyl alcohol, 367, 368
Detergency, effect of molecular weight on, 1023
—, of carboxylic acids, 935
—, of hydroxy acids, 935
Detergent compositions, 1022, 1023, 1024

Detergents, alkylnaphthalene sulphonic acids, 1022, 1023
—, alkylnaphthene-sulphonic acids, 1023, 1024
—, chlorinated hydrocarbons, 1022, 1024
—, ethionic acids, 1022
—, from acid sludge, 1023, 1024
—, — butyl alcohol, naphtha, sulphonated fatty acids, 1024
—, — butylene, 1024
—, — drying oils, 1023
—, — mineral oils, 1022, 1023, 1024
—, — naphthenic acids, 1068, 1069, 1085
—, — oil-soluble, water-soluble amines, 1023, 1024
—, — sulphonated petroleum, 1023, 1024
—, methods for comparison, 1023
—, mineral-oil sulphonates, 1020, 1022-1024
—, naphthasulphonic acids, 1023, 1024
—, paraffin wax oxidation products, 1024
—, pyridine compounds, 1022
—, sodium salts of sulphated alcohols, 1022
—, standardization, 1023
Determination, ethylene oxide, 551
—, olefins, 1129-1131
Detonation of motor fuels, nuclear theory, 977
Dewaxing of lubricating oils, 705, 706
—, with acetone, 411
—, with ethylene oxide, 550
—, with methylene dichloride, 705
Diacetates, by esterification of chlorinated paraffins, 795
Diacetone, acetylene solvent, 262
Diacetone alcohol, production, 409, 410
ββ' Diacetoxydiethyl ether, 556
Diacetylene, butadiene from, 159
—, by electropyrolysis of alcohol, 256
—, carbon black by partial combustion of, 242
—, decomposition, 223
—, explosibility of, 665
—, from acetylene, 265
—, — amylene and hydrogen, 266
—, — benzene, 259
—, — butadiene tetrabromide, 644
—, — hydrocarbons, 152, 259, 274
—, — methane, 256
—, properties of, 644
—, removal from acetylene, 664
Diacetylenes, by action of electric discharge on acetylene, 668
—, in cracking gas, 115
Dialcoholates, from alcohols, 596
Dialkyl ethers, by dehydration of alcohols, 370
—, ethylene glycol, 525, 526
—, from β,β'-dichlorodiethyl ether, 498
—, propylene glycol, preparation, 530
Dialkyl sulphates, alkyl esters from, 325
Diallyl, pyrolysis of, 75
—, reaction with sulphuric acid, 661
Diallyl ether, formation, 661
Diamines, by action of nitrogen oxides on olefins, 581
1,2-Diaminoethane derivatives, from dichloroethane, 818
Diaminoethylene, 581
Diamylenes, formation, 380, 603, 604
—, halogenation of, 1126
—, oxidation of, 605, 880
—, polymerization of, 606
—, properties of, 604
—, reactions of, 604, 605
—, uses as antidetonants, 613
Diamyl ether, from chloropentanes, 790, 791
Diaryl compounds, by benzene pyrolysis, 189
Diaryl ethers, from β,β'-dichlorodiethyl ether, 498
Diazoacetic ester, reaction with butadiene, 652
Diazobenzene-p-sulphonic acid, 1021
Diazomethane, reaction with butadiene, 652
Dibasic acid anhydrides, formation of keto acids, 1058, 1059
Dibasic acids, by oxidation of cracked gasoline, 837, 838
—, reaction with higher secondary alcohols, 402
Dibenzyl, cyclohexene derivative of, 561
—, from ethylene oxide and benzene, 545
Dibenzylamine, in pyrolysis of alkylbenzenes, 147
Dibromides, distillation of, 1123
—, from allenes, 632
—, — monolefins, 1121
—, reaction with potassium iodide, 1123
Dibromoacetone from isopropyl alcohol, 374
Dibromobenzene, production, 768
1,4-Dibromobutadiene, from butadiene, 641, 643
2,3,-Dibromobutadiene, from butadiene tetrabromide, 644
1,3-Dibromobutane, from methylcyclopropane, 746
2,3-Dibromobutane, butadiene from, 634
Dibromobutanes, by bromination of butanes, 720
2,4-Dibromo-2-butene, from monovinylacetylene, 669
1,2-Dibromocyclobutane, bromination of, 746, 747
Dibromodimethylpropanes, 724, 726
1,1-Dibromoethane, from vinyl bromide, 477, 478
Dibromoethylene, germicide, 706
—, purification of, 675
Dibromohexane, from n-hexane, 742
Dibromoisoprene, from isoprene tetrabromide, 645
Dibromoisoprene sulphone, reaction with zinc in alcohol, 655
1-5-Dibromopentane, pentamethylene sulphide from, 453
3,4-Dibromophenylbutadiene, 642
Dibromopropane, from cyclopropane, 746
1-3-Dibromopropane, from allyl bromide, 480, 481
2,3-Dibromo-1-propene, conversion to allene, 632
Dibutylamine, reaction with ethylene chlorohydrin, 497
Dibutyl ether, from butenes, 379
Dibutylresorcinol, oxidation inhibitor, 913
Dibutyltoluene, from p-ter.-butyltoluene, 200
Dicarboxylic acids, by nitration of naphthenes, 1047
—, glycol esters of, 520, 521
—, separation from monocarboxylic acids, 955
Dichlorides, from chlorinated olefins, 139
—, from decanaphthenes, 752
—, of isopentane, 724, 725, 731, 732
Dichlorinated cycloparaffins, reactions of, 815-818
Dichlorinated paraffins, diolefins from, 817
—, hydrolysis of, 507, 795
—, reactions of, 815-818
Dichloroacetaldehyde, from acetylene, 683
Dichloroacetic acid, addition to amylene, 330
Dichloroacetone, from isopropyl alcohol, 373
Dichloroacetylene, preparation and properties, 675
o-Dichlorobenzene, 758, 767
p-Dichlorobenzene, formation, 758, 759, 761, 764, 767
Dichlorobenzenes, production, 759, 763
1,2-Dichlorobutane, from 1-butene, 501
1,4-Dichlorobutane, butadiene from, 634
Dichlorobutanes, butadiene from, 803
—, by chlorination of petroleum fractions, 720
—, from butane, 718, 720
—, from butenes, 481
—, solvent properties, 481
1,3-Dichloro-1-butene, formation, 648
1,4-Dichloro-2-butene, butadiene tetrachloride from, 644
2,4-Dichloro-2-butene, formation of, 639
2,4-Dichlorobutene, from monovinylacetylene, 669
3,4-Dichloro-1-butene, butadiene tetrachloride from, 644
Dichloro compounds, by chlorination of gasoline fractions, 727, 728
1,2-Dichlorocyclobutane, bromination of, 746
Dichlorocyclohexane, cyclohexadiene from, 749
—, from cyclohexane, 748, 749
—, pyrolysis of, 816
1,1-Dichlorocyclopropane, from cyclopropane, 745
Dichloro derivatives of pentane, 724, 731, 732
Dichlorodibromobutane, 746, 747
2,2-Dichloro-1,3-dibromopropane, from dichlorocyclopropane, 745
ββ' Dichlorodiethyl ether, as solvent, 498
—, chemical reactions of, 498
—, divinyl ether from, 682
—, from ethylene chlorohydrin, 497
—, reaction with alkalies, 555, 682
—, selective solvent, separation of paraffins and naphthenes, 35

ββ'-Dichlorodiethyl selenide dichloride, 577
ββ'-Dichlorodiethyl selenide oxide, 577
ββ'-Dichlorodiethyl sulphide, properties, 576
Dichlorodifluoromethane, from carbon tetrachloride, 707, 709, 710
—, manufacture of, 707, 708, 710
—, physical properties, 709
1,1-Dichlorodimethylmethane, 742
2,3-Dichlorodioxan, 556
Dichloroethane, from ethane, 713
—, from natural gas, 690, 714
—, reaction with cellulose xanthate, 742
—, solvent for olefin separation, 141
—, solvent in chlorohydrin formation, 493
1,2-Dichloroethyl acetate, from vinyl acetate, 682
Dichloroethylene, as refrigerant, 704
—, chloroacetyl chloride from, 675
—, from chloroethylene, 674, 675
—, from 1,1,2-trichloroethane, 674, 675
—, 1,1,2-trichloroethane from, 675
—, uses of, 675
trans-1,2-Dichloroethylene, from acetylene, 672
Dichloroethyl sulphate, from ethylene dichloride, 474
Dichloroheptane, isolation of, 735
Dichlorohexane, from n-hexane, 736
—, hydrogen chloride from, 805
—, pyrolysis of, 816
Dichlorohexatriene, from divinylacetylene, 670
Dichloro hydrocarbons, from olefins, by hypochlorous acid, 501
Dichloroisopentane, from isopentanes, 725
Dichloromesitylene, 779
Dichloromethane, (*see* Methylene dichloride)
2,4-Dichloro-2-methylbutane, 646, 659, 725
3,4-Dichloro-2-methylbutane, from isopentane, 724, 725
Dichloro-methylcyclopentane, from Caucasian petroleum fraction, 817
Di(dichloromethyl)-trichlorobenzene, 779
Dichloroparaffins, conversion to phenoxychloroparaffins, 741, 817
Dichloropentanes, from pentane, 723
—, from petroleum, 724
3,4-Dichlorophenylbutadiene, 642
Dichloropropanes, by chlorination of isopropyl chloride, 717
—, by chlorination of propane, 717, 718
—, catalytic chlorination of, 717
—, formation, 373
—, from cyclopropane, 745
Dichlorosulphides, formation, 1133
Dichlorotetrabromobutane, from, 1,2-dichlorocyclobutane, 746, 747
Dichlorotoluenes, 769, 771, 774, 775
Dichlorotribromobutane, from 1,2-dichlorocyclobutane, 746, 747
Dichlorovinyl ether, from chloroethylene, 674
Dicyclic acids, from naphthenic acids, 1072
Dicyclopentadiene, from cyclopentadiene, 621, 622, 657
—, reaction with phenylazide, 622
Dicyclopentadiene quinone, 650
Dicyclopentyl, in casinghead naphtha, 18
—, in straight-run gasoline, 25
Dienes, see Diolefins
Diesel fuels, 986
—, distillation characteristics, 1148
—, use of diacetylene in, 665
—, use of nitroparaffins in, 986
Di-esters of ethylene glycol, 511, 528
—, production, 518, 519
Diethanolamine trinitrate, 552
Diethanolamines, preparation of, 541, 552
Di-ethers of diethylene glycol, uses, 528
Diethylacetal, from ethanol, 678
Diethylamine, by ethyl chloride-ammonia reaction, 806
—, reaction with ethylene oxide, 543
—, reaction with isopropylethylene oxide, 558
β-Diethylaminoethanol, 543
3-Diethylaminopropanol-2, preparation, 557
Diethylaniline, antioxidant, 907, 909
—, sulphur dyes from, 431
Diethylbenzene, production, 560
Diethylcarbinol, reaction with sulphuric acid, 638
Diethylcyclohexane, 199
Diethyldioxan, from 1,2-butylene glycol, 555, 556
Diethyl disulphide, from distillates, 448
Diethylene dioxide, 554
Diethylene disulphide, occurrence in crude ethyl alcohol, 335
Diethylene glycol, 512, 526-528
—, by-product in hydrolysis of ethylene oxide, 537
—, physical properties, 526, 527
—, reaction with sulphuric acid, 555
Diethylene glycol diacetate, 556
Diethylene glycol dinitrate, 527
Diethylene glycol ethers, from β,β'-dichlorodiethyl ether, 498
Diethylene glycol monoacetate, 527, 528
Diethylene glycol monoethyl ether, 528
Diethyl ether, formation of, 786, 787
—, from ethylene, 307
Diethyl fumarate, hot-wire ignition curves, 969
Diethyl ketone, properties, 262, 416
Diethyl maleate, hot-wire ignition curves, 969
3,3-Diethylpentane, vapor-phase oxidation, 856
Diethyl selenium, antiknock compound, 982, 984
Diethyl sulphate, from ethyl alcohol, 344, 346
—, from ethylene, 321, 335-341
—, from ethylsulphuric acid, 344
—, physical properties, 344
—, reaction with 1-chloro-2-hydroxypropane, 497
—, solvent for aromatics, 34, 1143
—, utilization of, 344
Diethyl tartrate, solvent for diolefin separation, 160
Diethyl tetrasulphide, 449
Diethylthiophene, 428
Diethyl trisulphide, 438
Diffusion method of combustion analysis, 1098
Diglycol stearate, 528
Diguanidine derivatives, of paraffins, 807, 808
Dihalides, diolefins from, 815
—, glycols from, 505
—, reaction with guanidine, 808
Dihalogenoethanes, from acetylene, 472
1,3-Dihalogenpropane, from 3-halogenopropylene, 327
Dihydroanthracene, anthracene from, 200
Dihydrobenzene, from cyclohexane, 430
—, polymerization of, 264
—, reaction with maleic anhydride, 651
Dihydrobenzene rubber, 623
Dihydrobiphenyls, from benzene, 269
Dihydrocivetone, from civetone, 83
Dihydronaphthalene, condensation with aniline, 572
—, pyrolysis of, 84
5,6-Dihydropyrindine, isolation from shale oil, 825
—, synthesis of, 828
Dihydroxydiethyl oxide, 555
ββ'-Dihydroxydiethyl selenide oxide, 577
Dihydroxystearic acid, 505, 506
2,4-Dihydroxytoluene, from toluene, 922
ββ'-Diiododiethyl ether, 584
Diisoamyl, action of aluminum chloride on, 194
—, chlorination of, 735
—, ignition of, 966
—, nitration of, 1046
—, oxidation of, 836
—, reaction with sulphur chloride, 1060
—, tetrachloromethane from, 735
Diisobutene, bromination, 465, 466, 1129
—, condensation with phenols, 566
—, formation, 590, 600
—, from acetone, 410
—, from ethylene, 79
—, from isobutene, 77, 378
—, hydrogenation, 600
—, hydrolysis of, 884
—, oxidation, 880
—, polymerization of, 600, 601
—, properties, 601
—, reaction with mineral acids, 325
—, reaction with ozone, 884
—, stability, 601
—, structure of, 884
—, uses, 613

Diisobutene oxide, preparation, 534
Diisobutene ozonide, catalyst for polymerization of styrene, 611
Diisobutenyl, 657
Diisobutyl, action of aluminum chloride on, 194
—, chlorination of, 735, 737
—, nitration of, 1044, 1045
Diisobutyl disulphide, from distillates, 448
Diisobutylene, *see* Diisobutene
Diisopropenyl, hydrogenation of, 657
Diisopropyl, action of chlorosulphonic acid on, 1008
—, action of sulphuric acid on, 1007, 1008
—, bromination of, 742
—, chlorination of, 734, 736
—, from Baku petroleum, 735, 736
—, in natural-gas gasoline, 17
—, isolation of, 32
—, nitration of, 1043
Diispropylacteal, properties, 371
Diisopropylbenzaldehyde, from diisopropylbenzene, 930
Diisopropylamines, from isopropyl chloride, 806
Diisopropylbenzene, 561
—, diisopropylbenzaldehyde from, 930
Diisopropylcarbazole, production, 573
Diisopropyl disulphide, from distillates, 448
Diisopropylphenol, formation of, 566
Diisopropylphenyl isopropyl ether, formation of, 566
Diisopropyl sulphate, decomposition of, 348
—, from propylene, 348, 355, 371, 372
—, properties of, 348, 372
3,5-Diisopropyltoluene, from p-cymene, 200
Diketones, from oxidation of hydrocarbons, 960
Dimercuric chloride compounds of thiophene, 454
Dimers of conjugated diolefins, by pyrolysis, 79
Dimetallic derivatives of glycol, 511
Dimethylacetal, by oxidation of gas oil, 840
Dimethylallene, 301, 632
—, polymers of, 615, 616
Dimethylaniline, as oxidation inhibitor, 984
—, carboxylation, 930
—, reaction with pinacone chlorohydrin, 637
—, stabilization of gasoline with, 898
2,6-Dimethylanthraquinone, production, 653
Dimethylbenzenesulphonyl chloride, 780
Dimethylbutadiene, addition compounds of, 643
—, autoxidation of, 893
—, effect on gasoline, 900
—, preparation of, 637
—, tetrabromides of, 659, 1145
1,1-Dimethylbutadiene, 660
—, dimer, 620
—, polymerization of, 619
—, synthetic rubber from, 627
1,2-Dimethylbutadiene, dimer, 620
—, polymerization of, 619, 660
—, reaction with maleic acid, 660
1,3-Dimethylbutadiene, reaction with maleic acid, 660
1,4-Dimethylbutadiene, dimer, 620
—, reaction with maleic acid, 660
2,3-Dimethylbutadiene, autoxidation of, 893
—, dimer, 619, 620
—, from acetone, 637
—, from depolymerized rubber, 625
—, from pinacone, 637
—, 1,4-hydrobromide of, 646
—, polymerization of, 616, 619, 625
—, pyrolysis of, 79
—, reaction with ammonium bisulphite, 655
—, — hydrogen bromide, 647
—, — maleic acid, 660
—, — toluene, 653
—, synthetic rubber from, 627
—, tertiary alcohol from hydrobromide of, 646
2,3-dimethylbutadiene rubber, depolymerization of, 619
2,2-Dimethylbutane, from isobutylene, 266
—, reaction with antimony chloride, 1061
2,3-Dimethylbutane, in straight-run gasoline, 22
—, pyrolysis of, 130
2,3-Dimethyl-2-butene, from isobutylene, 266
Dimethylcyclobutane, from cyclohexane, 198
—, in straight-run gasoline, 23
Dimethylcyclohexane, by pyrolysis of 1,4-dimethyl-3-cyclohexene, 85
—, chlorinated compounds from, 751, 753
—, sulphonation of, 1010
1-1-Dimethylcyclohexane, dehydrogenation, 181
—, oxidation of, 853
1,2-Dimethylcyclohexane, in straight-run gasoline, 25
—, isomerization, 199
1,3-Dimethylcyclohexane, bromination, 753
—, chlorination, 751
—, in straight-run gasoline, 25
—, isomerization of, 199
—, oxidation, 856
—, reaction with sulphur, 430
—, tetrabromo-m-xylene from, 754
1,4-Dimethylcyclohexane, isomerization, 199
—, tetrabromo-p-xylene from, 754
1,3-Dimethylcyclohexanol, formation, 856
1,4-Dimethyl-3-cyclohexene, pyrolysis of, 85
Dimethylcyclopentane, by pyrolysis of cycloheptane, 86
—, chlorinated product, properties, 753
1,1-Dimethylcyclopentane, in straight-run gasoline, 23, 27
1,3-Dimethylcyclopentane, 4-methyl-2-hexanone from, 891
—, 5-methyl-2-hexanone from, 892
—, oxidation of, 856, 892
—, peroxide, reaction with potassium iodide, 892
1,3-Dimethyl-1-cyclopentanol, formation, 856
Dimethylclopropane, action of sulphuric acid on, 1009
1,1-Dimethylcyclopropane, pyrolysis of, 83
—, trimethylethylene from, 746
m,m'-Dimethyldibenzyl from dimethylcyclohexane, 430
1,2-Dimethyldicyclo-[0,1,1]-butane, 198
1,2-Dimethyl-3-4-diethylidenecyclobutane, 615
Dimethyldioxan, 555, 556
Dimethyl ether, from methyl chloride, 782-786
Dimethylethylcarbinol, from amylene, 331, 380
Dimethylethylcyclohexane, in straight-run gasoline, 25
—, nitration of, 1050
1,3-Dimethyl-5-ethylcyclohexane, chlorinated products from, 752
—, 2,4,6-tribromo-1,3-dimethyl-5-ethylbenzene from, 754
Dimethylethylpentane, sulphonation, 1010
Dimethylfulvene, 891
Dimethylfulvene diperoxide, 891, 892
Dimethylglyoxime, solubility in isopropyl alcohol, 365
2,6-Dimethylheptane, nitration of, 1045
2,5-Dimethylhexane, nitration of, 1044
—, oxidation of, 855
2,4-Dimethyl-2-hexyl-1,3-dioxolane, 557
Dimethylisopropylcarbinol, 384, 385, 403
Dimethylnaphthalene, from kerosene, 27
1,4-Dimethylnaphthalene, by pyrolysis of acetylene, 82
2,6-Dimethylnaphthalene, from kerosene, 28
Dimethylnitropentane, 1043
2,7-Dimethyloctane, nitration of, 1045, 1046, 1051
2,6-Dimethyl-1-5,7-octatriene, from isoprene, 617
3,7-Dimethyl-2-octene, isomerization, 603
Dimethylol urea, 498
2,2-Dimethylpentane, from isobutylene, 266
—, in straight-run gasoline, 22, 27
—, nitration of, 1043
2,4-Dimethylpentane, from isobutylene, 266
—, nitration of, 1044
3,3-Dimethylpentane, vapor-phase oxidation, 856
Dimethylphenylcarbinol, oxidation, 926
Dimethylphenylpyrazolone, 1037
2.2-Dimethylpropane, pyrolysis of, 63, 130
Dimethyl-n-propylcarbinol, 384, 403
Dimethylpropylmethane, in natural-gas gasoline, 17
—, isolation of, 32
Dimethylpyridine, from shale tar, 827
6.7-Dimethylquinizarin, 653
2,3-Dimethylquinoline, separation of, 822, 826
2,4-Dimethylquinoline, separation of, 822, 826
2,8-Dimethylquinoline, isolation, 826

Dimethyl sulphate, action on naphthenes, 1143
—, action on paraffins, 1143
—, selective solvent for aromatics, 34, 1143
Dimethylthiophene, 428
2,3-Dimethylthiophene, from naphtha, 455
—, from shale oil, 463
3,4-Dimethylthiophene, from naphtha, 455
1,3-Dimethyl-3-vinyl-6-cyclohexene, from isoprene, 618
Dinaphthalenes, production, 563
β-Dinaphthol, from β-naphthol, 929
Dinaphthyl, from naphthalene, 89, 199
—, perylene from, 199
2,2′-Dinaphthyl ether, from β-naphthol 929
Dinitro alcohols, from olefin-nitrogen pentoxide reaction, 581
m-Dinitrobenzene, 430
—, reaction with nitrogen pentoxide, 1044
Dinitro-ter-butylxylyl methyl ketone, 400
2,4-Dinitrochlorobenzene, identification of mercaptans by, 1150
Dinitro compounds, from olefin-nitrogen pentoxide reaction, 581
Dinitrodicyclohexyl, 1048
Dinitrodimethylbutane, 1043
Dinitrodimethylheptane, 1045
Dinitrodimethylhexane, 1045
Dinitrodimethyloctane, 1046
Dinitrodimethylpentane, 1044
Dinitrohexane, 1042
Dinitromethylbutane, 1042
Dinitrooctane, 1044
n-Dioctyl succinate, 402
Diolefin tetrabromides, reduction of, 640
Diolefins, absorption of, 142, 1124
—, addition reactions of, 641
—, aliphatic, properties, 153
—, analytical determination, 659
—, autoxidation of, 619, 642
—, chemical reactivity of, 633, 641, 642
—, chlorine addition, 471
—, classification of, 631
—, compared with monolefins, 642
—, condensation with maleic acid, 653
—, conjugated, 1,4 addition compounds of, 641, 642
—, —, analytical determination, 654, 658
—, —, by decomposition of dichlorinated derivatives of paraffins, 817
—, —, condensation reactions, 650-654
—, —, ethylation, 656
—, —, miscellaneous reactions of, 654-657
—, —, peroxides, 654
—, —, polymerization of, 79, 614, 616-622
—, —, properties of, 640-642
—, —, reaction with bromine and chlorine, 642-645
—, —, reactions with halogen acids, 645-648
—, —, reaction with maleic anhydride, 119
—, —, reaction with naphthazarin, 653
—, —, reaction with sulphur dioxide, 654, 655, 660
—, —, reaction with sulphuric acid, 649
—, —, synthesis of, 633
—, dehydrogenation of, 223
—, diozonides of, 654
—, effect on gasolines, 900
—, from acetylene-olefin hydrocarbons, 158
—, — aliphatic alcohols, 159
—, — bituminous coal, 133
—, — butanes, 174
—, — cracking gas, 334
—, — dihalogen compounds, 815, 817
—, — ethylene, 259, 262
—, — hydrocarbons, 134, 176, 262
—, — oils, 133, 262, 633
—, — olefins, 80
—, — petroleum, 157, 161, 162
—, — tars, 133
—, halohydrins of, 648
—, identification of, 658, 659
—, in cracked gasoline, 118, 119, 145
—, in cracking gas, 114, 115
—, in gasolines, 631
—, intermediates in formation of aromatic hydrocarbons, 162, 169
—, isolation of, 1145
—, monozonides of, 654
Diolefins, occurrence of, 660
—, peroxide formation of, 642
—, polymerization of, 588, 614, 616, 625, 626, 627, 628, 631, 633
—, polymerized, hydrogenated, 613
—, production, 153-160
—, purification of, 141, 643
—, pyrolysis of, 79
—, reaction with acrolein, 652
—, — acrylic acid, 652
—, — amines, 656
—, — ammonia, 656
—, — benzenes, 204
—, — citraconic acid anhydride, 652
—, — cyclohexanone, 652
—, — ethyl sulphate, 656
—, — itaconic acid anhydride, 652
—, — maleic anhydride, 659, 1145
—, — ozone, 654
—, — sulphur dioxide, 575
—, — sulphuric acid, 642, 649
—, resins from, 204, 642
—, separation of, 159-160, 640, 641
—, synthetic rubber from, 625-628
—, tars from, 642
—, tetrahalides of, 643, 1121
—, thermal stability of, 95
—, treatment with aluminum chloride, 203
—, uses of, 633
Dioxan, 554-556
—, as solvent, 141, 555
—, compound with boron fluoride, 596
—, formation of, 540, 547, 548
—, from ethylene glycol, 512, 533
—, properties, 555, 556
—, reactions of, 555, 556
Dioxan derivatives, from glycols, 533
Dioxan homologues, preparation, 555
Dioxolanes, 556, 557
Dioxymethyl peroxide, decomposition, 883
—, from ethylene, 878, 879, 883
Dipentene, butadiene from, 157
—, from isoprene, 617, 618
—, — α-pinene, 890
—, — rubber, 627
—, properties, 617, 618
—, pyrolysis of, 154
—, reaction with ammonium bisulphite, 575
—, — isoprene, 657
Diphenyl, cyclohexene derivative of, 561
—, from acetylene, 82, 180
—, — benzene, 88, 89, 188, 189, 199, 269
—, — isobutene, 179
—, sulphur dyes from, 431
—, use in manufacture of phenol, 767
—, uses of, 189
Diphenylamine, as antioxidant for oils, 907, 913
—, effect of esterification of propylene, 327
—, effect on gas-phase oxidation, 980
—, effect on ignition of cotton, 890
—, reaction with p-nitrosophenol, 897
—, stabilization of gasoline with, 897, 898
9,10-Diphenylanthracene, 200
1,4-Diphenylbutadiene, 652, 654
1,3-Diphenyl-1-butene, 612
Diphenylchloroacetyl chloride, diphenyl ketene from, 413
9,10-Diphenyl-9,10-dihydroanthracene, dehydrogenation of, 200
1,1-Diphenyleneethylene, polymerization of, 612, 613
1,1-Diphenylethylene, polymerization of, 612
—, reaction with nitrogen trichloride, 579
1,2-Diphenylethylene, polymerization of, 613
Diphenylguanidine, adsorption by carbon blacks, 248, 249
Diphenylhydrazine, antioxidant, 907
Diphenyl ketene, 413
Diphenylmethane, carboxylation of, 930
—, cyclohexene derivative of, 561
—, from toluene, 267
—, from tribenzyl borate, 1060
—, oxidation, 915
—, production, 564
—, pyrolysis of, 89

Diphenylmethane dyes, formation, 860
Diphenylolpropanetetracarbinol, 498
Diphenyl oxide, as heat-transfer medium, 189
—, from phenyl halides, 767
Diphenylpropane, nitration of, 1046
Diphenylpropene, reaction with nitrogen trichloride, 579
Diphenylsemicarbazide, stabilization of gasoline with, 898
Diphenyl sulphide, in petroleum oils, 421
—, use in production of thiophenols, 767
Diphenylsulphone complexes, catalysts for polymerization, 600
Diprene, from isoprene, 617, 618
Dipropargyl, from acetylene, 668
—, from acetylene trimer, 268
Dipropylcarbinol, from heptene-3, 385
Dipropyl ketone, from heptane, 1055
Di-n-propyl ketone, 416
Disc process for carbon black, 234
Disinfectants, from sulphonation of shale oil distillates, 1037
—, use of formaldehyde in, 786, 860
—, — isopropyl alcohol in, 363, 366
—, — sulphonated hydrocarbons in, 1001
—, — sulphonic acids in, 1014
Dispersing agents, from alcohols and glycols, 539
—, — chlorohydrin and amines, 498
—, — glycol ethers and sulphonated acids, 525
—, — halogenated ethers, 809
—, — halogenated hydrocarbons and amines, 808
—, — polymerized olefin oxides, 548
—, — sulphonated ethers, 809
—, — sulphonated hydrocarbons, 1019
Distillation curves, with Podbielniak apparatus, 1110
—, with Rosen and Robertson apparatus, 1114
Distillation, destructive, as mechanism of petroleum formation, 36
—, dry, of rubber, 154
Distillation pressures, Podbielniak apparatus, 1107
Distillation range of gasolines, variation of knock-rating with, 986
Distillation tests of petroleum fractions, 1147, 1148
Distyrene, 611, 612
Disulphides, corrosion by, 422
—, formation, 1133
—, from mercaptans, 432, 433, 437, 459
—, from petroleum distillates, 31, 421, 448, 449
—, properties of, 449, 450, 452
—, pyrolysis of, 456, 457
—, reactions of, 448, 449
Disulphonic acid, from paraffin hydrocarbons, 1008
—, — sulphonation of kerosene, 1007
Ditolyl, from benzene, 199
—, — isobutene, 179
—, — toluene, 88
Ditolylamines, stabilization of gasoline by, 897
Divinylacetylene, from acetylene, 669, 670
—, from acetylene trimer, 268
—, plastics from, 670, 671
—, reactions of, 670
Divinylbenzene rubber, 625
Divinyl ether, properties of, 682
Divinylethynyl-mercury, 685
Dixylylamines, stabilization of gasoline with, 897
Doctor solution, 438, 439, 1149
Doctor test, mercaptans, 1149
Dodecanaphthene, chlorinated, 753
—, from amylene, 78
Dodecanaphthenic acid, from naphthenic acids, 1071
Dodecane, chlorination of, 737, 738
—, condensed with alkylene oxides, 1059
—, nitration of, 1045
—, solubility of hydrogen sulphides in, 423
Dodecene, sulphonation of, 1033
Dolomite catalyst for water-gas reaction, 283, 286
Driers for paints, 565, 995, 1030
—, use of salts of keto acids in, 1059
Drugs, from ethylene chlorohydrin, 487
Dry cells, use of petroleum coke in, 228
Dry-cleaning preparations, 366, 1029, 1030
Drying oils, from acid sludge, 1030
—, from chlorinated petroleum fractions, 738, 741, 816
—, from kerosenes, 740, 805
—, from olefins, 613, 614, 804
—, from vinylacetylenes, 670
—, uses, 614
DuPrene, from chloroprene, 640
Durene, nitration of, 1046
Dyeing, use of isopropylated aromatics in, 375
Dyes, emulsions or suspensions of, 375
—, isopropylaniline as intermediate for, 367
—, oil-soluble, 1029
Dyestuffs, by nitration of petroleum, 1052, 1053
—, from acid sludges, 1013
—, — condensation of ethylene glycol with halogenated dibenzanthrones, 516
—, — monochlorobenzene, 764
—, — sulphonic acids, 1021
—, purified with isopropyl alcohol, 364
—, use of ter.-butyl-β-naphthol in manufacture of, 401
—, use of sulphonated aromatic hydrocarbons in manufacture of, 1006
Dynamite, use of glycol dinitrate in, 582

E

Earthenware, effect in pyrolysis of ethane, 122
Earths, adsorbent, catalysts for polymerization of olefins, 589
Edeleanu extract, lubricating oils from, 565
—, source of aromatic hydrocarbons, 34
Eicosane, separation from triacontane, 33
Elaidic acid, 505, 506
Electrical decomposition, carbon manufacture, 218, 238
—, production of acetylene, 663
Electrical treatment, hydrocarbons, 255-264
Electric arc, action on coal, 262
—, —, coal tar, 257
—, — fuel oil, 259
—, — hydrocarbons, 217, 218, 221, 255-264
—, — methane-carbon dioxide, 260
—, — natural gas, 258
—, — tars, 262
—, — paraffin, 257, 261
—, — petrolatum, 257
—, — resins, 262
—, — toluene, 257
—, cracking, 255
—, methane-steam reaction, 260, 289, 290
—, natural gas chlorination, 688, 694
—, production of cyanides, 292-299
—, pyrolysis of methane, 149
Electric discharge, action on acetylene, 610, 668
—, carbon dioxide-methane reaction, 282
—, chlorination of ethane, 715
—, effect on oxidation, 715, 837, 843
—, ignition, 969
—, polymerization olefins, 610
Electrode composition, effect on hydrocarbon decomposition, 256, 257
Electrodes, carbon, 208, 218, 219
—, petroleum coke, 227
—, platinum, oxidation of benzene, 927
Electrolytes, isoprene treated with, 628
Electrolytic bromination, benzene, 768
Electrolytic chlorination, benzene, 761, 762
Electrolytic gas, use in explosion analysis, 1098
Electrolytic oxidation, of aromatics, 927, 928
—, of ethyl alcohol, 932
—, of ethylene, 991
—, of petroleum hydrocarbons, 832
—, of sulphur in oils, 1151
Electropyrolysis, of alcohol, 256
—, of oils, 219
Elektrion oils, 271
Elemi, solubility in amyl alcohol, 798
—, — glycol ethers, 525
—, — sec-hexyl acetate, 402
—, — isopropyl acetate, 373
—, — isopropyl alcohol, 366
Elf carbon black, 246

Emba crude oil, cracking of, aluminum chloride catalyst, 164
—, naphthenic acids from, 1063
—, oxidation of, 950
—, treatment with sulphur, 950
Emulsions, breaking of, 564
Emulsifying agents, ter-butylnaphthalene-sulphonic acid, 400
—, by halogenation of ethers, 809
—, ethylene absorption, 341, 343
—, from mineral oils, 1022, 1025-1027
—, isopropylated aromatics, 375
—, naphthenic acids, 1023, 1086
—, petroleum oxidation products, 994, 995
—, preparation, 541, 552, 559, 563
—, sulphides as, 456
—, sulphonated oxidized hydrocarbons, 1000-1002
—, sulphonates, 372, 809, 1020, 1024-1027
—, use in hydrolysis of chloropentanes, 790, 791, 793
—, — plastic compositions, 1031
—, — polymerization of diolefins, 628
Endodimethylene tetrahydrophthalic anhydride, 651
Endomethylene piperidazine, 652
3,6-Endomethylene tetrahydrophthalic anhydride, 651, 652
Endothermic reactions, in cracking, 98, 99
—, methane decomposition, 205, 220
End point, gasoline distillation, 1148
Energy of activation, polymerization of dienes, 617
—, cracking reaction, 100
Enolates, catalyst for oxidation, 938
Enzymes, precipitated by isopropyl alcohol, 367
Epichlorhydrin, 427
Equilibrium, carbon dioxide-methane reaction, 281
—, hydrolysis of ethyl chloride, 787
—, methane, carbon, hydrogen, 205
Equilibrium constants, cracking reactions, 65
—, ethyl chloride dissociation, 323
—, hydrolysis of methyl chloride, 782
—, methane-carbon dioxide reaction, 282
—, methane-steam reaction, 280
—, pyrolysis of aromatic hydrocarbons, 89
—, — ethane, 122
Erythrene, from acetylene, 265
Esthonian shale oil distillates, conversion to aromatics, 164
—, desulphurization of, 460
Essences, use of isopropyl esters, 373
Ester gum, solubility in various solvents, 373, 394, 395, 402, 524, 525, 798
Esterification, alcohols, by hydrogen halides, 324, 703
—, of chloropentanes, 789, 793-795
—, of fatty acids, 539
—, of isopropyl alcohol, 367, 371, 372
—, of methanol, 703
—, of naphthenic acids, 1070-1072, 1083
—, of olefins with sulphuric acid, 143, 144, 320-331, 346, 372, 376, 387, 933
—, of oxidation products, 992
—, of oxidized distillates, 999
—, of polyglycols, 527, 528
—, of propylene, 355
—, of wax acids, 539, 997
Esters, butadiene from, 157
—, by butane oxidation, 835
—, by gasoline oxidation, 836
—, by oxidation of hexane, 868
—, — petroleum hydrocarbons, 987
—, conversion to acetone, 408
—, from alkyl halides, 781, 782, 784, 786, 793
—, from nitriles, 684
—, from olefins, 129, 301, 311, 312, 320, 333, 387, 388, 1005
—, from petroleum, 937, 938
—, ignition temperatures, 968
—, in mineral-oil oxidation, 936
—, in oxidized hydrocarbons, 991, 996, 997
—, intermediates, hydration of olefins, 301
—, —, formation of alcohols from alkyl chlorides, 790, 791
—, of hydroxyethers, 539
Esters, of keto acids, plasticizers, 1059
—, of montan wax acids, 1002
—, of polyglycols, 526
—, of secondary alcohols, 328, 392, 395, 401, 402
—, —, from cracking gas, 349
—, of tertiary alcohols, 328, 392, 397
—, of wax acids, 998
—, oxidation of paraffin, 1001
—, polyhydric alcohols, 152, 520, 521
—, reaction with boron fluoride, 596
Estimation, of hydrogen, 1095
—, of isopropyl alcohol, 367, 368
Estolides, 945
Ethane, acetylene from, 147
—, action of sulphuric acid on, 1007
—, bromination of, 715, 716
—, by pyrolysis of cyclohexane, 84
—, — higher paraffins, 50, 52-56, 58, 61, 188
—, — of methane, 43, 269
—, — olefins, 66, 68, 70-72, 127
—, by submerged combustion, 1000
—, carbon black, 243
—, chlorination, 472, 688, 690, 691, 702, 712-715
—, chlorine derivatives, 467
—, decomposition of, 205, 235, 257, 264, 268, 269, 272, 273
—, dehydrogenation of, 45, 342
—, —, equilibrium constants, 45
—, effect in carbon deposition, 236
—, — oxidation of acetaldehyde, 932
—, — pyrolysis of methane, 167, 168
—, effect of aluminum chloride on, 194
—, ethylene from, 872
—, from acetylene, silent discharge, 269
—, from coke-oven gas, electric arc, 258
—, from ethylene, 66, 68, 266, 269, 273
—, from hydrocarbons, electric arc, 257
—, in cracking gas, 114, 115
—, in natural gas, 12-14, 122, 242
—, maximum flame temperatures, 236
—, oxidation of, 834, 850-852, 857, 858, 860, 867, 885, 961, 965, 975
—, polymerized, silent discharge, 268
—, preparation of pure, 1113
—, pyrolysis of, 38, 43-49, 122, 126, 130, 149, 170-173, 180, 182, 183, 185
—, —, equilibrium constants, 122
—, —, mechanism, 43-45, 48
—, —, thermodynamic considerations, 44
—, —, velocity constant, 46
—, reaction with hydrogen sulphide, 425
—, — steam, 276
—, removal of from mixtures, 1116
—, separation of, 141, 1101

Ethyl ethylthiosulphonate, 449

Ethylglycerol, from ethylvinylcarbinol, 505
2-Ethylhexane, oxidation, 855
Ethylidene chloride, ethylene chlorination, 472
—, from vinyl chloride, 680
Ethylidene diacetate, preparation of, 682, 683
Ethylidene dissociation, 786
Ethylidene glycol, formation of, 678
Ethyl iodide, addition compounds from, 453
—, effect on ignition temperatures, 966
—, from ethylene, 322, 324
—, quaternary salts from nitrogen bases, 820
—, reaction with sulphones, 453
—, tetraethyl lead production, 813
Ethylisoamyl, 1007
Ethyl isopropyl ketone, production, 418
Ethyl ketol, 415
Ethyl lactate, solvent for acetylene, 664
Ethyl magnesium bromide, 813
Ethylmethylethylene, 380
Ethyl mercaptan, effect of metallic salts on, 446
—, ethylene from, 457
—, formation of, 431, 811, 812
—, from acetylene, 685
—, from distillates, 448
—, hydrogen sulphide from, 457
—, oxidation with air, 449
—, polymerized, silent discharge, 265
—, polysulphides from, 457
—, properties of, 432, 452
—, pyrolysis of, 451, 457
—, reaction with acetone, 433, 812
—, use in non-cutting oils, 456
Ethylnaphthalene, 147, 563
Ethyl naphthenates, 1070, 1072
Ethyl-α-naphthylamine, antioxidant, 907
Ethyl oleate, hydrogenated, 990
3-Ethylpentene-2, 385, 386
Ethyl peroxide, formation, 854
Ethylphenylcarbinol, oxidation, 926
Ethylpropylamine, 807
Ethylpropyl carbinol, 385
Ethyl salicylate, from ethylene dichloride, 518
Ethyl stearate, oxidation of, 959
Ethyl sulphate, reaction, diolefins, 656
Ethyl sulphide, ethylene from, 457
—, from distillates, 450
—, from ethyl mercaptan by pyrolysis, 451
—, hydrocarbon gases from, 456
—, hydrogen sulphide from, 456, 457
—, mercaptans from, 456
—, polysulphides from, 457
—, pyrolysis of, 457
—, reaction with methyl iodide, 451
—, — sulphur, 450
—, use in non-cutting oils, 456
Ethylsulphonic acid, properties, 1011
Ethyl sulphoxide, 451
Ethylsulphuric acid, ethyl alcohol from, 333, 1032
—, from ethylene, 321, 332, 333, 349, 1032
—, hydrolysis, 321, 332, 333, 340, 344, 1032
—, polymerization tendency, 594
Ethylsulphuryl chloride, 1035
Ethyl thioether, 452
Ethylthiophene, 455, 463
Ethyltoluene, from kerosene, 27
—, methylstyrene from, 146
—, production, 560
—, pyrolysis of, 146
Ethylvinylcarbinol, 505
Eucalyptus oil, 891
Eugenol, antioxidant, 907
Eurhodine, stabilization of gasoline, 897
Exothermic reactions, acetylene, 220, 221
—, in cracking, 98, 99
Explosion, analysis by, 1095-1098
—, process for carbon, 234
Explosives, from olefins, 881, 882, 883
Extractable matter, carbon black, 254
Extraction, alcohols with hydrocarbons, 394
—, lubricating oils, 366
—, mercaptans, 435-438
—, olefins, 354, 549
—, sulphonated compounds, 366, 1014, 1015, 1017

F

Factice, from ethylene dichloride-polysulphides, 475
Factors, influencing cracking, 100-105
—, influencing yield of carbon black, 241
Fat-hydrolyzing agents, from mineral oils, 1022, 1025
Fats, detergents from, 1023
—, emulsification, 1025, 1026
—, extraction with isopropyl chloride, 371
—, — trichloroethylene, 674
—, hydrolyzed with isopropylated aromatics, 375
—, latex from, 629
—, solubility in isopropyl chloride, 371
—, solvents, 614, 673, 674
—, sulphonated, 1019
—, synthetic, from wax acids, 960
Fat-splitting agents, sulphonated oils, 1015
Fatty acids, by bacterial oxidation, 1004
—, by dechlorination, 741
—, by oxidation of hexane, 853
—, by photochemical oxidation of paraffin oils, 939
—, by splitting of nitrosates, 581
—, condensation with ethionic acid, 1032, 1033
—, decolorization, 1025
—, destructive distillation, 721
—, distinguished from wax acids, 941, 959
—, effect of sulphuric acid, 1033
—, from butane, 1055
—, from Grignard compounds, 813
—, from lignin, 949
—, from lignite-tar oil, 938
—, from olefins, 814, 948
—, from oxidation of hexane, 938
—, — hydrocarbon solvents, 955
—, from paraffin oils, 939
—, from paraffins, 959
—, from paraffin wax, 738, 830
—, mechanism of formation, 959
—, octane from, 735
—, sulphoaromatic, preparation of, 1025
—, sulphonated, treatment of butyl alcohol, 1024
—, —, derivatives of higher paraffins by, 817
Fatty acid salts, oxidation of oils, 934-936, 938
—, oxidation of paraffin wax, 945
—, treatment of halogenated ethanesulphonic acids, 1033
Fatty acid soaps, in lubricants, 1031
Fenchyl alcohol, 890
Fermentation, mechanism of petroleum formation, 36
—, primary alcohols from, 332, 391
Ferralloy, hydrocarbon pyrolysis, 136
Ferric acetate, action on mercaptans, 447
Ferric bromide, catalyst, bromination of toluene, 778
—, —, formation of ethylidene bromide, 478
—, reaction with cuprene, 671
Ferric carbonate, absorption of hydrogen sulphide, 424
Ferric chloride, action on ethyl alcohol, 343
—, catalyst, alkylation of phenols, 810
—, —, chlorination of aromatics, 756, 757, 760, 764, 765, 770, 771, 773, 774
—, —, chlorination of methane, 690, 691, 698, 699, 701
—, —, compound with ethylene, 323
—, —, condensation olefins with aromatics, 559
—, —, condensation olefins with hydrocarbons, 562
—, —, condensation of olefins with organic chlorides, 569
—, —, esterification of glycols, 541
—, —, esterification of olefins, 144
—, —, ethylene reacted with hydrogen chloride, 322, 323
—, —, formation of acetals, 371
—, —, formation of chlorohydrins, 491, 492
—, —, in cracking, 191, 193, 197, 202
—, —, natural gas chlorination, 692
—, —, polymerization olefins, 589, 600, 612
—, chlorination of aromatics, 756, 757, 760, 764, 765, 770, 771, 773, 774
—, condensation of alkyl chlorides and phenols, 399, 400

Ferric chloride, condensation of alkylene oxides and hydrocarbons, 1059
—, effect on aluminum chloride cracking, 191
—, extraction of sulphur compounds, 461
—, formation of complexes with oils, 192
—, oxidation of mercaptans, 433
—, ozonized fractions treated with, 988
—, promoter, production of ketones, 411
—, tetrachloroethane by, 673
Ferric hydroxide, absorption of hydrogen sulphide, 425
Ferric nitrate, indicator, 1123
Ferric oxide, absorption of hydrogen sulphide, 425
—, catalyst, asphalt manufacture, 842
—, —, conversion of naphthenic acids to ketones, 1084
—, —, methane-steam reaction, 469
—, —, olefin chlorine addition, 469
—, —, oxidation of methane, 848
—, —, oxidation of transformer oils, 909
—, chlorohydrin formation, 493
—, effect on oxidation of petroleum, 906
—, evaluation of transformer oils, 911
—, hydration of olefins, 307
—, oxidation catalyst, 837, 838, 848, 893
—, reduced by ethylene, 67
Ferric phosphate, catalyst, carbon dioxide-ethylene reaction, 586
Ferric salts, hydration of acetylene, 676
Ferric silicate, cataylst, polymerization propylene, 599
Ferric sulphate, formation of dioxan, 555
—, oxidation of wax acids, 955
—, ozonized fractions treated with, 988
—, removal of gums, 902, 903
Ferric vanado-chromate, catalyst, oxidation hydrocarbons, 915
Ferricyanic complexes, 412
Ferricyanides, oxidation of mercaptans, 433
Ferrites, use in methane-carbon monoxide reaction, 932
Ferrocyanic complexes, 412
Ferro-nickel, electrodes, 263
Ferro-silicon, catalyst, hydrocarbon pyrolysis, 136, 182, 186, 187, 224
Ferroso-ferric oxide, catalyst, methane-steam reaction, 287
—, —, oxidation of methane, 862
Ferrous chloride, catalyst in cracking, 197
—, chlorohydrin formation, 492
Ferrous oxide, catalyst, production of hydrogen, 285
Ferrous salts, double compounds with olefins, 582
Ferrous sulphate, catalyst, ethylene absorption, 339, 341
—, estimation of peroxides by, 899
—, purification of acetylene, 664
Ferrous sulphide, catalyst, polymerization of acetylene, 668
Fireclay, catalyst, hydrocarbon pyrolysis, 136
Fire extinguishing agents, 706, 709, 710
Fixed carbon content, carbon black, 244
Flame, in pyrolysis, 218, 224
Flame propagation, rate, 974, 975, 976
Flames, hydrocarbon-air, characteristics, 975
Flame speed, olefins-air, 972
—, relation to maximum pressure, 975
Flame temperatures, carbon black production, 236
—, factors affecting, 236
Flash point, determination of, 1152
Flat flame for black production, 236
Flavoring materials, 362, 364, 396
Floor polishes, oxidized paraffin, 997
Florida earth, catalyst, lubricating oil, 609
—, refining hydrocarbons, 609
—, separation of olefins, 143
Floridin, catalyst, polymerization olefins, 589, 598-604
Flotation agents, sec.-butyl xanthate, 394
—, from acetylene, 685
—, oxidized hydrocarbons, 1000, 1001, 1002
Flow rate, chlorination methane, 689, 692
—, hydrogen from cracking processes, 175
—, pyrolysis hydrocarbons, 177, 184, 189
Flue gases, removal of hydrogen sulphide from, 424
Fluoboric acid, acetals by, 678
Fluoranthrene, by pyrolysis of acetylene, 82, 180
—, from pitch, 227
Fluorene, 82, 89, 227
Fluorides, catalysts in pyrolysis, 559
Fluorinated hydrocarbons, from chlorinated hydrocarbons, 708, 709
Fluorine, acetylene pyrolysis, 180
—, reactivity with paraffins, 686, 707
Fluoroboroethylene, formation, 596
Fluorochloromethanes, 707, 710
—, from fluorine-methane reaction, 707
—, properties, 710
Fluorosulphonic acid, action on ethylene, 342
Fluorspar, 595
Foam-producing agents, ter.-butylbenzene sulphonic acid, 400
—, by hydrocarbon oxidation, 837, 839
—, isopropylated aromatics, 375
—, monoalkyl ether esters, 525
—, preparation, 539
—, sulphonated polymerization products, 1024
Foodstuffs, ethylene oxide, 549
Foodstuffs, use of isopropyl alcohol in, 364
Formaldehyde, addition to blown residues, 1003
—, by oxidation of ethylene, 833
—, — ethane, 834, 851, 867
—, — n-hexane, 867, 868
—, — hydrocarbons, 833, 836, 838, 856, 867, 989
—, — isopentane, 867
—, — methane, 833, 858, 859, 931
—, — methyl alcohol, 860, 868
—, — paraffin wax, 857
—, — pentane, 852
—, — petroleum oils, 868
—, — propane, 867
—, carbon monoxide from, 887, 888
—, condensation reactions, 860
—, effect on ignition, 966
—, formic acid from, 887, 888, 931
—, from acetylene, 268, 885-887
—, from amyl alcohol, 405
—, from carbon oxides, 861
—, from furfural, 917
—, from glyoxal, 887, 888
—, from hydrocarbons, 854, 937
—, from methane, 847, 848, 872
—, from methanol, 786, 860; 868
—, from olefins, 873, 874, 876-879, 882-884
—, from ozonides, 882, 883, 884
—, from phosgene, 418
—, from propylene glycol, 530
—, from side-chain aromatics, 926
—, from water gas, 267
—, hexamethylenetetramine from, 882, 883
—, ichthyoform, 1036
—, in reaction of nitric oxide on hydrocarbons, 299
—, intermediate, combustion ethane, 850
—, —, formation of hydrogen cyanide, 299
—, —, oxidation of methane, 846, 848, 965
—, oxidation of, 861
—, oxidation prevented, 882
—, partial oxidation of acetaldehyde, 870
—, polymerization, 861, 869
—, properties, 861
—, purification of ichthyolsulphonic acid, 1037
—, — naphthenic acids, 1037, 1069
—, reaction with ammonia, 861
—, — mercaptans, 433
—, — olefins, 586-587
—, — sulphur dioxide extracts, 586-587
—, removal of gum from gasoline, 901
—, stabilization by ammonia, 863
—, uses of, 550, 628, 629, 860, 861, 1031
Formalin (formaldehyde), 860
Formamint, 860
Formates, from methyl chloride, 782
—, use in hydrolysis of alkyl chlorides, 792
Formic acid, acylation of olefin oxides, 538
—, addition to olefins, 330
—, by oxidation of ethane, 834, 851, 867
—, — formaldehyde, 861, 931
—, — hydrocarbons, 838, 856

Formic acid, by oxidation of methane, 846, 848, 864, 931
—, — petroleum distillates, 894
—, from acetylene, 268, 885-888
—, from brown-coal paraffin, 956
—, from carbon monoxide and water, 931
—, from cumene, 756
—, from formaldehyde, 887, 888
—, from hexadecane, 959
—, from maleic acid, 918
—, from naphthenic acids, 1085
—, from olefins, 874, 877-879, 883
—, from ozonides, 882, 883, 884
—, from Pennsylvania crude oil, 935
—, from petroleum distillates, 937
—, from quinone, 916
—, from stearic acid, 959
—, from triacontane, 958
—, hydration of olefins, 300
—, oxidation of hydrocarbons, 855, 856
—, stabilization by ammonia, 862, 863
—, use in oxidizing mineral oils, 936
—, — paraffin, 943, 990
Formin, 860
Formosa petroleum, 27
Fractional condensation, hydrocarbons, 1103, 1118
—, in analysis, 1099, 1103
—, olefin separation, 126, 137-140
Fractional crystallization, azeotropic mixtures, 1147
—, isolation of pure paraffins by, 1147
—, picrates of nitrogen bases, 826, 827
Fractional-distillation curves, 1110
Fractional distillation, olefin separation, 137-141
—, separation of diolefins, 160
Fractional extraction of olefins, 354
Fractionating columns, analytical, 1101, 1110-1115
Fractionation, bromine addition products, 1121
—, of gases in analysis, 1093
—, of hydrocarbons, 17, 353, 1095
—, of liquefied petroleum gases, 17
—, purification of hydrogen, 230
Fractionation curves, 1109
Fractionation methods, low temperature, 1104-1115
Frankonite, condensation catalyst, 573
Free energy, of carbon-ammonia reaction, 296
—, of hydrocarbons, 65, 93, 94, 588
—, of methane-carbon dioxide reaction, 282, 283
—, of methane-steam reaction, 278-280
Free-energy equations, hydration of propylene, 314
—, alcohol synthesis, 305
Free radicals, by pyrolysis of n-butane, 55
—, — propane, 52, 53
—, decomposition of, 47, 48, 52, 53, 55
—, from benzene, 259
—, from methane, 166, 169, 269
—, from paraffin hydrocarbons, 47, 48, 52, 53, 55, 176
—, from pentane, 272
—, in nitrogen oxides-hydrocarbon reaction, 299
—, reaction with hydrocarbons, 47, 48, 52, 53, 55
—, *see also* Labile residues
Friedel-Crafts reaction, 404, 398, 400, 417, 570, 653, 1056-1060
Fuel gas, removing hydrogen sulphide from, 988
—, yield from natural gas, 216
Fuel ignition, nuclear theory of, 977
Fuel oil, decomposition, electric arc, 259
—, use as wood preservative, 1031
Fuels, 15, 16, 213, 214
—, by pyrolysis, 210
—, cigarette lighters, 550
—, examination of, 1148
—, ionization during combustion of, 983
—, organic acids from, by combustion, 978
—, reactions during combustion, 978
—, solid, preparation with hexamethylenetetramine, 860
—, use of tertiary alcohols, 398
Fuller's earth, adsorbent for naphthenic acids, 1082
—, antioxidant, for transformer oils, 909
—, catalyst, hydrogen sulphide-olefin reaction, 584
—, —, olefin-carbazol condensation, 573
—, —, oxidation of paraffin wax, 942
—, extraction of sulphur compounds, 459
Fuller's earth, oxidation of ceresin, 950
—, refining oil, 609
—, removal of asphaltenes from transformer oils, 910
—, — gasoline gum by, 902
—, revivified with isopropyl alcohol, 366
—, separation of olefins, 143
Fulvenes, 658, 891
Fumaric acid, from lignin, 949
—, from maleic acid, 918
—, tartaric acid from, 505, 506
Fumigants, alkyl formates, 396
—, ethylene dichloride, 472, 473
—, ethylene oxide, 549
—, isopropyl esters, 373
—, oxidized oils, 1002
Fuming sulphuric acid, absorption of acetylene, 1034
—, — paraffins, 1007
—, action on naphthenes, 1008, 1009, 1010
—, — nitrogen bases, 821
—, — petroleum, 934, 1005, 1016, 1035, 1037
—, — petroleum distillate, 1012
—, oxidation of hydrocarbon molecule, 1005
—, petrolatum by, 1006, 1011, 1017
—, separation of olefins with, 77
—, sulphonation of saturated hydrocarbons, 1006
—, sulphonic acids by, 1007
—, treatment of gilsonite fraction, 1020
—, unsaturated compounds from hydrocarbons by, 933
—, wetting agents by, 1029
Fungicides, from high-sulphur oils, 456
—, sulphonated products, 1061
Furane, maleic acid from, 917
Furfural, maleic acid from, 917
—, selective solvent for aromatics, 34, 1143
—, separation of diolefins, 640
Furfuralcohol, selective solvent for separation of paraffin and naphthene hydrocarbons, 35
Furnaces, cracking, 211, 212, 213, 214
Fusel oil, amylene hydration, 380
—, composition, 797, 798
—, dienes from, 155, 157, 633
Fushun shale tar, 827, 828

G

Gabian petroleum, 192
Galalith, 860
Galician gasoline, oxidation of, 835
Galician naphthenic acids, 1076
Galician petroleum, cyclohexane from, 23
—, decomposition by aluminum chloride, 198
—, fusion with alkalis, 1035
—, naphthenic acids, 1062, 1079
—, nitration of, 1042
—, sulphonic acids from, 1035
Galician spindle oil, oxidation of, 934
Gallic acid, effect on autoxidation, 890, 913
Gallium, catalyst, chlorination benzene, 759
Gardinol, 1022
Gas analysis, 875, 962, 1093, 1095
Gas composition, effect on yield of carbon black, 241
Gaseous catalysts for oxidation, 864-866
Gaseous hydrocarbons, liquefaction of, 137-139
Gaseous products, of cracking, utilization of, 91, 350
Gases, by vapor-phase cracking of gas oil, 132
—, dehydration of, 349, 355
—, desulphurization of, 349, 355
—, non-condensible, 219
—, purification, 213
Gas-gasoline ratio, influence of time-temperature index, 103
Gas, in petroleum, 11
Gas naphtha, solvent for separation of hydrocarbons, 142
Gas oil, cracking of, 98, 132, 133
—, dehydration of sec.-butyl alcohol, 394
—, distillation characteristics, 1148
—, iodine value of, 935
—, naphthenic acids from, 1063
—, oxidation of, 838, 840, 935, 990

Gas oil, separation of acetylene, 152
—, — higher olefins, 142
—, sulphonated, 1019
Gasolines, absorption of oxygen, 902
—, accelerated oxidation test, 896
—, acetylene from, 872
—, action of sulphuric acid, 352, 1006, 1007
—, aniline points of, 1142
—, anti-knock value, 110, 111, 985
—, aromatic hydrocarbons in, 33, 34, 561, 562, 1142
—, by oxidation, 991-993
—, by pyrolysis, 37, 91, 130, 132, 165
—, calculation of unsaturates in, 1142
—, characteristics, 813
—, chlorination, 485, 727, 730, 731
—, cracking of, 96, 99, 103, 108
—, determination of gum content, 894-896
—, dienes in, 631
—, effect of diolefins, 900, 901
—, — olefins, 900, 901
—, — peroxides, 901
—, — sunlight, 902
—, extraction of acids from, 902
—, — oil by, 939
—, — sulphonic acids, 1014
—, — sulphur compounds from, 460
—, from naphthenes, by aluminum chloride, 203
—, from natural gas, 15, 242, 355
—, from Rangoon wax, 191
—, gum formation, 642
—, —, mechanism of, 899
—, gum in, 893-903
—, gum induction periods, 898
—, gumming tendency, 110, 113
—, Gyro process, 113
—, inhibitors in, 898
—, iodine number, 104
—, lead tetraethyl in, 813
—, mechanism of gum formation in, 902
—, oxidation of, 835, 836, 854, 895, 900, 973, 980
—, phenols from, 902
—, prevention of gum formation, 896-898, 903
—, products from, 613, 914, 917
—, refining with aluminum chloride, 190-193, 201
—, — sulphuric acid, 352, 1006, 1007
—, reforming, 112
—, removal of gum from, 901-903
—, — methane from gases, 290
—, — occluded air from, 903
—, — peroxides from, 901
—, — sulphur from, 427
—, separation of soap emulsion with, 1067, 1068
—, shale-oil, treatment with ozone, 903
—, solvent in chlorohydrin formation, 490
—, stability tests, 895, 896, 898
—, stabilization of, 15, 897, 898
—, straight-run, 20-26
—, sulphur content, test for, 1150
—, testing of, 1147
—, treated with phthalic anhydride, 1059
—, treatment of cracked fractions, 900
—, use with natural gas, 218
—, yields of, 11, 91, 92, 103, 106-108, 110, 191
Gastex carbon black, 250
Gelatin, dehydrated with isopropyl alcohol, 366
—, precipitation by tumenolsulphonic acids, 1038
—, use in plastic compositions, 860, 1031
Gelatins, by glycol dinitrate, 517, 518
Gels, catalysts for photochemical oxidation, 939
Geraniol, formation, 650
Geranyl acetate, formation, 649
German carbon black, 246, 252
German crudes, thiophene in, 454
German naphthenic acids, 1062, 1079, 1081
Germicides, halogenated hydrocarbons, 706
Gilsonite, nitration of, 1053
Gilsonite distillates, sulphonated, 1020
Girbotol, 552
Glass, catalyst for chlorination, 478, 729
—, — mineral oil oxidation, 936
—, effect in oxidation of waxes, 942, 943
—, — polymerization of acetylene, 82
—, — pyrolysis of hydrocarbons, 64, 71
—, effect on ignition temperatures, 967, 968
Glass packing, oxidation of acetaldehyde, 932
—, — paraffins, 951
Glow discharge, action on hydrocarbons, 275, 849, 987
Glucinum halides, refining oils, 597
Glues, 860, 1027, 1028, 1038
Glutaric acid, 929, 1047
Glutathione, 496
Glycerol, anti-freeze properties, 515
—, by oxidation of methyl alcohol, 989
—, catalyst, diolefins, polymerization, 619
—, condensation with olefin oxides, 538
—, esterification of wax acids, 999
—, from allyl alcohol, 494, 505, 506
—, — fats, 1025
—, — petroleum hydrocarbons, 799
—, hydration of ethylene, 311
—, reaction with boron fluoride, 596
Glycerol diacetate, 160, 664
Glycerol dichlorohydrin, from allyl chloride, 799
Glycerol monoacetate, 664
Glycerophosphates, precipitated by isopropyl alcohol, 367
Glycol—*see also* Ethylene glycol
Glycol, butadiene from, 157
—, by hydration of ethylene oxide, 510, 535
—, by oxidation of ethylene, 991
—, — methyl alcohol, 989
—, dehydration, 526, 534
—, diethylene, 526-528
—, di-metallic derivatives of, 511
—, esterification of wax acids, 997, 999
—, extraction of lubricating oils, 516
—, from α-chlorohydrins, 487, 496, 508-510
—, — ethyl naphthenates, 1072
—, — hydrocarbon peroxides, 900
—, — olefins, 10, 123, 505, 506, 510, 511, 871, 873, 876, 877
—, — olefin dichlorides, 506, 507
—, ketone formation, 532
—, mono-metallic derivatives of, 511
—, nitration of, 517
—, oxidation of, 514
—, polyesters from, 521
—, polyglycols from, 526
—, reaction with boron fluoride, 596
—, — sulphuric acid, 555
Glycol acetals, 512, 513
Glycolaldehyde, 514
Gycolamine, 581
Glycol diacetate, 160, 518, 519, 586, 587
Glycol di-esters, 160, 518, 519, 540, 586, 587
Glycol di-formates, 519
Glycol dinitrate, 515-517, 581
—, gelatins from, 517, 518
—, stabilization, 550
—, toxicity, 517
Glycol esters, from ethylene chlorohydrin, 487
—, from ethylene dichloride, 507, 518
—, from ethylene glycol, 518-521
—, from olefin oxides, 518, 519
—, of dicarboxylic acids, 520, 521
Glycol ethers, 160, 521-523, 539, 548, 549
Glycollic acid, 514, 530, 674
Glycol monoacetate, 34, 160, 518, 519, 520, 1143
Glycol mono-formate, 519, 664
Glycol oleate, 519
1,2-Glycols, higher, 529-532
1,3-Glycols, from olefins and formaldehyde, 586-587
Glycol stearate, 519
Glycol succinates, structure, 521
Glyoxal, 514, 876, 877, 885-888
Glyoxylic acid, 514
Gold, catalyst for ammonia-hydrocarbon reaction, 297
—, — aromatization, 186
—, — oxidation of hydrocarbons, 863, 864, 875, 876
—, — vinyl ethers, 682
—, effect on ignition temperatures, 968
—, hydration of olefins, 307, 314
Gold-copper, catalyst, oxidation of alcohols, 869-870
Gold salts, action with acetylene, 667

Goodwin carbon black, 245, 250, 253, 254
Grahamite, nitration of, 1054
Graphite, 215, 218, 235, 247, 248, 250
—, catalyst, aromatization, 182, 185
—, —, chlorination hydrocarbons, 699, 731
—, —, olefins-acetylene pyrolysis, 187
—, —, pyrolysis of methane, 39, 40, 136, 166
—, from natural gas, 208, 216
Graphite, electrodes, 762, 927
Graphitization, coke, 229
Gray benzol, by pyrolysis, 86
Greases, from halogenated hydrocarbons, 742
—, from oxidation products, 996
—, reaction with sulphur, 1061
Green acids, 1016, 1021, 1030
Grignard reaction, 371, 749, 750, 801, 812, 813
Grinding compounds, preparation, 1031
Grit, in carbon black, 254
Grozny paraffin wax, nitration of, 1053
—, oxidation of, 941, 943
Grozny petroleum, cracking of, 101
—, hydrocarbons in, 30
—, oxidation of, 950
—, sulphur compounds of, 450
Guanidine, reaction with dihalogen derivatives, 808
Gulf Coast petroleum, naphthenic acids from, 1068
—, straight-run gasoline from, 20
Gum content, determination of, 894-896
Gum formation, accelerated oxidation test for, 896
—, catalyzed by mercaptans, 421, 422
—, cracked gasolines, 642, 871
—, in gasolines, prevention of, 896-898, 903
—, mechanism of, 902
—, removal by sodium vapor, 427
Gum-forming compounds, removal by ozone, 988
—, test for, 1150
Gum-forming properties, liquid-phase gasoline, 110
—, olefins, 1126
Gum-inhibiting index, 898
Gums, acids from, 902
—, analyses of, 901
—, by oxidation, 840, 894
—, from peroxides, 900
—, in gasoline, action in engines, 894
—, precipitated by isopropyl alcohol, 367
—, purification of, 16
—, removal from gasoline, 902, 903
—, solubility in sec.-butyl alcohol, 394
Gum tests, 984, 1153
Gyro process, cracking, 111, 112

H

Halides, catalysts, ammonia-carbon monoxide reaction, 298
—, —, condensation of olefins with acetyl chloride, 569
—, —, — olefins with aromatics, 260, 559, 563, 565
—, —, — olefins with phenols, 565, 566, 567
—, —, polymerization of diolefins, 618, 623
—, —, polymerization styrene, 611
—, —, production of acetone, 408
—, dehydrogenation catalysts for alcohols, 405
—, metallic, reaction with olefin oxides, 540
Halogen acids, action on ter.-butyl alcohol, 397
—, addition to acetylene, 666
—, hydration catalysts, 305, 306
—, reactions with conjugated diolefins, 645-648
Halogenated alkylbenzenes, pyrolysis of, 147
Halogenated ethers, extraction of mineral oils with, 991
Halogenated hydrocarbons, acetylene separation with, 152
—, extraction of mineral oils with, 991
—, fluorinated derivatives from, 709
—, from acid extract, 485
—, ignition temperatures, 968
—, lubricants from, 742
—, oxidation to acids, 931
Halogenated paraffins, adhesives from, 742
—, condensation with amines, 808
—, reaction with alkalis, 742
—, — cellulose xanthate, 741
Halogenation, butane, 483
—, cycloparaffins, 744-753
—, hydrocarbons, estimation by, 1128
—, isopropyl alcohol, 373
—, of methane homologues, 711
—, olefin determination by, 1131
—, secondary alcohols, 433
—, unsaturated oxygenated products, 837
Halogen hydrides, *see* Hydrogen halides
3-Halogenopropylene, addition of hydrogen halides to, 327
Halogens, action on iodomethanes, 707
—, action on tertiary alcohols, 397, 403
—, addition to acetylene, 666
—, catalyst, in cracking, 107
—, —, pyrolysis of hydrocarbons, 134, 135, 152, 225
—, compounds with dioxan, 556
—, ethylene addition, 464
—, hydrocarbon derivatives, nomenclature, 466, 467
—, interchange of, in alkyl halides, 800
—, reaction with alcohol, 392
—, — mercaptans, 432, 433
—, — thiophene, 454
—, substitution by hydrogen, 478
Halohydrins, of higher olefins, 502-504
—, properties of, 486
Heat, effect of, adsorption of olefins, 143
—, —, dechlorination of mono-chloro paraffins, 804
—, —, olefins from alkyl halides, 801, 802
—, —, production of synthetic rubber, 625, 626
Heat content, change of, in pyrolysis of hydrocarbons, 172
Heated surfaces, ignition of gases by, 964
Heat effect, of cracking, 98
—, production of gasoline by cracking, 99
Heating elements, use in pyrolysis of methane, 148, 149
Heating time, effect of, acetylene from methane, 151
—, —, on unsaturated hydrocarbons, 125
—, —, pyrolysis of ethane, 123
Heating value of natural gas, 242
Heat of reaction, ethyl chloride dissociation, 323
—, methane chlorination, 687
Heat transfer, high temperature, materials for, 189
—, use of ethylene glycol for, 516
Heavy oils, cracking, by aluminum chloride, 190
—, sulphur content, tests for, 1150
Helium, analysis and separation of, 1099
—, in natural gas, 12, 13, 14
Helium ions, catalyst, for acetylene polymerization, 273
Hemimellitene, from kerosene, 27
—, in straight-run gasoline, 26
Hendecane, *see* Undecane
Heptachlorohexane, from gasoline, 730
Heptadecane, action of aluminum chloride on, 194
Heptaisobutylene, properties of, 601
Heptaldehyde, autoxidation of, 851
—, by oxidation of octaldehyde, 855
Heptanaphthene, by pyrolysis of amylene, 78
—, decomposition by aluminum chloride, 198
Heptanaphthenic acids, 1069, 1070
Heptane, action of nitrogen pentoxide on, 1044
—, bromination of, 742, 743
—, 2-bromoheptane from, 742
—, by pyrolysis of amylene, 78
—, — wax, 60
—, chlorinated, olefins from, 803
—, chlorination of, 735, 736, 739
—, condensation with alkylene oxides, 1059
—, critical inflexion temperature of, 966
—, decomposition, electric arc, 257
—, from *Pinus sabiniana*, 735
—, heptyl bromide from, 743
—, incomplete combustion of, 853
n-Heptane, critical solution temperature with aniline, 1138, 1139
—, effect on butyl sulphide pyrolysis, 457
—, in natural-gas gasoline, 18
—, in straight-run gasoline, 22, 24, 27
—, knock rating of, 985

n-Heptane, minimum ignition temperature of, 967
—, nitration of, 1043, 1044
—, oxidation of, 836, 915
—, pyrolysis of, 61, 62
—, reaction with antimony chloride, 1061
—, — nitrosyl chloride, 1054, 1055
—, — sulphur, 428
—, solvent for thiophanes, 453
—, sulphonation of, 1007
—, thermal stability of, 90
Heptane-octane mixture, hydrolysis of, 61
n-Heptanol formation, 1059
Heptanol-2, 402
3-Heptene, hydration by benzenesulphonic acid, 385
—, polymerization of, 607
Heptenes, action of chlorous anhydride on, 504
—, addition of acetic acid, 331
—, by decomposition of diamylene, 604
—, by pyrolysis of wax, 60
—, hydration, by acids, 300, 313
—, reaction with sulphuric acid, 385, 386
sec.-Heptyl acetate, from heptylene, 331
Heptyl alcohol, from 3-heptane, 385
sec.-Heptyl alcohol, 402
—, dehydration of, 394
Heptylbenzene, from benzene, 562
Heptyl bromide, from heptane, 743
Heptylenes, *see* Heptenes
Heptyl esters, from monochlorinated heptanes, 799
Heptyl mercaptan from distillate, 448
n-Heptyl mercaptan, properties of, 432
Hexabromobenzene, from benzene, 768
Hexabromocyclohexane, formation of, 768
Hexabromohexahydrotriphenylene, 671
Hexabromohexane, from n-hexane, 742
Hexabromohexene from divinylacetylene, 670
Hexabromoisobutane, by isobutane bromination, 721
—, by isobutene bromination, 483
Hexabromoisobutylene, by bromination of isobutane, 721
Hexachlorobenzenes, from chloroform pyrolysis, 692
—, — benzene, 757, 758, 761, 762, 764, 774
—, — diisoamyl, 735
—, — kerosene, 738
Hexachlorobutadiene, from diisoamyl, 735
Hexachlorocyclohexane, formation of, 757
—, from benzene, 757, 759, 761
Hexachloroethane, by acetylene chlorination, 476
—, by chlorination ethane, 712, 713
—, by ethylene chlorination, 476
—, by natural gas chlorination, 691, 694, 700
—, by tetrachloroethane chlorination, 476
—, from carbon tetrachloride-methane reaction, 706
—, — isobutane and iodine chloride, 721
—, — kerosene, 738
—, — natural gas, 714
Hexachloropropane, by chlorination of propane, 717
Hexadecane, acidic substances from, 959
—, mechanism of pyrolysis, 63
—, oxidation of, 758, 759
—, —, effect of turpentine, 957
—, pyrolysis of, 62, 63, 131
Hexadecene, isomerization of, 590
—, mechanism of pyrolysis, 77
—, mercuric salt complex, 1132
—, polymerization of, 78, 80, 606, 607
—, pyrolysis of, 76, 77, 606
—, —, effect of pressure, 78
—, —, effect of temperature, 78
—, reaction with sulphuric acid, 386
1,5-Hexadiene, autoxidation of, 893
—, polymerization of, 620
—, reaction with sulphuric acid, 661
2,4-Hexadiene, autoxidation of, 893
Hexadienes, by butane pyrolysis, 57, 174
Hexaethylbenzene, 560
Hexahydrobenzaldehyde, production of, 417
Hexahydrobenzoic acid, from petroleum, 1082
Hexahydrocymene, dehydrogenation of, 85
Hexahydrophenol, from phenol, 634
Hexahydro-o-phenylenediacetic acid, 929, 930
Hexahydroterephthalic acid, production of, 624
Hexahydrotoluene condensed with alkylene oxides, 1059
Hexahydroxylene, dehydrogenation of, 85, 181
—, from petroleum, 430
Hexaisobutylene, properties of, 601
Hexamethylenetetramine, 860, 863
—, carbon black adsorptive capacity for, 248
—, formation, 861
—, from formaldehyde, 882, 883
—, from methylene dichloride, 705
—, use in oxidation of paraffins, 945
Hexanaphthenic acids, 1069
Hexane, absorption of oxygen by, 754
—, action of aluminum chloride on, 194, 197
—, — sulphuric acid on, 1007, 1010
—, bromination of, 742
—, butadiene from, 155
—, butane from, 194
—, by pyrolysis of amylene, 78
—, — wax, 60
—, chlorinated, olefins from, 803
—, combustion, effect of nitrogen, 976
—, compression strength of, 978
—, condensed with alkylene oxides, 1059
—, critical inflexion temperature of, 966
—, decomposition by electric arc, 257
—, dehydrogenation of, 859
—, effect on oxidation of benzaldehyde, 980
—, from acetylene pyrolysis, 180
—, from acetylene, silent discharge, 265
—, from ethane, 272
—, from ethylene, 195, 872, 876
—, —, by silent discharge, 269
—, halogenation of, 744
—, incomplete combustion of, 853
—, oxidation of, 852, 854, 938, 979, 990
—, —, with chromyl chloride, 832
—, —, with ozone, 868
—, partial oxidation of, 859
—, pentane from, 194
—, propane from, 194
—, reaction with acetyl chloride, 1058
—, — antimony chloride, 1061
—, slow phosphorescent combustion of, 983
—, solvent, cyclopentadiene isomers, 643
—, —, hydrogen sulphide, 423
—, —, oxidation of olefins, 880
n-Hexane action of sulphur trioxide on, 1008
—, chlorination of, 727, 734, 736
—, critical inflexion temperature of, 967
—, from divinyl-acetylene, 670
—, in straight-run gasoline, 22, 24, 27
—, mechanism of pyrolysis, 60, 61
—, minimum ignition temperature of, 967
—, nitration of, 1041, 1042, 1051
—, oxidation of, 867
—, pyrolysis of, 59, 60, 172
—, reaction with carbon monoxide, 418
—, — sulphur, 428
Hexane-air, combustion products, 973
—, ignition temperatures of, 978
—, rate of flame propagation in, 975
Hexanesulphonic acid, 1007
Hexanoic acid, by oxidation of hexane, 868
—, formation, 856
—, from hexadecane, 959
—, from paraffin wax, 944
—, from pentane, 939
Hexanol, from olefins, 318
n-Hexanol from fusel oil, 797
2-Hexanol, from 1-hexane, 384, 607
—, from 2-hexane, 385
—, use of, 402
Hexanolamine, 542
Hexatriene, by pyrolysis, 177
1-Hexene, by ethylene polymerization, 595
—, from ethylene, by silent discharge, 266, 269
—, hydration of, 384, 607
—, polymerization of, 607
2-Hexene, hydration of, 385
—, reaction with N-chlorourea, 503
Hexene chlorohydrins, formation of, 503
—, reactions of, 503
Hexene derivatives, from benzene, 563

2-Hexene oxide, reaction with ammonia, 542
Hexenes, absorption of oxygen by, 889
—, alcohols from, 313, 318
—, alkylsulphuric esters from, 313
—, by acetylene pyrolysis, 81
—, by butane pyrolysis, 174
—, by cracking spray oil, 163
—, by cyclohexane pyrolysis, 85
—, by oxidation of hexane, 852, 867
—, by pyrolysis of ethylene, 66, 68
—, — wax, 60
—, chlorination by sulphuryl chloride, 484
—, condensation with benzene, 563, 1128
—, dipolymers of, 1127
—, double compound with mercuric acetate, 583
—, from ethylene, 876
—, from hydrolysis of hexyl chlorides, 792
—, from monochlorhexanes, 384
—, from propylene, 879
—, hydration, by acids, 300, 313, 318
—, hydrogen halide addition to, 329
—, polymerization of, 78
—, pyrolysis of, effect of pressure, 78
—, reaction with formic acid, 330
—, — ozone, 885
—, — sulphur, 429
—, — sulphuric acid, 376, 383-385
Hexyl acetate, from hexyl chloride, 792
sec.-Hexyl acetate, properties of, 402
sec.-Hexyl alcohol, by hydration of olefins, 383, 401
ter.-Hexyl alcohol, dehydration of, 392, 394
—, properties of, 403
Hexyl alcohols, by hexene hydration, 384
—, from lower alcohols, 345
Hexylamine, by reduction of nitrohexane, 1042, 1043, 1051
Hexylbenzene, formation of, 1128
—, from benzene, 562, 563
Hexyl bromide, from propylene, 326
Hexyl chloride, from propylene, 326
—, hydrolysis of, 791, 792
Hexylene acetochlorohydrin, 503
Hexylene oxide, reaction with hydrochloric acid, 503
Hexylene polymers, cyclicization of, 78
—, decomposition of, 78
Hexylenes, *see* Hexenes
Hexyl esters, from monochlorohexane, 799
Hexyl formate, from hexene, 330
Hexyl halides, from hexene, 329
Hexyl hexanoate, by oxidation of hexane, 868
Hexyl-p-phenylenediamine, stabilization of gasoline by, 897
Hexylresorcinol, stabilization of chloroethylene by, 674
Hexylsulphonic acid, properties of, 1011
Hexylsulphuric esters, from hexenes, 384
Hexylylresorcinol, 811
Hiding power of carbon black, 254
Higher alcohols, by hydration of olefins, 391
—, by hydrogenation of acids, 990
—, by hydrolysis of higher alkyl halides, 786, 787, 799
—, by oxidation of waxes, 1001
—, from alkylene oxides and hydrocarbons, 1059
—, from carbon monoxide, 799
—, from cracked gasoline, 349
—, from higher alkyl halides, 799
—, from lower alcohols, 799
—, from oxidized paraffin wax, 990, 995, 996
—, use in coatings, 995, 996
Higher sec. alcohols, from petroleum, 401
—, oxidation to ketones, 402
—, use in purification of slack wax, 398
Higher ter. alcohols from petroleum, 402, 403
—, uses, 403
Higher alkyl halides, hydrolysis of, 786, 787, 788, 799
Higher diolefins, 637-638
Higher glycols, dehydration of, 531
Higher 1,2-glycols, 529-532
Higher olefins, by polymerization of olefins, 80, 145, 355
—, by thermal degradation hydrocarbons, 145
Higher olefins, mechanism of pyrolysis, 75, 76
—, polymerization of, by pyrolysis, 75
—, production by pyrolysis of ethane, 122
—, pyrolysis of, 75-77, 144
—, separation of, by gas oil solvent, 142
High-frequency discharge, use, oxidation of hydrocarbons, 993
Hollow electrodes, use of, 261
Hot-wire ignition curves, 969
Humidity, effect on yield of carbon black, 241
Humus sulphur content, of Colorado oil shale, 463
Hydraphthal, use in detergents, 1022
Hydration, acetylene to acetaldehyde, 675-678
—, allyl chloride, by sulphuric acid, 500
—, amylenes, by dilute acids, 318
—, β-butylene oxide, 531
—, catalytic, of 2-butene, 316-318
—, —, of ethylene, 306-312
—, —, of propylene, 307, 313-315
—, cyclic olefins, by sulphuric acid, 389
—, dimethyl ether, 783
—, ethylene, 303, 305-307, 311-313, 318, 332
—, ethylene oxide, 510
—, heptenes, 313
—, hexenes, 313, 318, 383-385
—, isobutene, 313, 315, 318, 328
—, iso-olefins, 389, 390
—, olefin oxides, 526
—, olefins, 143
—, —, catalysts for, 300-319
—, —, higher alcohols from, 397, 401, 403
—, —, oxalic acid, as catalyst, 331
—, —, phosphoric acid, as catalyst, 303, 304, 307
—, —, use of sulphuric acid, 792
—, —, with dilute mineral acid, 353
—, pentenes, sulphuric acid as catalyst, 382, 387
—, propylene, 305, 307, 318, 348
—, —, free-energy equations, 314
—, propylene homologues, 376-389
Hydrazine, reaction with olefin oxides, 544
Hydrazine hydrochloride, tests of sulphur by, 1151
Hydrazoic acid, treatment of naphthenic acid, 1077
Hydrindene, by pyrolysis of acetylene, 81
Hydriodic acid, esterification of isopropyl alcohol, 371
—, hydration of ethylene, 318
—, — isobutene, 328
—, reaction with olefins, 300, 320, 328, 329
—, treatment of polyvinyl bromide, 681
Hydroaromatic bases, in California petroleum, 827
—, relation to alkaloids, 819
Hydroaromatic olefin oxides, production of, 536
Hydroaromatics, in kerosene, 28
Hydrobromic acid, acetylene addition, 472, 477, 478
—, allyl bromide addition, 480, 481
—, catalyst, bromination hydrocarbons, 1131
—, —, formation of fumaric acid, 918
—, effect, ethylene bromination, 477
—, esterification of isopropyl alcohol, 371

—, wetting agents from, 1033
Jellies, from cuprous mercaptides, 445
Jelly, petroleum, composition of, 29

K

Kalista carbon black, analysis of, 246
Kauri, solvents for, 373, 395, 402, 525
Kentucky carbon blacks, 251
Kentucky cokes, analysis of, 227
Kerosene, acetylene from, 872
—, acids from, 939
—, aromatic derivatives from, 561, 562
—, aromatic hydrocarbons in, 33, 34
—, as a solvent, 142, 230, 493, 741
—, bacterial oxidation, 1004
—, burning tests, 1153
—, carbon from, 216
—, chlorination of, 738, 939
—, classification of, 26
—, drying oils from, 740, 805
—, flash point of, 1152
—, from crude petroleum, 26-28
—, hexachlorobenzene from, 738
—, hexachlorethane from, 738
—, hot wire ignition curves, 969
—, maleic acid from, 1063
—, naphthenic acids from, 1063
—, nitration of, 1054
—, nitrogen compounds from, 821
—, oxidation of, 992, 993, 1002
—, perchloromesole from, 738
—, pyrolysis of, 61, 222
—, reaction with ammonia, 216
—, — olefin oxides, 545, 1059
—, — sulphur chloride, 1060
—, refining of, 1148
—, removal of aromatics from, 1143
—, soaps from, 939

Kerosene, sulphonation of, 1007
—, sulphonic acids from, 1020
—, sulphur dyes from, 430, 431
—, sulphur in, 1008, 1150
—, testing of, 1147
—, tetrachloromethane from, 738
—, used in purifying hydrogen, 230, 231
Ketene, as acetylating agent, 399, 414
—, chemical properties, 413
—, decomposition of, 414
—, physical properties, 414
—, preparation of, 413, 414
—, reactions of, 414
Ketols, formation of, 856
Ketones, acetylene solvents, 262
—, alkylation of, 419, 574
—, bisulphite compounds, 1084
—, by dehydration of glycols, 531
—, by dehydrogenation of alcohols, 415
—, by Friedel-Crafts reaction, 417, 418, 1056-1059
—, by hydrolysis of ozonides, 831, 844, 882, 939
—, by isomerization of olefin oxides, 546
—, by nitration of naphthenes, 1048, 1051, 1052
—, by oxidation of hydrocarbons, 831, 834, 837, 843, 938, 939, 987, 990, 1001
—, — pinene, 889
—, catalyst, polymerization of styrene, 611
—, condensation with olefins, 574
—, cyclic, formation of, 419, 547
—, effect on antiknock value, 984
—, from alkylbenzenes, 1055
—, from aromatic alcohols, 926
—, from butene-2, 318
—, from ceresin, 950
—, from cyclohexane, 197
—, from ethylene, 307
—, from Kimmeridge shale oil, 463
—, from naphthenic acids, 1084, 1085
—, from olefins, 129, 419, 502, 559, 843, 844, 871, 882
—, from olefins and acid chlorides, 568-570
—, from oximes, 579
—, from paraffins, 951
—, from secondary alcohols, 391, 396, 402, 404
—, from water vapor and hydrocarbons, 274
—, from wax acids, 998
—, gum inhibitors, 897
—, ignition temperatures, 968
—, in oxidized hydrocarbons, 991, 992
—, properties of, 408, 409, 415, 416
—, reaction with cyclopentadiene, 658, 891
—, — ethylene oxide, 556
—, — hydrocyanic acid, 410
—, — mercaptans, 433
—, sulphide solution for removal of sulphur, 427
—, utilization of, 411, 412, 413, 414, 415, 416
—, unsaturated, condensation products from, 585
—, —, from cycloparaffins by aluminum chloride, 197, 198
—, x-ray examination of, 958
Ketone complexes, promoters, polymerization of ethylene, 594
Ketone oximes, reaction of hydrocarbons and nitrosyl chloride, 1055
Ketonic acids, by Friedel-Crafts reaction, 565, 1058, 1059
Ketoses, condensation with olefin oxides, 538
α-Ketotetrahydronaphthalene, from hydroaromatic compounds, 926, 930
Kettleman Hills, crude oil from, 11
Kieselguhr, adsorption of mercaptans by, 446
—, catalyst for esterification of olefins, 324
—, — pyrolysis, 134
—, for extraction of sulphur compounds, 461
—,.separation of acetylene by, 134
—, use in olefin-sulphite reaction, 575
Kimmeridge shale oil, refining of, 463
—, sulphur compounds in, 463
Kissling reagent, for extraction of oxidized products, 911
Knock-inducers, effect of, on ignition, 969, 971
—, —, mechanism of combustion, 977
Knocking, of motor fuels, 982
Knocking tendency, effect of chain length, 985
Knock rating, bouncing pin method, 984
—, measurement of, 984-986
Knock-suppressing compounds, 983
Knock-suppressors, effect on ignition, 969, 971
—, — mechanism of combustion, 977
Knoop's rule, β-oxidation, 960
Koetei petroleum, aromatics in, 25,
Kontakt, 1014, 1020, 1022, 1026
Krasnodar gasoline, photochemical chlorination of, 794
Kurokawa petroleum, effect of ozone on, 844

L

Labile oxygen, 267
Labile residues, from ethane, 44
—, from ethylene, 66
—, from hydrocarbons, 107
—, from methane, 40
—, polymerized, 40
—, reaction of, 44, 66
—, *see also* Free radicals
Lachman process, extraction of sulphur compounds, 460
Lacquer plasticizers, extracted from petroleum oxidation products, 366
Lacquers, compositions, 548
—, dichlorodiethyl ether as diluent, 498
—, from acid sludge, 1030
—, from polymerized butadiene, 617
—, manufacture of, 541
—, methanol solvent in, 785
—, oxygenated solvents for, 992
—, resins in, 498
—, use of amyl esters, 797, 798
—, — sec.-butyl acetate, 394-396
—, — higher secondary alcohol esters, 401, 402
—, — isopropyl acetate, 373
—, — isopropyl alcohol in, 366
—, — nitrated distillates, 1052, 1053
—, — oxidized paraffin esters, 998
Lacrimatory oil, 2,3-dimethylbutadiene hydrobromide, 647
Lacrimatory substances, from nitrosyl chloride reactions, 1055
Lactic acid nitrile, solvent, diolefin separation, 160
Lactone method, constitution of naphthenic acids, 1078
Lactones, from oxidation of paraffin wax, 960, 1001
—, glycols from, 511
Lactonic acids, from hexadecane, 959
Lag on ignition, definition, 964
Lakes, suspension of, 375
Lampblack, 234, 243
—, analysis of, 246
—, by incomplete combustion, 234
—, early use, 252
—, from carbon monoxide, 218
—, from chlorination of hydrocarbons, 687
—, from hydrocarbons, 214, 215, 218, 219
—, from hydrocarbons and air, 220, 221
—, from natural gas, 207, 216, 217, 224
—, from oil, 218
—, from tar, 218
—, in hydrocarbon-sulphur reaction, 429
—, precipitated, 220
—, production, 206, 207
—, properties, 250
—, removal of, 216-220
—, separation, by filtration, 218, 219
—, use in printers ink, 252
—, use in production of cyanides, 293
—, volatile matter content, 245
Lamp method, total-sulphur test, 1150
Lanadin, 1022
Lanthanum, catalyst, chlorination of benzene, 759
Lanthanum oxides, catalysts, petroleum pyrolysis, 157, 158
Latex, butadiene polymerized in presence of, 628
—, synthetic, from chloroprene, 639
Latex mixtures, preparation of, 629
Laurylsulphonic acid, 1011
Lava burner tips, 241
Lead, absorption of hydrogen sulphide, 425
—, catalyst, ethylene chlorine addition, 470
—, —, for hydrocarbon-steam reaction, 285
—, —, glycol production, 511

Lead, catalyst, natural gas chlorination, 691
—, —, olefins-acetylene pyrolysis, 187
—, —, oxidation of transformer oils, 908, 909
—, —, oxidation of petrolatum, 934
—, —, polymerization of olefins, 610
—, —, production of olefin oxides, 536
—, —, pyrolysis of mineral oils, 134
—, distillation of butadiene in plant of, 641
—, effect on ignition temperatures, 967
—, — oxidation of petroleum oil, 934, 935
—, — pressure oxidation, paraffin wax, 942
—, heat absorbent, oxidation of hydrocarbons, 923
—, molten, dehydrogenation catalyst for alcohols, 405
—, —, use in hydrocarbon decomposition, 220
—, reaction with vinyl compounds, 680
—, removal of gasoline gum by, 902
—, sulphur from distillates with, 427
—, use in chlorination vessels, 728, 729
Lead ammonium chloride, reaction, with aromatics, 774, 780
Lead arsenate, use in insecticide, 1027
Lead borate, aromatization catalyst, 183
—, oxidation catalyst, 863
Lead chloride, catalyst, methane chlorination, 690
—, —, nuclear chlorination of toluene, 771
—, —, oxidation of methane, 864
—, —, pyrolysis of alkyl chlorides, 802
—, lead tetraethyl from, 813
Lead chromate as catalyst, oxidation of gas mixtures, 1098
—, oxidation of methane, 848, 864
Lead compounds as catalysts, ethylene absorption in sulphuric acid, 340
—, oxidation of paraffin wax, 944, 953
—, oxidation of petroleum fractions, 933
—, preparation of lubricating oils by oxidation, 901
Lead dioxide, catalyst, oxidation of hydrocarbons, 920
—, —, oxidation of transformer oils, 909
—, removal of gum from gasoline by, 903
Lead disulphide, formation in sweetening, 442
Lead electrodes, for benzene oxidation, 927, 928
Lead methyl mercaptide, 443
Lead mercaptides, basic, 441, 442
—, formation of peroxides, 442, 443
—, neutral, 441, 442
—, reaction with hydrocarbon peroxides, 900
—, removal of sulphur from distillates by, 427
—, sulphonic acids from, 1011
Lead monoxide, antioxidant for transformer oils, 909
Lead naphthenate, 1089, 1090
—, catalytic activity, 935
—, use in varnish dryers, 1090
Lead oxide, catalyst activator, 345
—, catalyst, oxidation of methane, 863
—, —, formation of dioxan, 555
—, —, oxidation of paraffin oil, 934
—, —, surface combustion of carbon, 981
—, desulphurization of hydrocarbon gases with, 460
—, effect on chlorohydrin formation, 489
—, oxidation catalyst, 833, 840, 993
—, treatment of petroleums with, 460
—, — sulphur oils with, 459
—, use in sweetening, 438, 439
Lead peroxide, catalyst, production of plastics, 630
Lead phosphate, aromatization catalyst, 183
—, catalyst, oxidation of methane, 863
—, —, hydration of ethylene, 308
Lead resinate, autoxidation catalyst, 890
Lead-salt method, separation of wax acids, 950
Lead salts, action with acetylene, 667
—, effect on oxidation of lignite paraffin, 949
—, of oxidized paraffins, 995
Lead silicates, aromatization catalysts, 183
Lead soap, anticatalyst, oxidation of transformer oils, 909
Lead-sodium alloy, lead tetraethyl from, 813
Lead sulphate, effect on ethylene absorption in sulphuric acid, 335
—, formation in doctor test, 439, 440
—, use in hydration of ethylene, 311
—, — sweetening, 439
Lead sulphide, absorption of mercaptans, 445, 446
—, catalyst for oxidation of mercaptans, 441
—, formation during sweetening, 439
—, in refining of gasoline, 446
—, test for mercaptans, 1150
Lead sulphonates, use as driers, 1030
Lead tetra-acetate, reaction with cyclic olefins, 587
Lead tetraethyl, addition to lubricants, 996
—, anticatalyst, oxidation of turbine oils, 912
—, antidetonating properties, cause of 977
—, antioxidant, for lubricating oils, 907
—, —, for amylene, 879
—, as antidetonant, 983
—, from halogen derivatives of ethane, 801
—, effect on active oxygen, combustion of fuels, 978
—, — gas-phase oxidation, 980
—, — ignition temperatures, 966, 967, 969, 978
—, — ionization of fuel vapors, 983
—, — liquid-phase oxidation, 980
—, — methane oxidation, 848
—, — oxidation of benzaldehyde, 980
—, — oxidation of hydrocarbons, 979
—, — pentane-air ignition, 973
—, — peroxide formation, 978
—, — pressure increase of explosive mixtures, 974
—, — rate of oxidation, 981
—, in fuels as secondary standard, 985
—, production with organic metallohalides, 813
Lead tetrasalts, reactions of, 893
Lead vapors, effect on ignition temperatures, 979
Leather waste, wetting agents from, 1024
Lebeau's reagent, preparation of, 1094
Le Chatelier's theorem, applied to cracking processes, 104
Levulinic acid, selective solvent for aromatic hydrocarbons, 34, 1143
Light, action on copper mercaptides, 445
—, activating methane chlorination, 693, 694, 699-701
—, activating natural gas chlorination, 688, 690, 694, 695
—, effect on decomposition, asymmetric-dichloroethylene, 815
—, — olefin bromination, 465, 466, 477
—, — oxidation of aromatic hydrocarbons, 926
—, — peroxide formation, 443
—, — polymerization of olefins, 591, 625
—, use in chlorination, 723-730
—, — chlorination of pentanes, 722
—, — condensation of olefins with acid chlorides, 949
Light hydrocarbons, pyrolysis of, 134, 135
Light oil, by pyrolysis of methane, 40
Lignin, acids from, 949
—, oxidation, 949
Lignite, pyrolysis of, 133
Lignite paraffins, oxidation of, 942, 949
Lignite tar, asphalt from, 949
—, composition of, 948
—, cyclopentadiene from, 1145
—, wax acids from, 948
Lignite-tar creosote, oxidation of, 987
Lignite-tar oil, treatment with sulphur dioxide, 938
Lignite wax, oxidation of, 957, 997
Lignoceric acid, from paraffin wax, 941
Ligroin, action of sulphuric acid on, 1008
Lime, absorption of carbon dioxide by, 232
—, catalyst, in naphtha-steam reaction, 277
—, —, production of acetone, 407, 408
—, —, pyrolysis cyclohexane, 158
—, —, pyrolysis of methane, 39
—, dechlorination of acetylene tetrachloride with, 673
—, — trichloroethane with, 675
—, in pyrolysis of ethylene, 67
—, use in pressure oxidation of wax, 942
—, — carbon production, 229
—, — hydrolysis of methyl chloride, 781, 782, 783, 784, 785
—, — pyrolysis of oils and tars, 209
Limonene, pyrolysis, 154
—, velocity of autoxidation of, 893
Linalool, 650

Linoleic acid, reaction with wax alcohols, 999
Linoleum, use of oxidized paraffin in, 998
Linseed oil, oxidation in presence of wax, 1003
—, solubility in amyl alcohol, 798
—, — sec.-butyl acetate, 395
—, — sec.-butyl alcohol, 394
Linseed oil substitutes, by polymerization of olefins, 613, 614
—, from acid sludges, 1013, 1030
—, from chlorinated petroleum, 740, 741
—, from olefins and ozone, 844
Liquefaction, of acetylene, 664
—, of butanes, 139
—, of butylenes, 139
—, of gas mixtures, 140
—, of gases, separation by, 355
—, of gaseous hydrocarbons, 137, 1103
—, of methane-ethylene-propylene mixture, 140
—, of olefins, critical pressure of, 137, 138
—, of propylene, 140
Liquefied hydrocarbons, scrubbing with, 140
Liquefied olefins, separation by isothermal vaporization, 139
Liquid air, cooling with, 138, 1110
Liquid hydrocarbons, from natural gas, 150
—, decomposition in electric arc, 218
—, from olefins, 195
—, pyrolysis of, 130
Liquid nitrogen, cooling with, 138, 139
Liquid olefins, industrial uses of, 348, 349
Liquid-phase cracking, 103, 108, 109, 110
—, definition of, 92
Liquid-phase oxidation, of aromatic hydrocarbons, 925-926
—, of hydrocarbons, 839-842, 933-936
—, of hydrocarbons to acids, 931
Liquid-phase pyrolysis, of paraffin hydrocarbons, 130
Liquid products, of cracking, utilization of, 91
Liquid soaps prepared with isopropyl alcohol, 366
Liquid sulphur dioxide, solvent, separation of olefins, 141
Liquors, detection of isopropyl alcohol in, 367
Litharge and soda, "doctor solution", 1149
Litharge, use in sweetening, 441
Lithium carbide, hydrolysis of, 662
Lithium, catalyst, pyrolysis of aromatics, 146
Lithium chloride, electrolyzing agent, chlorination of benzene, 761
Lithium naphthenates, 935
Lithium salts, separation of soap emulsion with, 1067, 1068
Lithographic inks, 237
Lithographic varnish, 252
Lithographic work, carbon blacks for, 252
Lithopone, manufacture of, 228
Long blacks, definition of, 244
Long inks, definition of, 244
—, from carbon blacks, 252
Louisiana carbon blacks, 251
Louisiana natural gas, composition, 242
—, yield of carbon black, 242
Lovibond tintometer, 1148
Low-boiling olefins, conversion to high-boiling, 134
Lower aliphatic alcohols, pyrolysis of, 159
Lower olefins, higher olefins from, 145, 159
—, saturated hydrocarbons from, 145
—, separation from gas mixtures, 137
Low-luster artificial silk, 370
Low-temperature fractional condensation, analysis by, 1103
Low-temperature fractionation, methods of, 1104-1115
—, separation of olefins by, 137
Low-temperature methods of analysis, 1101
Low-temperature refining, with ozone, 988
Lubricants, by condensation of olefins and aromatics, 559, 562, 564, 565
—, by hydrocarbon oxidation, 838, 906, 996
—, by polymerization of olefins, 352, 353, 613, 834
—, diethers of diethylene glycol as, 528
—, from halogenated hydrocarbons, 742
—, from mineral oils, 1030, 1031
Lubricants, from olefins, by aluminum chloride, 197
—, from oxidized paraffin wax, 994
—, from oxidized petroleum, 837
—, in residual oils from aluminum chloride cracking, 191
—, propylene glycol as, 529
—, sodium naphthenate as, 1088
—, synthetic, characteristics of, 202
—, —, by aluminum chloride, 196
—, textile, 1028, 1029
—, use of sulphonated hydrocarbons, 1001
Lubricating oils, absorption of oxygen, 903
—, antioxidants for, 907, 908
—, asphaltenes in, 904
—, autoxidation of, 987
—, carbenes in, 904
—, carbonization of, 904
—, catalytic oxidation of, 992
—, cause of failure of, 903
—, color stabilization of, 553
—, composition of, 29
—, conditions for obtaining high viscosity-index, 191
—, — low pour points, 191
—, cyclohexane in, 30
—, dehydration of sec.-butyl alcohol with, 394
—, determination of deterioration of, 904, 905
—, dewaxing with methylene dichloride, 705
—, effect of metals on resin content, 906
—, — oxidation on viscosity of, 904, 905
—, — resin content on lubricating powers, 906
—, — ozone on, 845
—, extracted with isopropyl alcohol, 366
—, evaporation tests of, 904
—, from acid extract of olefins, 353
—, from brown-coal tar oils, by aluminum chloride, 201, 202
—, —, by boron fluoride, 201
—, from Edeleanu extract, 565
—, from ethylene, 200, 202
—, from mineral oils, by aluminum chloride, 201
—, —, by boron fluoride, 201
—, —, by silent electric discharge, 270, 271
—, from olefins by aluminum chloride, 200, 202, 609
—, from paraffin wax, by aluminum chloride, 201, 203
—, from petroleum residues, by aluminum chloride, 201
—, —, by boron fluoride, 201
—, from tars, by boron fluoride, 201
—, —, by aluminum chloride, 201
—, impurities removed by glycol-phenol mixture, 516
—, naphthenes in, 30
—, oxidation catalysts for, 905
—, oxidation inhibitors for, 907-908
—, oxidation of, 903-906
—, oxidation tests for, 903, 1153
—, oxidized paraffins in, 952
—, polynaphthenes in, 30
—, pour point, reduction of, 741, 810
—, protective action on metals, increase of, 906
—, refining, extent of, 1148
—, refining with dichlorodiethyl ether, 498
—, — sulphuric acid, 1006, 1008, 1012
—, synthesis, by polymerization of olefins, 129, 200, 201, 353, 593, 606
—, —, from middle oils, 201
—, sulphonated, 1019
—, tests of, 1148
—, treated with sulphur chloride, 1060
—, use of nitrogen bases in, 828, 829
—, viscosity reduction by ozonization, 988
Lubricating stocks, naphthenic acid soaps from, 1066
— redistillation of, 1066
Luminescence, during oxidation of hydrocarbons, 854, 855

M

Magnesia, catalyst activator, 280, 408
—, catalyst, chlorination of olefins, 469
—, —, oxidation of alcohols, 406
—, —, reaction of diolefins with amines, 656

Magnesia, effect on pyrolysis of methane, 39
—, saponification of wax acids with, 953
Magnesite, catalyst, chlorination of ethylene, 470
Magnesium, action on chlorocyclohexane, 749
—, catalyst, pyrolysis of hydrocarbons, 38, 47, 125, 128, 146
—, —, formation of cuprene, 672
—, —, methane-carbon monoxide reaction, 932
—, extraction of sulphur compounds by, 462
—, molten, use in decomposition of hydrocarbons, 220
—, oxidation catalyst, 945
—, reaction with acetone, 411
—, — alkyl chlorides, 812, 813
—, use in distillation of butadiene, 641
Magnesium alkyl halides, 812
Magnesium amalgam, production of diacetone alcohol, 410
—, reaction with acetone, 411
Magnesium bromide, catalyst, polymerization of acetylene, 668
Magnesium carbonate, aromatization cataylst, 182
—, oxidation catalyst, 867, 909
Magnesium chloride, action on vinylacetylene, 669
—, catalyst, formation of alkyl halides, 371
—, —, hydration of ethylene, 312
—, —, methane chlorination, 699
—, extraction of mercaptans with, 436
—, production of halohydrins, 493
Magnesium chromate, catalyst for pyrolysis of benzene homologues, 146
Magnesium compounds, absorption of carbon monoxide and diolefins with, 160
—, — hydrogen sulphide with, 424
—; catalysts, benzene pyrolysis, 189
—, —, carbon monoxide-hydrogen reaction, 232
—, effect on detergents, 1024
—, oxidation, catalyst, 947
—, use in organic synthesis, 812
Magnesium hydrosulphide, 423, 424
Magnesium hydroxide, removal of hydrogen sulphide with, 423
—, use in sweetening, 443
Magnesium naphthenate, 1089
Magnesium oleate, catalyst for oxidation, 936
Magnesium oxide, catalyst activator, 280, 289, 290
—, catalyst, formation of ethylene oxide, 536
—, —, formation of higher alcohols, 345
—, —, hydration of ethylene, 312
—, —, hydrocarbon-nitrogen reaction, 295
—, —, methane-steam reaction, 280, 288-290
—, —, pyrolysis of paraffin hydrocarbons, 135, 150
—, catalyst support, 223
—, desulphurization of hydrocarbon gases with, 460
—, oxidation catalyst, 833, 849, 909, 915
—, use in production of halohydrins, 493
Magnesium pyrophosphate, isomerization of olefin oxides, 419, 547
Magnesium resinate, catalyst for oxidation, 936
Magnesium silicate, catalytic effect in propylene polymerization, 599
Magnesium soaps of oxidized paraffin wax, 954
Magnesium sulphate, catalyst, isomerization of olefins, 547
—, —, production of ketene, 414
—, use in polymerization of diolefins, 629
—, — salting out chlorohydrins, 493
Magnetic iron oxide anode, 762
Mahogany acids, 1016, 1018, 1021, 1028, 1029, 1031
Malachite green, oil-soluble, 1029
Maleic acid, catalyst for partial oxidation of wax, 943
—, condensation with diolefins, 653, 660
—, — olefins, 568
—, from benzene, 915, 916, 917, 918, 923
—, from furfural, 917
—, from paraffin hydrocarbons, 836, 838
—, from petroleum, 914, 915, 916, 918, 937
—, from quinone, 916, 917
—, from toluene, 916, 917
—, production of, 916-918
—, tartaric acid from, 506
Maleic anhydride, absorption of diolefins by, 1124
—, condensation with diolefins, 119, 651, 652, 659, 660, 1145
—, — olefins, 568
—, reaction with chloroprene, 639
—, — 1,2-dihydrobenzene, 651
—, treatment of cracked gasoline fractions with, 900
Malic acid, by hydrocarbon oxidation, 838
Malonic ester, condensation with naphthenic acid bromides, 1072
Malthas, insulating materials from, 740
Manganates, oxidation catalysts, 946
Manganese, catalyst, ammonia-carbon monoxide reaction, 298
—, —, chlorination of ethylene chloride, 475
—, —, hydration of olefins, 307, 314
—, —, pyrolysis of hydrocarbons, 134, 158, 221, 223
—, effect on ignition temperatures, 979
—, oxidation catalyst, 511, 833, 834, 836, 864, 865, 869, 870, 942, 951
—, removal of gum by, 902
—, use in distillation of butadiene, 641
—, used to dissolve nickel in molten iron, 220
Manganese acetate, catalyst for acetylene-steam reaction, 677
—, oxidation catalyst, 856, 870
Manganese acetylacetonate, oxidation catalyst, 936, 945, 947
Manganese alloys, catalysts for methane-steam reaction, 291
Manganese borate, aromatization catalyst, 183
Manganese butyrate, oxidation catalyst, 869
Manganese carbide, hydrolysis of, 662
Manganese chloride, catalyst for chlorination, 690, 775
Manganese-copper, aromatization catalyst, 187
—, oxidation catalyst, 869, 870
Manganese compounds, catalysts, carbon monoxide-hydrogen reaction, 232
—, —, ethylene absorption in sulphuric acid, 340
—, oxidation catalysts, 906, 953
Manganese dioxide, catalyst, acetylene-steam reaction, 677, 678
—, —, carbon dioxide from monoxide, 289
—, —, hydrocarbon decomposition, 222
—, —, production of acetone, 407
—, oxidation catalyst, 406, 832, 833, 834, 847, 848, 918, 919, 920, 926, 929, 934, 944, 949, 950, 993, 1003
—, purification of phthalic anhydride, 924
—, use in chlorination, 493, 764, 765
Manganese dioxysulphate, oxidation catalyst, 919, 920
Manganese naphthenate, driers, 1090, 1091
—, oxidation catalyst, 935, 936, 945, 990, 1001, 1034
Manganese oleate, oxidation catalyst, 934, 936, 994
Manganese oxide, catalyst activator, 281, 288
—, catalyst, hydrocarbon decomposition, 221
—, —, reduction of naphthenic acids, 1084
—, combustion retarder, 868
—, oxidation catalyst, 836, 840, 863, 864, 869, 944, 995
Manganese phosphate, aromatization catalyst, 183
—, catalyst, hydration of ethylene, 309
Manganese resinate, oxidation catalyst, 890, 926, 936
Manganese salts, catalysts production of acetone, 407
—, extraction of sulphur compounds with, 460
—, oxidation catalysts, 949
—, of oxidized paraffin, 995
—, of sulpho-acids, 935
—, use in electrolytic oxidation, 927
Manganese sesquioxide, oxidation catalyst, 893
Manganese silicate, aromatization catalyst, 183
—, oxidation catalyst, 944
Manganese stearate, oxidation catalyst, 926, 934, 945, 958
—, removal of sulfur compounds by hydrogenation with, 934

Manganese sulphate, catalyst, production of ketene, 414
—, use in electrolytic oxidation, 928
Manganese sulphonates, 1027, 1030
Manganese tridecanaphthenate, 1089
Manganic salts, dehydrogenation catalysts, 405
Manganites, oxidation catalysts, 946
Manila, solubility in sec.-hexyl acetate, 402
Marcasite, in Colorado oil shale, 463
Marcol, 994
Marquardt composition, catalyst, 150
Marseilles soap, reaction with isethionic condensation products, 1034
Mastic, solvents for, 366, 373, 395, 525, 798
Mazout, cracking of, 110
Mechanism, cracking by aluminum chloride, 192
—, of carbon black formation, 235
—, of production of coke, 234, 235
—, oxidation, olefins, 877, 879
—, pyrolysis of gaseous paraffins, 168, 169, 172, 173
Medicinal extracts, use of isopropyl alcohol in, 362, 364, 365
Medicinal paraffins, production of, 1012, 1016, 1017
Medicinal products, by oxidation of oils, 1002
Mellitic acid, from coal, 930
—, from cuprene, 671
m-Menthadiene, from isoprene, 617, 618
Menthane, chlorination of, 752
—, dehydrogenation of, 181
—, from octatriene, 617
—, nitration of, 1049
—, menthenol acetate from, 587
—, oxidation of, 893
Menthanedisulphonic acid, 575
Menthene oxide, isomerization of, 547
Menthenol acetate, from menthene, 587
Menthone, as antiknock 980
—, formation, 415
Mercaptals, 433, 448
Mercaptans, action of air on, 440
—, — sodium hypochlorite on, 459
—, adsorption by metallic sulphides, 445
—, — nickel, 461
—, condensation with unsaturated compounds, 585
—, conversion to disulphides, 421
—, — polysulphides, 438, 440
—, corrosion by, 422
—, decomposition with alkalies, 435, 436, 437
—, determination of, 432, 439, 1150, 1151
—, distinction between primary and secondary, 441, 442, 445
—, extraction of, 435
—, formation of, 431
—, from alkyl chlorides, 811
—, from alkyl disulphides, 1152
—, from alkyl sulphides, 456, 457
—, from olefin-hydrogen sulphide reaction, 425, 584-585
—, gum-formation catalysts, 421, 422
—, identification of, 1150
—, inhibitors in polymerization of butadienes, 630
—, in petroleum oils, 31, 421, 422, 1149
—, oxidation of, 432, 435, 439, 440, 441, 444, 446, 458, 459
—, properties of, 452
—, pyrolysis of, 451, 452, 457
—, reactions of, 431, 434, 435, 437, 438, 445
—, removal from distillates, 434, 435, 446, 447, 448, 1149, 1151
—, stabilization of gasoline with, 898
—, tests for, 1149, 1151
—, use in detection of gas-main leaks, 432
Mercaptan group, bathochromic action of, 434
Mercaptides, formation of, 432
—, hydrolysis of, 436
—, oxidation of, 442
Mercapto acid esters, 434
Mercaptoisohexane, 433
Mercaptoles, 433
Mercuriated olefins, 584
Mercuric acetate, action on mercaptans, 446, 447
—, double compounds with olefins, 582, 583
—, ether formation with, 583
—, extraction of sulphur compounds by, 459
Mercuric acetate, hydration of vinylacetylene with, 669
—, reaction with aromatic hydrocarbons, 1132
—, — diolefins, 1145
—, — vinylacetylene, 685
—, salts with acetylene, 666
—, use in determination of olefins, 574, 1132
Mercuric acetylide, 667
Mercuric chloride, action on mercaptans, 432
—, — vinylacetylene, 669
—, addition compounds with thioethers, 450
—, catalyst, acetylene-hydrogen chloride reaction, 680
—, —, hydration of ethylene, 307
—, —, olefin-organic chloride condensation
—, effect on catalysts in cracking, 202
—, extraction of sulphur compounds by, 459
—, formation of complexes with oils, 192
—, isolation of thiophanes with, 452
—, reaction with sulphur compounds, 453, 454
—, treatment of cracked distillates with, 454
Mercuric chloride salts of acetylene, 666-667
Mercuric chloride salts of nitrogen bases, 826
Mercuric cyanide, as antidetonant, 983
—, reaction with olefins, 1132
Mercuric iodide, action on thiophanes, 453
—, addition compounds with thioethers, 450
—, formation of sulphonium compounds, 449
Mercuric halides, use in refining, 609
Mercuric naphthenates, 1089, 1090
Mercuric nitrate, absorption of ethylene by, 1122
—, catalyst for nitration, 582
Mercuric oxide, action on mercaptans, 447
—, catalyst, hydration of acetylene, 676
—, —, oxidation of paraffin wax, 941, 943
—, —, production of dioxan, 555
—, use in acetal formation, 678
—, — acetylene-organic acids reaction, 681, 683
Mercuric palmitate, use in determination of olefins, 1132
Mercuric phosphate, catalyst, acetylene-steam reaction, 677
Mercuric salts, absorption of olefins by, 142, 582
—, double compounds of olefins with, 582-584
—, effect on oxidation of lignite paraffin, 949
—, reaction with tetramethylethylene, 1132
Mercuric stearate, determination of olefins with, 1132
Mercuric sulphate, absorption of acetylene by, 664
—, — ethylene by, 582
—, catalyst, acetylene-steam reaction, 676, 677
—, —, formation of vinylsulphuric acid, 679
—, —, glycol-acetylene condensation, 513
—, —, hydration of monovinylacetylene, 669
—, determination of olefins with, 1132
—, polymerization of ethylene with, 1032
—, reagent for isopropyl alcohol, 367, 368
Mercuric sulphide, adsorption of mercaptans by, 440, 446
Mercuric vanadate, catalyst, acetylene-steam reaction, 677, 933
Mercurous acetate, salt with acetylene, 667
Mercurous acetylide, 666
Mercurous chloride, action on vinylacetylene, 669
Mercurous nitrate, determination of sulphides with, 1152
Mercurous salts, catalysts, polymerization of ethylene, 594
Mercurous sulphate, catalyst, ethylene polymerization, 336
Mercury, catalyst in cracking, 107
—, heat absorbent in oxidation, 916, 917, 923, 924
—, oxidation catalyst, 833, 849, 874
—, reaction with sulphur, 1149
—, removal of gasoline gum with, 902
—, removal of sulphur from distillates with, 427
Mercury atoms, excited, action on hydrocarbons, 272
—, —, use in polymerization of ethylene, 594
Mercury compounds, catalysts, ethylene absorption in sulphuric acid, 340
—, —, pyrolysis of alkylbenzenes, 147
—, oxidation catalysts, 906, 933, 944
Mercury light, action on hydrocarbons, 272
—, —, hydration of acetylene, 664, 870, 887

Mercury naphthenates, antidetonants, 983
Mercury salts, addition to acetylene, 666-667
—, determination of olefins with, 1131
—, extraction of sulphur compounds with, 460
Mercury sulphonates, 1027
Mercury vapor, use in pyrolysis of paraffins, 135
Mercury-vapor lamp, use in chlorination, 693, 694, 700, 701, 714, 719, 724, 727, 728, 729, 730, 731
Mesitylene, chlorination of, 779
—, condensation with cyclohexene, 561
—, from acetone, 410
—, from acetylene, 81, 180
—, nitration of, 1046
—, occurrence in petroleum, 26, 27, 1035
Mesityl oxide, condensation with aliphatic alcohols, 411
—, glycols from, 506
—, production, 409, 410, 411, 568
Metal surfaces, function in carbon deposition, 235
Metals, pickling of, 829
Metaphosphates, catalysts, pyrolysis of paraffins, 134
Metaphosphoric acid, absorption of ethylene by, 322
Metastyrene, 610
Methane, acetaldehyde from, 932
—, acetic acid from, 932
—, acetone from, 932
—, acetylene from, 147, 148, 149, 150, 151, 180, 296, 663, 871, 872
—, action of nitric oxide on, 299
—, aromatics from, 147, 161, 166-170
—, bromination of, 706, 707
—, butadiene from, 147
—, by decomposition of coal-tar, 258
—, — diamylene, 604
—, — hydrocarbons by α-radiation, 273
—, — hydrocarbons by cathode-rays, 274
—, — hydrocarbons in electric arc, 257, 259, 262
—, — hydrocarbons in mercury light, 272
—, — hydrocarbons in semi-corona discharge, 269
—, — hydrocarbons, in silent discharge, 268, 269
—, — hydrocarbons, in ultraviolet light, 272
—, — methyl ether, 265
—, — sodium acetate, 787
—, by hydrolysis of metallic carbides, 663
—, by pyrolysis of acetylene, 82, 668
—, — aromatics, 89, 164
—, — butanes, 53, 54, 55, 56, 57, 63, 123, 129, 130
—, — butenes, 72, 73, 180
—, — cyclohexane, 84, 181, 182
—, — cycloparaffins, 274, 856
—, — ethane, 43, 44, 45, 46, 47, 257, 268, 269, 272
—, — ethylene, 65, 66, 67, 68, 257, 262, 273
—, — hexadecene, 77
—, — hexanes, 59, 60, 61, 130
—, — higher hydrocarbons, 61
—, — isoprene, 79
—, — methyl halides, 802
—, — olefins, 135, 143, 273, 602
—, — paraffin hydrocarbons, 64, 106, 184, 188, 218, 257, 269, 273, 274
—, — pentanes, 58, 63, 130, 174
—, — pentenes, 74, 75, 80, 603
—, — petroleum distillates, 134, 162, 163, 222, 259, 274
—, — propane, 44, 49, 50, 52, 53, 123, 127
—, — propylene, 70, 71, 84, 273
—, by reduction of carbon monoxide, 184, 186, 295
—, carbon black from, 148, 207, 213, 215, 220, 222, 223
—, carbon monoxide from, 151, 874
—, chlorination of, 225, 686-703, 713, 784, 1039
—, —, by antimony pentachloride, 687, 701
—, —, by cupric chloride, 701
—, —, by phosgene, 687, 701
—, —, by sulphuryl chloride, 687, 701
—, chlorine derivatives of, 467
—, combustion, effect of nitrogen, 976
—, condensation with acetylene, 267
—, condensation with ethylene, 264
—, decomposition by electric sparks, 38
Methane, decomposition in α-radiation, 272, 273
—, — electric arc, 255, 256, 257, 259, 260, 263
—, — glow discharge, 274, 849
—, — silent discharge, 264, 268, 269
—, determination of small amounts of, 1098
—, effect of aluminum chloride on, 194
—, effect on pyrolysis of hydrocarbons, 128, 135, 223, 258
—, equilibrium values for pyrolysis of, 38, 39
—, formation from methyl chloride, 782
—, from acetaldehyde, 885
—, from acetic acid, 407
—, from acetone, 413
—, from anthracene oil, 258
—, from butylene ozonide, 883, 884
—, from coal-distillation gases, 32, 208, 210
—, from hydrogen and ethylene in silent discharge, 265
—, from olefins and hydrogen sulphide, 425
—, hydrocyanic acid from, 296
—, hydrogen from, by oxidation, 243, 931
—, —, by pyrolysis, 151, 213, 214, 215, 220, 222, 223
—, in cracking gas, 114, 115, 141, 144
—, in natural gas, 12, 13, 14, 212
—, in producer gas, 963
—, maximum flame temperatures, 236
—, mechanism of pyrolysis of, 39, 40, 41, 42, 43
—, methyl alcohol from, 989
—, oxidation of, 206, 207, 235, 239, 242, 285, 663, 833, 843, 846-849, 857-864, 867, 872, 874, 875, 931, 965
—, —, by silent electric discharge, 866-867
—, —, effect of inert gases, 850
—, —, effect of lead tetraethyl, 848
—, —, effect of nitric acid, 848
—, —, intermediate products, 965
—, —, mechanism of, 235, 846, 965
—, oxidation to acetylene, 663
—, — to carbon monoxide, 849
—, — to formaldehyde, 846, 860, 867, 872
—, — with carbon dioxide, 863, 867
—, — with gaseous catalysts, 864-866
—, — with oxides of nitrogen, 858
—, — with ozone, 862
—, preparation of pure, 1113
—, pyrolysis of, 38-43, 65, 99, 105, 121, 126, 136, 147, 150, 151, 166-173, 176, 182-187, 205, 213-215, 216, 220, 222, 223, 235, 296, 663, 861
—, —, by carbon filaments, 43, 121
—, —, thermodynamic considerations, 39
—, reaction with acetylene, 684
—, — ammonia, 292-293, 295-297
—, — carbon dioxide, 206, 279-293, 932
—, — carbon tetrachloride, 706
—, — chloromethanes, 692
—, — fluorine, 707
—, — hydrogen sulphide, 425
—, — nitrogen, 208, 292-295
—, — oxides of nitrogen, 298-299
—, — phosgene, 418, 1060
—, — steam, 206, 276-280, 283-293, 834
—, — sulphur, 428
—, — sulphuric acid, 849, 1007
—, separation from other gases, 140, 230, 290, 696, 1096, 1101, 1102, 1103
—, slow-oxidation, 846, 982
—, thermal relationships of combustion, 235
—, thermal stability of, 63, 64, 205
—, thermodynamic stability of, 93
—, use of, 16
—, —, in production of synthetic rubber, 629
Methane-air, flames, characteristics, 970, 975
—, ignition, 969, 971, 974, 978
—, inflammability limits, 239, 240, 861, 961, 962, 964, 970
—, rate of flame propagation, 975
Methane-ethylene, heat-exchange material, 140
Methane homologues, by pyrolysis of methane, 65
—, halogenation methods, 711
—, separation by steam distillation, 33
—, slow oxidation of, 958
—, thermal stability of, 64, 65
Methane-oxygen, ignition, 847, 861, 970
Methanol, *see* Methyl alcohol.

Methionic acid, from acetylene, 1034
3-Methoxy-4-ter.-butyltoluene, 567
Methyl acetate, by oxidation of gas oil, 840
—, from methyl chloride, 784, 786
—, hydrolysis of, 784, 786
1-Methyl-2-acetylcyclopentane, 1057, 1058
Methylacetylene, allene from, 632
—, from acetone, 411
—, from propylene dibromide, 481
—, polymerization of, 272
Methylacraldehyde, from propylene glycol, 529
Methylal of ethylene glycol, 512
Methyl alcohol, action with aluminum chloride and olefins, 196
—, by hydrolysis of methyl chloride, 703, 781, 782, 783, 784
—, by hydrolysis of ethylene chloroformate, 498
—, by oxidation of gas oil, 840
—, — methane, 846, 847, 848, 851, 854, 857, 858, 859, 989
—, — petroleum, 333
—, dehydration of, 159
—, esterification by hydrogen chloride, 703
—, extraction of oxidized paraffins, with 952
—, extraction of sulphonic acids with, 1014, 1015
—, from carbon monoxide, 232, 263, 288, 785, 989
—, from methane and steam reaction, 276
—, from methyl formate, 395
—, oxidation to formaldehyde, 786, 860
—, oxidation with air, 989
—, properties of, 785
—, reaction with boron fluoride, 596
—, removal of gum from gasoline with, 903
—, solvent in hydrolysis of methyl chloride, 680, 785, 953
—, toxicity of, 362
—, use in production of amyl alcohol, 792
Methyl alcohol-air, explosive limits, 963
Methyl alkyl ketones from higher β alcohols, 402
Methylallene, from crotonaldehyde, 632
—, pyrolysis of, 614, 615, 616
Methylallene tetrabromide, 632
Methylamine, reaction with vinyl acetate, 656
—, use as solvent, 140, 141, 516
Methyl-n-amylcarbinol, 402
Methyl amyl ether, from trimethylethylene, 383
Methyl-n-amylethylene, reaction with sulphur, 429
Methyl n-amyl ketone, 416, 1055
Methylaniline, reaction with olefin oxides, 543
—, stabilization of gasoline with, 897
Methylanthracene, 227
Methylbenzanthrone, oxidation of, 930
1-Methyl-2-benzoylcyclopentane, 1057
p-Methylbenzyl chloride, 777
Methyl bromide, 706, 707
2-Methyl-4-bromo-2-butene, 645
1-Methylbutadiene, condensation with maleic acid and anhydride, 660
—, polymerization of, 619
2-Methylbutadiene, condensation with maleic acid and anhydride, 660
—, dipentene from, 617
2-Methylbutadiene-1,2-oxide, from isoprene, 877
2-Methylbutane, *see* Isopentane.
Methylbutanols, 402, 416, 797
2-Methyl-4-butene-2-ol, 636
sym.-Methyl-ter.-butylallene dibromide, debromination of, 485
Methyl butylcarbinol, *see* 2-Hexanol.
Methyl n-butyl ketone, by reduction of nitrohexane, 1042
—, from n-hexane, 1051
—, properties, 416
2-Methyl-1, 3-butylene glycol, isoprene from, 159
β-Methylcarboxyquinoline, 820
Methyl chloride, by chlorination of methane, 688-703
—, — of natural gas, 690, 691, 692, 694, 698, 700, 703, 731
—, by decomposition of ter.-butyl hypochlorite, 399.
—, by esterification of methyl alcohol, 703
—, chlorination of, 688, 697, 703, 704
—, hydrolysis of, 703, 704, 782, 783, 784, 785, 786
—, hydrolysis with steam, 782-785, 787
Methyl chloride, properties, 703
—, purification of, 152, 696, 704
—, pyrolysis of, 783, 802
—, toxicity, 709
—, uses, 152, 664, 703
2-Methyl-3-chlorobutane, from isopropylethylene, 329
Methylcyclobutane, in cracked gasoline, 119
—, pyrolysis of, 84
Methylcyclobutene, by pyrolysis of methylenecyclobutane, 84
Methylcycloheptane, by pyrolysis of cyclooctane, 86
Methylcyclohexane, action of sulphuric acid on, 1010
—, bromination of, 751
—, by pyrolysis of hydrocarbons, 78, 85, 86
—, chlorination of, 745, 750, 753
—, dehydrogenation of, 85, 181, 1144
—, effect of aluminum chloride on, 199
—, in straight-run gasoline, 22, 25, 27
—, nitration of, 1048, 1049
—, pyrolysis of, 84
—, reaction with antimony chloride, 1061
—, — sulphur, 430, 1061
Methylcyclohexanol, adipic acid from, 929
—, isoprene from, 635
Methylcyclohexanone, production of, 198, 419, 420
—, use as acetylene solvent, 262
Methylcyclohexene, by isomerization of methylenecyclohexane, 85
—, by pyrolysis of butenes, 179
—, double compound with mercuric acetate, 582
Methylcyclohexadiene, 179
1-Methyl-4-cyclohexyl-3-hydroxybenzene, 567
Methylcyclopentadiene, by pyrolysis of butanes, 57, 174
Methylcyclopentane, by pyrolysis of cyclohexane, 85
—, chlorination of, 747
—, from cyclohexane, 197, 198
—, from hexane, 197
—, from petroleum, 1147
—, halogenation of, 747, 748
—, in straight-run gasoline, 23, 27
—, nitration of, 824, 1047
—, reaction with acetyl chloride, 197
Methylcyclopentenes, from cyclohexane, 197
Methylcyclopentyl residues, 1079
Methylcyclopropane, action of sulphuric acid on, 1009
—, bromination of, 746
—, pyrolysis of, 83
Methyldiazomethane, reaction with butadiene, 652
Methyldiethylcarbinol, 402
Methyldiethylethylene, oxidation, 880
Methyldiphenylamine, stabilization of gasoline with, 897
Methyl disulphide, properties of, 452
—, use in adhesives, 456
—, — sweetening, 443
Methyl esters of naphthenic acids, 1070, 1083
Methyl ether, decomposition in silent discharge, 265
—, from methyl chloride, 782, 783, 784, 785, 786
Methylethylacetic acid, 856
Methylethylcarbinol, 345
Methyl ethyl ether, 786
Methylethylethylene, absorption, by sulphuric acid, 380, 381, 382
—, addition of hydrogen halides, 329
—, from amylene, 881
—, from ethylcyclopropane, 83
—, hydration of, 403
—, oxidation of, 881
—, polymerization of 382, 604
—, reaction with sulphuric acid, 380, 381, 382, 389
sym.-Methylethylethylene oxide, hydration of, 537
Methyl ethyl ketone, by oxidation of wax, 857
—, from acetylene, 159
—, from butane, 1055
—, from sec.-butyl alcohol, 379, 396
—, from 2-chlorobutanol-3, 501
—, from isobutylene glycol, 531
—, from methyl vinyl ketone, 415

Methyl ethyl ketone, from propylene oxide, 547
—, properties, 416
—, uses, 262, 416
2-Methyl-3-ethylpentane, oxidation of, 855
2-Methyl-6-ethylpyridine, from shale tar, 827
Methyl ethyl sulphide from petroleum, 450
Methyl formate, isobutyl formate from, 395
—, hydrolysis of, 792
Methylglutaric acid, by nitration of naphthenes, 1047
Methylglyoxal, from propylene, 879
—, from propylene glycol, 530
2-Methylheptane, isolation from petroleum, 33
3-Methylheptane, oxidation of, 855
Methyl heptanapthenecarboxylate, 1072
6-Methyl-2-heptanone, 856
5-Methyl-1-heptene, polymerization of, 607
Methyl heptyl ketone, 856
2-Methylhexane, *see* Isoheptane.
Methylhexanone, 892
5-Methyl-1-hexene, polymerization of, 386, 607
4-Methyl-2-hexyl-1,3-dioxolane, 557
Methyl hydrogen peroxide, 859
Methyl iodide, action on thiophanes, 453
—, pyrolysis of, 802
—, reaction with ethyl sulphide, 451
—, — trimethylene sulphide, 453
Methyl isoamyl ketone, 856
Methyl isobutyl ketone, 856
Methylisopropylcarbinol, 380, 401, 402
1-Methyl-4-isopropylcyclohexane, halogenation of, 745
Methyl isopropyl ketone, from dimethylallene, 301
—, from 3-methylbutanol-2, 402, 416
—, from trimethylene oxide, 419, 546
—, from trimethylethylene glycol, 531
—, properties, 416
Methyl isopropyl sulphide from petroleum, 450
2-Methyl-3-ketobutanol, from acetylene, 159
Methyl mercaptan, adsorption by sulphides, 445
—, properties of, 431, 432, 452
Methylmesityl oxide, 568
Methylnaphthalene, from acetylene, 82, 180
—, from isobutene, 179
—, from kerosene, 28
—, phthalic anhydride from, 922
Methyl-α-naphthylamine, antioxidant, 907
Methyl neopentyl ketone, 884
Methyl octanaphthenecarboxylate, 1072
4-Methyl-4-octene, 656
Methyl octyl ketone, 856
2-Methyl-2,4-pentadiene, autoxidation of, 893
3-Methyl-1,3-pentadiene, polymerization of, 627
3-Methyl-1,4-pentadiene, from acetylene trimer, 268
2-Methylpentane, *see* Isohexane.
3-Methylpentane, in straight-run gasoline, 22, 27
—, nitration of, 1042
4-Methylpentanol-2, 402
2-Methyl-1-pentene, 384
2-Methyl-2-pentene nitrosate, 580
3-Methyl-2-pentene, from diamylene, 604
—, polymerization of, 607
4-Methyl-1-pentene, 75, 813
Methyl peroxide, formation of 854
Methylphenylcarbinol, from ethylbenzene, 926
—, styrene from, 147
Methylphenyl-1,3-dioxolane, 557
Methylphenylfulvene diperoxide, 892
2-Methylpropane-1,2-diol, from isobutylene, 531
Methyl n-propyl acetone, 417
Methyl-n-propylcarbinol, 401, 402
Methyl propyl ketone from ethylene and acetone, 574
—, from pentanol-2, 402, 416
—, properties, 416
—, use as acetylene solvent, 262
Methylpyridines, separation, 820, 828
2-Methylpyridine, from shale tar, 827
Methylpyrrolidine, isoprene from, 636
β-Methylquinoline, 820
6-Methylquinizarin, 653
Methylstyrene, from ethyltoluene, 146
—, polymerization of, 612
Methylstyrene oxide, 547
Methylsuccinic acid, from propylene dichloride, 480
Methylsuccinonitrile, 480
Methyl sulphonates, 1021
Methylsulphonic acid, properties, 1011
Methyl thioether, properties of, 452
Methyl thiophene, from acetylene, 426
—, from naphtha, 455
2-Methylthiophene, in Kimmeridge shale oil, 463
2-Methyltricosane, slow-combustion of, 857
2-Methyl-2-undecene, polymerization of, 607
—, reaction with sulphuric acid, 386
Methyl vinyl ketone, 415
Methylene, attempts to produce, 782
Methylene blue, adsorption by carbon blacks, 248
Methylenecyclobutane, pyrolysis of, 84
Methylenecyclohexane, 85
Methylenecyclopentane, 579
Methylenecyclopropane, pyrolysis of, 84
Methylene dibromide, from methane, 706, 707
Methylene dichloride, butadiene isomers from, 643
—, by chlorination of methane, 688-695, 697, 698, 699, 701, 702, 703, 784, 785
—, — methyl chloride, 688, 697, 703, 704
—, — natural gas, 690, 691, 692, 694, 695, 698, 700, 703
—, chlorination of, 705
—, hexamethylenetetramine from, 705
—, physical properties, 704
—, separation from methyl chloride, 704
—, solvent action, 704, 705
—, stabilization of, 704
—, uses, 704, 705
Methylene glycol, 858
Methylene radical, 266
Methylene tetrahydrophthalic anhydride, 653
Mexican petroleum, asphalt in, 11
—, chlorinated, insulating materials from, 740
—, chlorination of, 740
—, sulphur compounds in, 11, 421
Mica disc, use in decomposition of natural gas, 218
Microanalysis of gases, 1095
Micronex black, 245, 250, 253, 254
Mid-Continent cokes, analyses of, 227
Mid-Continent gas oil, cracking of, 100, 101, 145, 146
—, pyrolysis of, 124, 132
Mid-Continent petroleum, cycloparaffins from, 23, 25
—, straight-run gasoline from, 20
Middle oils, condensation with chlorinated methanes, 203
Mineral matter, in petroleum oils, 1125
Mineral oil distillates, varnish materials from, 741
Mineral oils, analysis of, 1143
—, coke-forming value of, 911
—, distillation residues, pyrolysis of, 133
—, electric decomposition of, 259, 262
—, emulsifying agents from, 1022, 1023, 1024
—, oxidation of, 936, 939
—, polymerization of, 202, 629
—, pyrolysis of, 133, 134
—, reaction with oleum, 1033
—, — sulphur chloride, 576
—, saponifiable products from, 1066
—, separation from alkali sludge, 1067, 1068
—, solubility in isopropyl ether, 370
—, styrene from, 146
—, sulphonated, production of, 1008, 1013-1020, 1037
—, —, properties, 1022, 1023, 1024
—, —, uses of, 1022-1031
—, tanning materials from, 1033
—, tar-forming value of, 911
—, treatment with ozone, 939
—, tumenolsulphones from, 1037
Mineral oil sulphonic acids, production of, 1008, 1013-1020, 1037
—, properties, 1020
Moisture, effect on pyrolysis of 2-pentene, 75
—, — pyrolysis of amyl chlorides, 803
Moisture contents of carbon blacks, 212, 244, 253
Molecular weights, naphthenic acids, 1063
—, olefin polymers, 80

Moloxide theory of combustion, 854
Moloxides, formation, 853, 858
Molten chlorides, dehydrogenation catalysts for alcohols, 405
Molten lead, use in pyrolysis of hydrocarbons, 130
Molten tellurium, catalyst for pyrolysis of butane, 135
Molybdates, catalysts for diphenyl production, 189
—, dehydrogenation catalysts for alcohols, 405
Molybdenum, aromatization catalyst, 182
—, catalyst, ammonia-carbon monoxide reaction, 298
—, —, carbon dioxide-methane reaction, 281
—, —, chlorination of benzene, 759
—, —, diphenyl production from benzene, 189
—, —, hydration of olefins, 307, 314
—, ignition temperatures with, 969
—, —, in cracking, 113
—, —, methane-carbon monoxide reaction, 932
—, oxidation catalyst, 836, 868
—, —, pyrolysis of hydrocarbons, 40, 134, 136, 146, 166, 189
Molybdenum electrodes, use of, 261
Molybdenum oxide, catalyst, decomposition of hydrocarbons, 223
—, —, hydrogenation of benzene, 460
—, —, methane-steam reaction, 288
—, —, petroleum pyrolysis, 157, 158
—, oxidation catalyst, 833, 834, 836, 837, 843, 864, 869, 870, 914, 915, 916, 917, 919, 921, 922, 924, 925, 929, 938, 992
Molybdenum pentachloride, catalyst, chlorination of hydrocarbons, 690, 730, 756, 758, 770, 771
—, reaction with benzene, 764
Molybdenum sulphide, catalyst, hydrogenation of benzene, 460
Molybdenum sulphides, extraction of sulphur compounds with, 460
—, catalysts, diphenyl production, 189
Molybdenum trichloride, catalyst, chlorination of benzene, 730, 764
Molybdenum trioxide, effect on pyrolysis of ethane, 123
—, use in deodorizing soaps, 938
Molybdic acid, catalyst, ethylene absorption in sulphuric acid, 334
—, —, hydration of acetylene, 676
—, oxidation catalyst, 833
Monel metal, effect on pyrolysis of propylene, 70
Monoalkyl ethers of ethylene glycol, 521, 522, 523-525
— propylene glycol, 530
Monobasic naphthenic acids, in Russian petroleum, 1062
Monobromobutenes, from 1-butene dibromide, 482
Monocarboxylic naphthenic acids, by oxidation of naphthenes, 1064
Monochlorinated hydrocarbons, reactions of, 806-808, 814, 815
Monochlorinated paraffins, alcohols from, 792
—, ethers from, 808
Monochlorinated wax, condensation with aromatics, 741
Monocyclic acids of petroleum, 1072, 1073
Monocyclic saturated hydrocarbons, thermal stability of, 83
Monoethanolamine, production, 541, 551, 552
Monoethanolamine dinitrate, 552
Monoethanolamine oleate, uses, 554
Monoethyl ether of ethylene glycol, 521, 523
Monolefins, compared with diolefins, 642
—, separation from diolefins, 641
—, *see* Olefins
Monometallic derivatives of glycol, 511
Mononaphthenes, isolation of, 33, 1071
Monovinylacetylene, from acetylene, 669
Montan wax, action of ozone on, 948
—, amides of, 1002
—, chlorination of, 740
—, deresination, 520
—, driers from, 995
—, from lignite tar, 948
—, oxidation of, 943, 946, 951, 996, 1002
—, oxidized, reaction with alkylene oxides, 541
—, rust-preventative from, 1031
Montan wax, sulphonation of, 1002
—, wax acids from, 948, 996
Motor fuels, addition of amino compounds to, 1054
—, by cracking petroleum fractions, 91, 92
—, by oxidation of hydrocarbons, 836, 840, 844, 991, 992, 993
—, by pyrolysis of gaseous hydrocarbons, 164, 165, 169, 175, 186
—, examination of, 1148
—, naphthenic acids in, 1086
—, use of isopropyl alcohol as, 366
—, use of methanol in, 786
Mustard gas, 576
Mustard oils, from acetylene, 684
Myrcene, from isoprene, 617, 618, 625
—, oxidation of, 893
—, polymerization of, 619
Myricyl mercaptan, 432
Myristic acid, in petroleum distillates, 944, 1063, 1076
Myristylsulphonic acid, properties, 1011

N

Nail polishes, use of isopropyl alcohol, 364
Naphthalene, bacterial oxidation, 1004
—, butylene derivatives, 563, 564
—, by pyrolysis of acetylene, 81, 82, 180, 668
—, — butadiene, 79

—, decomposition, 208, 209
—, —, electric arc, 218, 219, 258, 260
—, dichloroethane from, 714
—, dry, 12, 13, 14
—, ethane content, 242
—, formaldehyde from, 860
—, fractional-distillation curve of, 1110
—, graphite from, 208
—, hydrogen chloride from, 224
—, hydrogen from, 208, 209, 212-216, 219, 277, 931
—, hydrogen sulphide content, 236
—, illuminants from, 212
—, incomplete combustion to acetylene, 663
—, lampblack from, 207, 224, 225
—, maximum flame temperatures, 236
—, methane content, 242
—, methane from, 212
—, nitrogen content, 212, 236, 242
—, occurrence of, 12, 13
—, oxidation of, 834, 843
—, oxidation to formaldehyde, 864, 865
—, oxidation to form gasoline, 993
—, oxygen content, 236
—, partial combustion, 239
—, photochemical chlorination, 688, 689, 694, 695, 700, 714
—, production of cyanides from, 294
—, pyrolysis of, 91, 121, 128, 150, 167, 172, 182, 184, 206, 216, 224, 229
—, reaction with ammonia, 216
—, — steam, 989
—, recovery of gasoline, 242
—, reforming by oxidation, 844
—, removal of hydrogen sulphide from, 424
—, — oxygen from, 988
—, separation of ethane from, 122, 123, 126
—, solvents by chlorination of, 715
—, tetrachloroethane from, 714
—, utilization of, 15-17, 260
—, water-vapor content, 236
—, wet, 12, 14, 15
Natural-gas gasoline, chlorination of, 727
—, composition of, 17, 18
—, hydrocarbons in, 24
—, low-temperature fractionation, 790
—, stabilization of, 129
Nekal, 1022
Neomerpin, 1022
Neopentane, *see* tetramethylmethane
Nernst approximation formula, 782
Neutral glycol succinates, structure, 521
New Brunswick gasoline, isohexane from, 24
Nickel, adsorption of sulphur compounds by, 461
—, catalyst, decomposition of hydrocarbons, 218, 220-223
—, —, dehydrogenation of cyclohexane, 83, 181
—, —, for dichloroethylene, 675

—, —, — hydrocarbons, 64, 106, 135, 136, 164, 205, 206
—, —, — methane, 38-41, 166, 167
—, —, — naphtha, 157
—, —, — pentane, 129
—, —, — propane, 49, 50, 127, 170
—, —, — solar oil, 127
—, —, reaction of acetylene and hydrogen sulphide, 426
—, —, reduction ethylene oxide, 548
—, —, synthetic rubber production, 629, 630
—, dehydrogenation catalyst, 85, 87, 405
—, dehydrogenation of cyclohexanes with, 163
—, desulphurization of hydrocarbon gases, 460
—, distillation of butadiene, 641
—, effect of, on action of aluminum chloride, 202
—, —, on methane decomposition, 205
—, —, on oxidation of oils, 905, 909, 934
—, —, on polymerization of actetylene, 82
—, —, on pyrolysis of petroleum, 163
—, electrodes, 263
—, hydration of olefins, 307, 314
—, hydrogenation of oxidized paraffin wax, 990
—, in petroleum ash, 31
—, molten bath, 220
—, oxidation catalyst, 833
—, removal of gasoline gum by, 902
—, — sulphur from distillates, 427
—, use in oxidation of gas oil, 935
Nickel acetylacetonate, 936, 983
Nickel borate, oxidation catalyst, 833
Nickel carbide, ammonia-carbon monoxide reaction, 298
—, during hydrocarbon pyrolysis, 39, 106
Nickel carbonate as catalyst, hydrogenation of acetone, 412
—, methane-carbon dioxide reaction, 932
Nickel carbonyl, antidetonating properties, 977
—, carbon monoxide catalyst, 218
Nickel chloride as catalyst, diphenyl production, 189
—, natural gas chlorination, 691
—, pyrolysis of alkyl chlorides, 802
Nickel chromate, methane-steam reaction, 289
Nickel compounds, catalysts, for ethylene absorption sulphuric acid, 340, 342
—, — oxidation of paraffin wax, 953
Nickel hydroxide, catalyst for acetylene-hydrogen sulphide reaction, 684
Nickel-kieselguhr catalyst for hydrogenation, 936
Nickel naphthenate, paint, 1091
Nickel nitrate, catalyst for natural gas chlorination, 691
—, — sulphur removal, 988
Nickelous sulfate, effect on ethylene absorption, 1118, 1120
Nickel oxide, absorption of hydrogen sulphide, 425
—, catalyst activator, 345
—, catalyst, carbon monoxide and hydrogen, 232
—, —, methane-steam reaction, 280, 288, 290, 291
—, —, oxidation of hydrocarbons, 915, 918, 951
—, —, — methane, 847, 848, 863, 864, 987
—, —, production of acetone, 408, 411

Nickel oxide, catalyst, pyrolysis of methane, 39
—, effect on oxidation of petroleum, 906
—, oxidation catalyst, 833, 842
—, removal of sulphur compounds from naphthas, 461, 462
Nickel phosphate, oxidation catalyst, 833
Nickel resinate, catalyst, autoxidation, 890
Nickel salts, action with acetylene, 667
—, catalysts, methane bromination, 706
—, effect on oxidation of lignite paraffin, 949
—, extraction of sulphur compounds from gasoline, 460
Nickel soap, anticatalyst, oxidation of transformer oils, 909
Nickel sulphide, removal of sulphur compounds, 423, 424, 440, 460
Nickel vanadate, pyrolysis catalyst, 224
Nickel vapor, effect on ignition temperatures, 979
Nicotine, insecticides, 1027, 1028
—, stabilization of gasoline, 898
Nicotine sulphate, 1001
Nitrated castor oil, 1053
Nitrated phenols, odor of, 400
Nitrates, catalysts in cracking, 107
Nitration, of alkyl chlorides, 814
—, of aromatics, 1143
—, of ethylene, 516
—, of ethylene mixtures, 517
—, of ethylene oxide, 517
—, of isobutyl chloride, 814
—, of glycol, 517
—, of methylcyclopentane, 824
—, of naphthenic bases, 824
—, of paraffin hydrocarbons, 1040-1046
—, of petroleum distillates, 1052-1054
—, of sulphoglycol, 517
—, of tertiary carbon atoms, 1006
—, of toluene fraction of cracked petroleum, 165
—, production of liquid fuels, 993
Nitric acid, action on amyl nitrite, 580
—, — cyclohexadiene dimer, 623, 624
—, — hydrocarbons, 1039-1054
—, — thioethers, 451
—, — thiophanes, 453
—, catalyst, oxidation hydrocarbons, 919
—, compound with dioxan, 556
—, deodorization of soaps, 938
—, determination aromatics, 1141, 1142
—, effect on oxidation of methane, 848
—, evaluation of transformer oils, 912
—, formation of fumaric acid, 918
—, formed by submerged combustion, 1000
—, glycol dinitrate from glycol, 516
—, hydration, of olefins, 300
—, naphthenic acid purification, 1069
—, nitration of alkyl chlorides, 814
—, oxidation of aromatics, 929
—, — hydroaromatics, 929, 930
—, — paraffins, 949
—, — petrolatum, 949
—, — propylene glycol, 530
—, — pyrroline, 917
—, — residues, 1003
—, — wax acids, 955
—, oxidizing agent, 844
—, plastics from action on petroleum, 628, 629
—, purification of alcohols with, 351, 352
—, — hydrocarbons with, 934
—, reaction with acetylene, 683
—, — cuprene, 671
—, — thiophene, 454
—, — trimethylene sulphide, 453
—, resins from olefins with, 582
—, separation of naphthenes from paraffins, 35
Nitric esters, from olefin-nitrogen pentoxide reaction, 581
Nitric oxide, action on cuprous oxide catalyst, 357
—, — metallic catalyst, 343
—, from oxidation of paraffin wax, 946
—, production of hydrocyanic acid, 298
—, reaction with olefins, 581-583, 1134
Nitric-sulphuric acid, determination of aromatics, 1141
Nitrides, formation of, 294
Nitriles, from acetylene, 684, 685
—, from ketones and hydrocyanic acid, 410
—, production, 571, 684, 810
—, —, catalysts for, 684
—, reaction with boron fluoride, 596
—, saponification, 684
Nitrobenzaldehyde, determination of acetone, 369
Nitrobenzene, antioxidant, for lubricating oils, 907
—, benzaldehyde from, 920
—, carboxylation, 930
—, catalyst, condensation butadiene, 653
—, critical solution temperature, 1136, 1139, 1140
—, determination of aromatics, 1140
—, effect on ignition temperatures, 969
—, emulsifying agent, ethylene absorption, 343
—, production, 608
—, purification of plastics, 628
—, selective solvent for naphthenes, 35
—, separation of acetylene, 152
—, solvent, olefin separation, 141
—, —, oxidation of anthracene, 925
—, stabilization of gasoline, 897
Nitrobenzene complexes, polymerization of olefins, 594, 600
p-Nitrobenzoic acid, from toluene, 929
Nitrocellulose, dehydrated with isopropyl alcohol, 366
—, oxidized solvents for, 930, 992
Nitro compounds, by nitrogen oxide-olefin reaction, 581
—, inhibitors, polymerization of butadiene, 630
—, polymerized ethylene, 265
—, properties, 1050, 1051
—, reduction of, 1050-1052
—, secondary, 1043, 1050, 1051
Nitrocotton, gelatinization of, 517
Nitrocresols, antioxidants for lubricating oils, 907
—, formation of, 832
Nitrocyclohexane, 1048
Nitrocyclohexanone, 1048
Nitrocyclopentane, 1047
Nitrodecanaphthenes, 1050
Nitrodecane, 1045
Nitro derivatives, acetylene polymers, 267
Nitrodimethylbutane, 1043
Nitrodimethylhexane, 1044
Nitrodimethyloctane, 1051, 1052
Nitrodimethylpentane, 1044
β-Nitroethanol, 516, 581, 582
β-Nitroethyl nitrate, 582
Nitroform, 581, 582
Nitrogen, analysis and separation of, 1099
—, antioxidant, for transformer oils, 908
—, cyanides from, 293
—, diluent, ammonia-hydrocarbon reaction, 297
—, —, butadiene formation, 159
—, —, chlorination hydrocarbons, 713
—, —, olefin-ammonia reaction, 571
—, —, oxidation of hydrocarbons, 873-875,905
—, —, — toluene, 918
—, —, pyrolysis of benzene homologues, 146
—, —, — paraffins, 135
—, —, — propane, 128
—, effect. carbon black production, 238
—, —, deblooming of petroleum distillates, 940
—, —, electrical decomposition hydrocarbons, 256, 262, 264, 266
—, —, methane chlorination, 690, 691, 693
—, —, methane-steam reaction, 278
—, —, flame propagation, 976
—, —, on inflammability limits, 963
—, —, oxidation of acetaldehyde, 932
—, —, — acetylene, 886
—, —, preparation of cuprene, 671
—, —, pyrolysis of benzene, 88
—, —, — butanes, 57
—, —, — methane, 43, 167, 168
—, —, — propane, 50
—, from anthracene oil, electric arc, 258
—, from coal gas, 209
—, from fuel gases, 215
—, in carbon black, 247
—, in natural gas, 12, 13, 212
—, liquid, refrigeration with, 1113

Nitrogen, liquid, use in purifying hydrogen, 230
—, occlusion of, by carbon black, 247
—, prevention of gum formation in gasoline, 903
—, reactions with hydrocarbons, 292-295
—, removal from hydrogen, 229, 230
—, separation and analysis of, 1099
—, separation of wax acids with, 954
Nitrogen bases, chloroplatinates from, 821, 826
—, extraction, 819, 820, 822, 825
—, from California oils, 819, 820, 828
—, from crude gasoline, 828
—, from ethane, 264
—, from ethylene, 264, 571
—, from methane, 264
—, from propylene, 264
—, inhibitors, pickling solutions, 829
—, oxidation, 820, 827
—, phthalones from, 821
—, picrates of, 826, 827
—, pyrindane, 828
—, stabilizers, cracked distillates, 829
—, use in lubricating oils, 828, 829
Nitrogen compounds, antioxidants, for lubricating oils, 908
—, extraction from oils, 821, 822
—, in petroleum, 31, 36, 819-829, 1125
—, isolation from acid extract, 822
—, of non-basic character, 821
—, oxidation, 822
—, polymerization, 822
—, sulphonation, 822
Nitrogen content, carbon black, 244, 246
—, natural gas, 236, 242
—, oils and tars, 209
—, petroleum oils, 819
—, producer gas, 963
Nitrogen dioxide, action on hydrocarbons, 831, 832
—, addition products with benzene, 832
—, catalyst, oxidation of hydrocarbons, 866
—, —, oxidation of methane, 865, 866
—, oxidation of hydrocarbons by, 931
—, — methane with, 864
—, — paraffin wax, 946
—, reaction with n-undecane, 946
—, treatment of soap, 938
Nitrogen-fixation apparatus, 218
Nitrogen-hydrocarbon reaction, endothermic nature of, 293
Nitrogen-hydrogen reaction, equilibrium in, 296
Nitrogen ions, catalysts, acetylene polymerization, 273
Nitrogen oxides, acetylene reaction, 887-888
—, by submerged combustion, 1000
—, catalysts, acetic acid, 677
—, —, carbon dioxide-ethylene reaction, 586
—, —, oxidation of acetylene, 888
—, —, — benzene, 929
—, —, — methane, 865, 867
—, —, — olefins, 876, 878
—, oxidation of anthracene, 925
—, — benzines, 938
—, — olefins, 887-888
—, — paraffin wax, 947
—, oxidation catalyst, 834, 837, 843
—, oxidizing agents, 831, 832
—, —, wax acids, 960
—, reactions with hydrocarbons, 292-293, 298-299
—, —, mechanism of, 299
—, reaction with olefins, 580-582
Nitrogen pentoxide, action on olefins, 581-582
Nitrogen peroxide, induction period, ethane, 850
Nitrogen tetroxide, action on olefins, 580-581
—, oxidation of toluene, 920
—, pressure oxidation of paraffin wax, 946
Nitrogen trichloride, reaction with olefins, 578-579
Nitrogen trioxide, reaction with olefins, 580-581.
Nitrogenous organic compounds, as antidetonants, 983
Nitroglycerol, cuprene as adsorbent agent for, 672
—, in explosives, 517, 518, 582
—, stabilization of, 550
Nitrohendecane, 1045
Nitroheptane, 1043
Nitrohexane, 1042
Nitrolamines, 580
Nitrolic acids, 1042, 1044, 1051
Nitromenthane, 1049
Nitromethane complexes, catalysts, polymerization olefins, 594, 600
Nitromethylbutane, 1042
Nitromethylcyclopentane, 1047, 1052
Nitromethylpentane, 1042
Nitronaphthalene, as antidetonant, 983
Nitronitrates, 581
Nitrononane, 1045
Nitrooctane, 1044
Nitroparaffins, use in Diesel fuels, 986
Nitrophenol, condensation with propylene, 566
m-Nitrophenylhydrazine, determination of acetone, 368
Nitroprusside test for acetone, 367
Nitro-resins, 1052-1054
Nitrosates, formation of, 580, 581, 832
Nitrosation with nitrosyl chloride, 1055
Nitrosites, 580
Nitroso-amines, 820
Nitrosobenzene, determination olefins, 1131
Nitrosochlorides, 579, 580
Nitroso compounds, from n-heptane, 1055
—, intermediates, 581
—, selective solvent for aromatics, 34
p-Nitroso-dimethylaniline, reaction with naphthols, 897
Nitrosyl chloride, inhibiting methane chlorination, 695
—, polymerization of isoprene, 625
—, reaction with olefins, 579-580
—, — paraffins, 1054, 1055
—, — terpenes, 579
Nitrotoluenes, chlorination of, 772
—, from aromatics fractions, 1053
—, oxidation, 928, 929
—, production, 608
Nitroundecane, 1045
Nitrous acid, action on olefins, 580
—, behavior toward nitro compounds, 1051
—, deodorization of naphthenic acids, 1069
Nitrous oxide-ethylene reaction, 299
Nitrous oxides, oxidation of toluene, 920
Nomenclature, halogenated hydrocarbons, 466, 467
Nonanaphthenes, by pyrolysis of amylene, 78
—, in straight-run gasoline, 25, 27
—, nitration of, 1050
Nonanaphthenic acid, 1071
Nonane, by pyrolysis of wax, 60
—, chlorination of, 736, 737
—, effect of aluminum chloride on, 194
—, nitration of, 1045, 1046
—, oxidation of, 855, 856
n-Nonane, in straight-run gasoline, 22, 24, 27
Nonanoic acid, from hexadecane, 959
—, from paraffin wax, 944
—, from n-undecane, 946
Nonanylic aldehyde, formation, 857
Non-aromatic hydrocarbons, separation from distillates, 35
Nonene, by pyrolysis of wax, 60
—, decomposition of diamylene, 604
Nonyl alcohols, 345
Nonylbenzene, production, 562
Nonyl chloride, 737, 738
Nonyl mercaptan, 445, 447
Nonylsulphonic acid, properties, 1011
Novocain, 496, 497, 498
Nujol, 995

O

Occluded air, removal from gasoline, 903
Occlusion of gas by carbon blacks, 247
Octachloromethylcyclohexane, 769
Octadecane, condensed with alkylene oxides, 1059
Octadecene, sulphonation of, 1033
Octadecylamine, condensation with olefin oxides, 543
Octahydrocinnamic-o-carboxylic acid, 929, 930
Octaldehyde, 855
Octanaphthenes, action of sulphuric acid on, 1010
—, by pyrolysis of amylene, 78
—, from petroleum, 629
—, in straight-run gasoline, 25

Octanaphthenes, reaction with sulphur, 430, 1061
—, xylenes from, 629
Octanaphthenic acid, 1071
Octanes, action of aluminum chloride on, 194
—, by pyrolysis of amylene, 78
—, by pyrolysis of wax, 60
—, chlorination of, 735, 737
—, combustion products, 973
—, critical inflexion temperature, 966, 967
—, from butane, silent discharge, 270
—, from ethane, ultraviolet light, 272
—, from fatty acids, 735
—, incomplete combustion, 853
—, in natural gas, 12, 15
—, octyl chloride from, 735, 737
—, oxidation, 854-856
—, pyrolysis of, 60-62
—, slow oxidation, 855
—, solubility of hydrogen sulphide in, 423
n-Octane, action of sulphuric acid on, 1007
—, from Oklahoma crude oil, 1147
—, in straight-run gasoline, 22, 24, 27
—, minimum ignition temperature, 967
—, nitration of, 1041, 1044, 1051
—, non-catalytic oxidation, 854
—, oxidation of, 836
—, pyrolysis of, 61, 62
—, reaction with benzoyl peroxide, 1061
—, reaction with sulphur, 428, 429
Octane number, definition, 985
Octanoic acid, from paraffin wax, 944
Octanol, from octane, 856
Octanone, from hexane and acetyl chloride, 1058
Octatriene, 617
Octenes, by decomposition of octyl chloride, 328
—, by pyrolysis of wax, 60
—, chlorohydrins from, 504
—, from diamylene, 604
—, isomerization of, by pyrolysis, 76
—, polymerization, by sulphuric acid, 386
—, production, 601
—, pyrolysis of, 76
1-Octene, 1128
—, polymerization of, 605, 606
2-Octene, 504, 607, 1128
Octyl acetate, 331
Octyl alcohols, from lower alcohols, 345
sec.-Octyl alcohol, 386, 402, 416
Octylamine, reaction with ethylene oxide, 544
Octylbenzene, production, 562
Octyl chloride, 328, 735, 737
Octylene, from butane, 270
—, from ethylene, 594
—, reaction with acetyl chloride, 568
—, — sulphur, 429
Octylene oxide, preparation, 534
Octyl mercaptan, from distillates, 448
Oenanthylic aldehyde, formation, 857
Ohio petroleum, hydrocarbons in, 24
Oil gas, alcohols from, 353
—, aromatics from, 161
—, bromination, 480
—, by pyrolysis of decane, 60
—, — octane, 60
—, — paraffin distillates, 60
—, chlorohydrins from, 491
—, cyclopentadiene from, 1145
—, ethylene from, 491
—, formed by pyrolysis, 37
—, from liquid hydrocarbons, 209
—, hydrocyanic acid produced from, 294
—, propylene chlorohydrin from, 491
—, solvent for hydrocarbons, 230
Oils, analysis with iodine monochloride, 574, 586
—, aromatic, by pyrolysis of natural gas, 91
—, asphalt content, 229
—, brown-coal tar, lubricating oils from, 201
—, by pyrolysis of methane, 166
—, — isobutylene, 77
—, — 2-pentene, 74
—, California, 218
—, coke from, 225, 228, 904
—, Conradson carbon from, 904
—, cracking temperature of, 192
—, crude, distillation, 225
—, cupric chloride complexes with, 192
Oils, dewaxing of, 705, 706
—, dispersion of, 937
—, drying, production of, 613
—, effect of electric arc on, 218
—, — ozone on, 906
—, electrical decomposition, 259, 262
—, electropyrolysis of, 219

—, aldehydes from hydrocarbons by, 938
—, desulphurization by, 461
—, effect on oils, 906
—, ketones from hydrocarbons by, 938

Ozone, oxidizing agent, 831, 844, 845
—, —, for wax acids, 960
—, oxidation of hydrocarbons with, 864, 868, 931
—, reaction with acetylene, 887
—, — diolefins, 654
—, — ethylene, 882, 883
—, — olefins, 605, 831, 844, 871, 877, 881-885, 1134
—, refining benzol, 988
—, removal of sulphur compounds, 459
—, treatment of mineral oils, 939
—, — shale-oil gasoline, 903
—, use in asphalt manufacture, 842
—, — resin formation, 998
Ozonides, acetylene trimer, 268
—, catalysts for polymerization, 618, 619, 626
—, decomposition of, 882, 883, 948
—, decomposition products, 627
—, from olefins, 831, 844, 871, 882, 883
—, from synthetic rubber, 627
—, hydrogen peroxide from, 882
—, hydrolysis of, 831, 844, 882, 883, 939
—, ketones from, 882
—, petroleum, properties, 885
—, properties, 882, 883
—, removal of, 939
—, yields, from ethylene, propylene, butylenes, 884
Ozonization, benzene homologues, 930
—, cracked gasoline, 844
Ozonized air, deodorant, 1069
—, oxidation of oil, 937
Ozonized oil, 938, 939
Ozonized oxygen, action on petroleum, 844
—, oxidation of ethylene, 877
—, removal of sulphur compounds, 459
Ozonizer, oxidation of olefins, 882
Ozonolysis, olefins, 884

P

Paint removers, isopropyl alcohol in, 366
—, use of ter.-butyl alcohol, 398
Paints, carbon black in, 252
—, from dichloroethyl sulphide, 576
Paint vehicles, by oxidation of hydrocarbons, 995
—, from polymerized hydrocarbons, 97, 614
Palladium, catalyst in ammonia-hydrocarbon reaction, 297
—, colloidal, absorption of hydrogen by, 1096
—, dehydrogenation catalyst, 85, 87, 181
—, hydrogenation catalyst, 478, 584
—, oxidation catalyst, 833, 847, 848, 869, 870, 875, 892
—, polymerization catalyst, 87, 629, 682
—, pyrolysis catalyst, 223
Palladium black, dehydrogenation catalyst, 163
—, pyrolysis catalyst, 85
Palladium salts, catalysts, ethylene absorption in sulphuric acid, 342
—, reaction with acetylene, 667
Palmitic acid, esterification of, 539
—, from cetyl chloride, 740, 814
—, from Ishikari distillates, 1076
—, from paraffin wax, 944
—, from spindle-oil extract, 1063
—, production of, 938
Palmitic anhydride, hydrogenated, 990
Panhandle coke, analysis of, 227
Panhandle gas oil, velocity constant of thermal decomposition of, 99
Paper sizes, oxidized paraffin wax, 994, 995
Paracumaron resin, solubility in thioether, 452
Paraffin, as diluent, olefin absorption in sulphuric acid, 349
—, carbon disulphide from, 956
—, chlorine derivatives, oxidation of, 947
—, decomposition, electric arc, 257
—, dehydrogenation with sulphur, 956
—, from lignite tar, 948
—, hydrogen sulphide from, 956
—, in petroleum oils, test for, 958
—, liquid, action of ozone on, 845
—, mechanism of oxidation, 956-959
—, oxidation, in ultraviolet light, 948
—, reaction with selenium, 956
Paraffin, reaction with tellurium, 956
—, soaps from, 945
—, test for, 958
Paraffin-air mixtures, ignition temperatures, 964
—, critical temperature, 966
Paraffin carboxylic acids, in naphthenic acids, 1076
Paraffin distillates, pyrolysis of, 60
Paraffin oil, chlorination of, 699
—, oxidation of, 934, 939
—, pyrolysis of, 175, 176
—, sulphonated, 1019
Paraffins, absorption of, 1095
—, acetylene from, 147
—, action of aluminum chloride on, 193-194
—, action of chlorosulphonic acid on, 1009
—, bacterial oxidation, 1004
—, bromination of, 693, 706, 742, 743
—, by petroleum pyrolysis, 161
—, by polymerization of olefins, 326, 347, 348, 379, 603, 613
—, by pyrolysis of acetylene, 668
—, — aliphatics, 59, 62, 63, 130
—, — cyclic hydrocarbons, 87
—, — olefins, 66-68, 70, 76-78, 80, 178, 180, 289, 290
—, — wax 60, 63
—, chlorination of, 686, 688, 692, 693, 719, 734, 736, 737, 739, 740, 817
—, condensed with alkylene oxides, 1059
—, cracking of, 96
—, critical solution temperature in nitrobenzene, 1140
—, decomposition of, 79, 219
—, dehydrogenation of, 45, 93, 96
—, demethanation of, 45
—, determination of, 1096, 1126, 1140, 1143, 1144
—, diguanidine derivatives of, 807, 808
—, electrochemical oxidation of, 948
—, emulsification with mineral oils, 1025
—, fatty acids from, 959
—, Friedel-Crafts reactions, 1056, 1057
—, from amylene-hydrocarbons, silent discharge, 266
—, from cycloparaffins by action of aluminum chloride, 199
—, from gasoline, 35
—, from hydrocarbons, silent discharge, 270
—, from isobutylene, silent discharge, 266
—, from isopropyl alcohol, 370
—, from mineral oils, 35
—, from olefins by action of aluminum chloride, 190, 195
—, from wet natural gas, 32
—, gaseous, available quantities, 830
—, in cracked gasoline, 116, 118
—, in petroleum, 11
—, in straight-run gasoline, 20, 21, 22, 27
—, isomers of, 32, 711
—, knock rating of, 985
—, nitration of, 1040-1046
—, nitrogen derivatives of, 808, 817
—, oxidation of, 830, 852, 943, 948-953, 959, 967
—, —, general theories, 960
—, purification with nitric and sulpuric acids, 934
—, reaction with phosgene, 418, 1058, 1060
—, — sulphur, 428, 956
—, — sulphur chloride, 1060
—, refining, by sulphuric acid, 948
—, resistance to chemical reagents, 1039
—, separation of, by distillation, 1095, 1101
—, —, by ethylene chlorohydrin, 498
—, —, from petroleum, 1146, 1147
—, sulphonation of, 1006, 1007, 1008
—, thermal stability of, 65, 95, 96, 97, 1039
—, unsaturated aliphatic acids from, 939
—, vapor pressures of, 1099
—, wetting agents from, 1029
Paraffin wax, action of aluminum chloride on, 194
—, — ozone on, 948
—, — sulphuric acid on, 1008
—, bacterial oxidation, 1004
—, chlorination of, 738, 739, 740, 741, 947
—, constituents of, 946
—, cracking of 168, 175, 176, 203

Paraffin wax, dechlorination of petroleum products with, 804
—, emulsifying agents from, 994
—, lubricating oils from, 201, 203
—, oxidation of, 857, 946-960, 990, 991, 1034
—, oxidized, detergents from, 1024
—, —, esterification of, 539
—, reaction with sulphur, 428, 429
—, separation from lubricating oils, 20
—, treatment with aluminum chloride, 191
—, vacuum distillation of, 957
Paraformaldehyde, from formaldehyde, 861, 869
Paraldehyde, production of, 547
Paraphenylenediamine, diazotization of, 598
Partial combustion, of hydrocarbons, 216
—, of natural gas, 239
Particle size of carbon blacks, 245
Peat, hydrocarbons from, 933
Peat oil fractions, refining with ozone, 988
Peat paraffins, oxidation of, 942
Penetrants, from dichlorodiethyl ether, 498
Penetrating agents, textile, 1028, 1029
Penniman process, hydrocarbon oxidation, 839, 840
Pennsylvania cokes, analyses of, 227
Pennsylvania distillates, oxidation of, 1000
Pennsylvania gas oil, velocity constant of pyrolysis, 99
Pennsylvania gasoline, paraffin hydrocarbons from, 24
Pennsylvania oils, nitrogen content, 819
Pensylvania petroleum, action of sulphuric acid on, 1007
—, oxidation products from, 935, 936
—, sulphur content of, 421
Pennsylvania petroleum fractions, pyrolysis of, 62, 130, 131
Pentabromoisobutanes, from isobutene, 483
Pentabromotoluene, formation of, 751, 778
Pentacetate, 396, 798
Pentachloroacetone, from lower chloroacetones, 374
—, from isopropyl alcohol, 373
Pentachclorobenzene, from benzene, 757, 758, 764
Pentachlorobenzyl chloride, from toluene, 774
Pentachcloroethane, by chloroform pyrolysis, 692
—, from acetylene tetrachloride, 715
—, from chloroethylene, 674
Pentachlorophenol, formation of, 761
Pentachlorotoluene, from toluene, 770, 774
Pentacyclopentadiene, 621, 622
Pentadecanaphthene, by pyrolysis of amylene, 78
—, chlorinated products of, 753
Pentadecene, by olefin polymerization, 608
1,3-Pentadiene, synthetic rubber from, 627
Pentaerythritol, condensation with ethylene oxide, 538
—, wetting agents from, 1086
Pentaethylbenzene, from kerosene, 28
—, production of, 560
Pentaisobutylene, formation of, 600
Pentamethylene sulphide, from 1,5-dibromopentane, 453
—, from petroleum, 453, 459
Pentane, action of sulphuric acid on, 1007
—, butadiene from, 155
—, by amylene pyrolysis, 77
—, by ethylene polymerization, 195, 872
—, chlorination of, 721-723, 726-732, 790-792
—, combustion, effect of nitrogen, 976
—, condensed with alkylene oxides, 1059
—, critical inflexion temperature, 966
—, decomposition of, mercury atoms, 272
—, determination of, 1116
—, fractional distillation of, 32
—, from cracking gas, 139, 355
—, from fatty acids, 721
—, from hexane, 194
—, from hydrolysis of chloropentanes, 794
—, from isohexane, 194
—, from wax, by pyrolysis, 60
—, in natural gas, 14, 32
—, incomplete combustion of, 853
—, ketone from, 939
—, monochlorinated, pyrolysis of, 635
—, oxidation of, 854
—, —, induction period, 852
Pentane, pyrolysis of, 58-59, 130, 183
—, recovery from chlorination process, 731-733
—, removal from gases, 1116
—, separation from butane, 1101
—, thermal chlorination, 731-733
n-Pentane, condensation with acetyl chloride, 417, 1057
—, critical inflexion temperature, 967
—, in natural-gas gasoline, 17, 18
—, in straight-run gasoline, 22, 24
—, minimum ignition temperature, 967
—, pyrolysis, 171, 172
—, reaction with ethylene oxide, 545
Pentane-air, combustion of, 972, 973
—, flames, characteristics of, 975
—, ignition, effect of lead tetraethyl, 973
—, ignition temperatures, 978
—, inflammability limits, 961
—, rate of flame propagation, 975
—, relative ignition temperatures, 965, 973
Pentanol-1, properties, 797
Pentanol-2, catalytic oxidation of, 416
—, properties, 401, 402, 797
Pentanol-3, properties, 797
Pentasol, 791, 794
Pentasulphides, organic, 450
Pentatricontol, 991
Pentene, addition of hydrogen halides to, 329, 398
—, action of aluminum chloride on, 194
—, by butane pyrolysis, 174
—, by n-butane-isobutane pyrolysis, 57
—, by hexane pyrolysis, 61
—, chlorination of, 483-485
—, classification of isomers, 383
—, from methylcyclobutane, 84
—, halogenation of, 1126
—, polymerization of, 382, 606
—, pyrolysis of, 74, 75
—, reaction with nitrogen pentoxide, 581
—, — sulphuric acid, 376, 380-383, 387
—, *see also* Amylene
Pentene oxides, hydration of, 558
1-Pentene, hydrogen iodide addition, 329
—, polymerization of, 604
—, pyrolysis of, 75
—, reaction with sulphuric acid, 382, 390
2-Pentene, addition of hydrogen halides to, 329, 330
—, chlorination of, 484
—, decomposition of, 603
—, dehydrogenation of, 74
—, demethanation of, 74
—, effect, production of synthetic resins, 204
—, from diethylcarbinol, 638
—, isoprene polymerization, 624
—, oxidation by permanganate, 880
—, polymerization of, 603, 604
—, pyrolysis of, 74, 75
—, reaction with aluminum chloride, 203
—, — nitrogen trichloride, 578
—, — sulphuric acid, 382, 390
—, thermal stability of, 90
2-Pentene dichloride, from 2-pentene, 484
2-Pentene-4-ol, from crotonaldehyde, 637
Pentoses, condensation with olefin oxides, 538
Pentyl halides, from pentenes, 329
Peppermint oil, use as insecticide, 1028
Peracetic acid, 932
Perbenzoic acid, from benzaldehyde, 920, 921
—, oxidation of isoprene with, 877
—, reaction with olefins, 534, 1134
Perborates, catalysts, isoprene polymerization, 626, 628
Perchlorate of 2,8-dimethylquinoline, 826
Perchloric acid, oxidation of maleic acid with, 918
Perchloromesole, from kerosene, 738
Perfumes, from aldehydes, 920
—, use of alkylated aromatics, 398
—, — isopropyl alcohol in, 362, 364, 365, 367
—, — isopropyl esters, 373
—, — secondary butyl esters, 396
Permanent gas, by pyrolysis of methane, 169
—, by pyrolysis of petroleum, 162, 164, 165

Permanganates, oxidation of olefins, 871, 880
—, removal of gum from gasoline, 903
Peroxide formation, combustion of ethane, 850, 851
—, — fuels, 977
—, — n-octane, 854
—, effect of inhibitors, 979
—, from diolefins, 642
—, oxidation of hexane, 853
—, — isopropyl ether, 371
Peroxide number, definition of, 899
Peroxides, action of, during detonation, 977, 984
—, catalysts, polymerization of diolefins, 618, 619, 654
—, —, polymerization styrene, 654
—, decomposition of, 980
—, determination of oxygen in, 899
—, effect on esterification of propylene, 327
—, effect on gum formation in gasolines, 900, 901
—, from amylene, 879
—, from ethylene, 877-879

—, solvent in hydration of propylene, 351
—, sulphur in, 450
—, test for paraffin in, 958
—, thiophene in, 454
—, use in news inks, 252
—, — wood preservative, 1031
—, viscosity of, 1152-1153
Petroleum oil sludge, solubility of, 950
Petroleum pitch, air-blown, 1003
Petroleum residues, cracking, by aluminum chloride, 201
—, —, by boron fluoride, 201
—, distillation of, 226
—, lubricating oils from, 201
Petroleum resin, soluble in thioethers, 452
Petroleum sludge, sulphonic acids from, 1025
Petroleum soaps, from alkali sludge, with sulphuric acids, 1066
Petroleum spirit, stabilization of gasoline, 898
Petroleum still gases, oxidation of, 864
Petroleum sulphonic acids, 1026, 1030
Petroleum tar, asphalt from, 1013
—, coke from, 228
Phellandrene, reaction with meleic anhydride, 651
5-Phenyl-1-chloropentane, reaction with aluminum chloride, 1056
Phenylcyclopentane, 84, 1057
Phenylcyclohexene, action of ozone on, 930
Phenylcyclohexene oxide, isomerization of, 547
Phenyldialkylethylene oxides, isomerization of, 547
5-Phenyl-2,3-dimethyl-2-pentene, properties of, 653
Phenyldiazonium fluoborate, 597
Phenyl disulphide addition to lubricants, 996
Phenylenediamine, antioxidant, for petroleum oils, 907, 909
Phenylethanol formation, 545, 548, 1059
Phenylethylene, 610
Phenylglycol, action with sulphuric acid, 555
—, from styrene, 510
Phenyl halides, vapor phase hydrolysis, 767
Phenylhydrazine, reaction with ethylene oxide, 544
—, solvent, aromatics, 34, 1143
—, —, diolefin separation, 160
Phenyl α-ketonaphthalene, 200
Phenyl mercaptan, formation of, 431
Phenylmethylcarbinol, from ethylbenzene, 926
Phenylmethylpentene, properties, 652, 653
Phenyl-α-naphthylamine, antioxidant, for lubricating oils, 907
Phenylnaphthylcarbazole, from pitch, 227
Phenylpropylthiol, 437
Phenyl selenomercaptan, stabilization of gasoline, 898
Phenyl sulphide, from cyclohexane, 430
Phenyl tetrazonium difluoborate, 598
Phenyl vinyl ketone, production of, 569
Phloroglucinol, stabilization of gasoline by, 897
Phorone, production of, 409
Phosgene, chlorinating methane with, 687, 701
—, condensation with olefins, 570
—, reaction with hydrogen, 418
—, — hydrocarbons, 1058, 1060
—, — paraffins, 418
Phosphates, aromatization catalysts, 186
—, catalyst activators, 291
—, catalysts, ammonia-hydrocarbon reaction, 297
—, —, carbon dioxide-ethylene reaction, 586
—, —, condensation of olefins with aniline, 571
—, —, condensation of olefins with aromatics, 560
—, —, dehydrogenation of alcohols, 405
—, —, esterification of olefins, 328
Phosphates, catalysts, hydration of acetylene, 677
—, —, hydrocarbon pyrolysis, 136
—, —, in cracking, 107
—, oxidation catalyst, 834, 870
Phosphatides, stabilization of gasoline by, 898
Phosphenylous acid, formation of, 875
Phosphides, dehydrogenation catalyst for alcohols, 405
Phosphine, in acetylene, 664
Phosphor bronze, effect on oxidation of petroleum, 905
Phosphorates, hydrolysis of, 875
Phosphoric acid, action on ethylene glycol, 555
—, absorption of ethylene, 322
—, catalyst, condensation of cresol and isopropyl alcohol, 375
—, —, condensation of olefins with phenols, 367
—, —, conversion of isopropylethylene to trimethylethylene, 74
—, —, for esterifying olefins, 328
—, —, hydration of acetylene, 676
—, —, hydrogen sulphide-olefin reaction, 585
—, —, hydrolysis of nitriles, 811
—, —, preparation of acetic anhydride, 682
—, —, preparation of acid chlorides, 815
—, —, preparation of acrylic acid esters, 571
—, — pyrolysis of alkylbenzenes, 147
—, dehydration catalyst, 303, 304, 307, 635
—, effect on ethylene absorption in sulphuric acid, 339
—, from phosphorates, 875
—, hydration catalyst, 303, 304, 307, 311, 312, 314, 316, 317
—, oxidation catalyst, 876, 886, 918
—, polymerization catalyst, 589, 599, 603, 613
Phosphoric esters of glycol ethers, 525
Phosphorite, oxidation of, 875
Phosphorus, action on cyclohexene, 875
—, chlorination catalyst, 722, 758
—, oxidation catalyst, 875
—, red, dehydration catalyst, 952
Phosphorus chloride, and sulphuric acid, sulphonating agent, 1034
Phosphorus compounds, catalyst, chlorination with, 739
Phosphorus halides, chlorination catalyst, 469, 756, 771
—, bromination catalyst, 768
Phosphorus oxychloride, polymerization of olefins with, 597
Phosphorus pentabromide, bromination with, 778
Phosphorus pentachloride, catalyst, polymerization of cyclopentadiene, 623
—, chlorination with, 771, 775, 780
—, isolation of undecanaphthenic acid with, 1073
—, reaction with acetylene derivatives, 685
Phosphorus pentoxide, catalyst activator, 291
—, catalyst, ethylene absorption in sulphuric acid, 339
—, dehydration with, 534
—, hydration catalyst, 307
—, polymerization catalyst, 599, 623
—, removal of gasoline gum with, 903
—, use in sweetening, 444
Phosphorous tribromide, reaction with ethylene glycol, 499
Phosphorus trichloride, chlorination catalyst, 769, 770, 776
Phosphoryl chloride, isolation of naphthenic acids with, 1073
Photobromination, toluene, 777, 778
Photochemical chlorination, 727-730
—, alkyl benzenes, 780
—, butane, 718, 719
—, cyclopropane, 745, 746
—, ethane, 713, 714
—, isobutane, 721
—, isopentane, 724, 726
—, Krasnodar aviation gasoline, 794
—, liquid hydrocarbons, 727-730
—, natural gas, 714
—, propane, 716, 717
—, toluene, 770, 775, 776
—, m-xylene, 779

Photochemical oxidation, naphthene hydrocarbons, 1064
—, paraffin oils, 939
Photochemical polymerization of ethylene, 594
Photochemical reaction of ethylene and ammonia, 571
Photoelectric colorimeter, 1148
Photographic films, use of ethanolamines in, 553
Phthalic acid, condensation with aromatics, 565
—, benzoic acid from, 921, 924
—, by hydrocarbon oxidation, 838
—, by oxidation of petroleum, 914, 919, 937
—, from naphthalene, 919, 922
—, from xylenes, 922
—, production of, 922-924
—, reaction with olefin oxides, 538
Phthalic anhydride, by oxidation of cracked kerosene, 838
—, by naphthene oxidation, 838
—, condensation with olefins, 565
—, esterification of amyl alcohol, 794
—, extractant for primary alcohols, 649
—, from anthracene, 924
—, from lignin, 949
—, from naphthalenes, 922
—, purification of, 923, 924
—, reaction with gasoline, 1059
—, — nitrogen bases, 821
—, resin with oxidized paraffins, 999
Phthalide compounds, stabilization of gasoline by, 898
Phthalones, from nitrogen bases, 821, 826
Pharmacology, of alcohols, 362, 364, 393, 394
Phenanthrene, bacterial oxidation of, 1004
—, by acetylene pyrolysis, 82, 180
—, by isobutene pyrolysis, 73, 179
—, from pitch, 227
Phenol, action on monochloroparaffin, 740
—, as a solvent, 597
—, butadiene from, 634
—, carboxylation of, 930
—, catalyst, oxidation of transformer oils, 909
—, catalytic hydrogenation of, 419
—, condensation with isobutylene, 400
—, — formaldehyde, 860
—, — propylene, 566, 567, 596
—, diolefins from, 633, 634
—, effect of silent discharge, 264
—, extraction of oil shale, 463
—, from benzene, 925, 927, 929
—, hexahydrophenol from, 634
—, production of, 766, 767
—, reaction with ethylene oxide, 538
—, — ethylene dichloride, 682
—, — nitrogen pentoxide, 1044
—, retardation of ignition of cotton by, 890
—, selective solvent for paraffins and naphthenes, 35
—, separation of diolefins by, 641
—, stabilization of gasoline by, 897
—, use in plastic compositions, 1031
Phenol-aldehyde resins, from alkylated phenols, 399
Phenolic substances, from spent doctor solutions, 448
Phenolic tars, use in asphalt manufacture, 842
Phenols, alkylation of, 399, 567, 568, 810
—, antioxidants, for lubricating oils, 907
—, by hydrolysis of aryl chlorides, 767, 785
—, condensation with cyclohexene, 566, 567
—, — olefins, 565-568
—, effect of ichthyolsulphonic acids on, 1037
—, from gas oil, 840
—, from gasoline, 835, 902
—, from shale oil, 463
—, from toluene, 919
—, in crude petroleum, 30
—, inhibitors, polymerization of butadienes, 630
—, oxidation of, 987
—, production of cyclic ketones, 419
—, resin-formation with cracked distillates, 998
—, — methylene dichloride, 705
—, stabilizing agents, 575
Phenoxychloroparaffin, 741, 817
Phenoxyparaffin, from monochloroparaffin, 740
—, production of, 809
Phenyl acetate, selective solvent, 35
Phenylacetaldehyde, cyanohydrin of, 546
—, from ethylbenzene, 1056
Phenylacetylene, from benzene, electric arc, 259
Phenylacetylenylphosphinic acid, 685
Phenylazide, reaction with polycyclopentadiene, 622
Phenylbutadiene, gum formation, in gasolines, 901
1-Phenylbutadiene, 642, 643
—, polymerization of, 619, 627
—, reaction with bromine water, 648, 649
—, — hydrogen bromide, 647
4-Phenyl-1-butene, pyrolysis of, 75, 89
Physical chemistry of cracking, 98, 99, 100
Physiological action of alcohols, 362-364, 393, 394
Phytosterol, as source of petroleum, 36
Piccolines, from acetylene, 684
Picene, by hydrocarbon pyrolysis, 226
—, occurrence in cracking tar, 89
Pickling inhibitors, mercaptans, 434
—, nitrogen bases, 829
Picrates of nitrogen bases, 822, 826
Picric acid, as antidetonant, 983
—, from toluene, 929
—, separation of nitrogen bases with, 828
Pigments, oil-absorbing capacity reduced, 614
—, dispersion of, 1029
Phenylsulphonic acid, breaking emulsions with, 1027
Pimelic acid, from stearic acid, 959
Pinacol, from acetone, 411
—, from tetramethylethylene, 581
Pinacoline, from pinacone, 411, 531, 532
Pinacoline oxime, 1043
Pinacone, dehydration by alumina, 637
Pinacone chlorohydrin, 637
Pine tar, oxidized, 1003
Pinene, autoxidation of, 889, 890
—, condensation with isoprene, 657
—, esterification of, 331
—, pyrolysis, 154
—, velocity of autoxidation of, 893
α-Pinene, oxidation of, 890, 891
β-Pinene, oxidation of, 890
Pinene oxide, preparation of, 534
Pintsch gas, butadiene from, 156
—, by pyrolysis of heptane-octane mixture, 61
Pinus sabiniana, heptane from, 735
Piperazine, separation of ichthyolsulphonic acid fractions by, 1037
Piperidine, as an antitoxidant, 907, 909
—, effect of, preparation of wetting agent, 817
—, from acetylene, 684
Piperonal, test for isopropyl alcohol, 367, 368
Piperylene, from cracking process, 154
—, from diethylcarbinol, 638
—, from 2-pentene-4-ol, 637
—, hydrogenation of, 657
—, identification, 660
—, in cracked gasoline, 119
—, polymerization of, 619, 627
—, reaction with maleic anhydride, 659
—, tetrabromides from, 644, 659, 1145
Pitch, coke from, 228
—, cracked by submerged combustion, 1000
—, cyclic hydrocarbons from, 227
—, from cracking with aluminum chloride, 193
—, from paraffins, 219
—, from petroleum pyrolysis, 165
—, insulating materials from, 740
—, oxidation of, 993
—, solubility in sec.-hexyl acetate, 402
Pitch sulphonates, used in breaking emulsions, 1026
Plasticizers, dibasic acid esters, 402
—, ter.-butyl-β-naphthol, 401
—, diethylene glycol monoethyl ether, 528
—, ethanolamines, 553
—, ethylene glycol monoethyl ether stearate, 525
—, esters of keto acids, 1059
—, ethyl sulphoxide, 451
—, from phthalic acid, 922

Plastics, calcium sulphonate, 1015
—, ethylene dichloride-polysulphides, 474, 475
—, from acetylene, 667
—, from chlorinated hydrocarbons, 474
—, from diolefins, 628, 629, 630
—, from divinylacetylene, 670
—, from hexamethylenetetramine, 860
—, from mineral oils, 1031
—, from oxidation products, 998, 999
—, from sulphur dioxide-olefin reaction, 575, 576
—, preparation, 1024, 1031
—, prepared with isopropyl alcohol, 366
—, resins in, 498
Plate process for carbon black, 234, 241
Platinized carbon, dehydrogenation catalyst, 198
Platinous salts, double compounds of olefins with, 582
Platinum, as promoter of detonation, 966
—, catalyst, ammonia-hydrocarbon reaction, 297
—, —, carbon monoxide-ammonia reaction, 297
—, —, for pyrolysis, 65, 84, 86, 135, 154
—, —, hydrocarbon-nitrogen oxide reaction, 298
—, —, methane-carbon monoxide reaction, 932
—, chlorination catalyst, 691, 715, 775
—, dehydrogenation catalyst, 85, 87, 181, 405, 413
—, determination of methane with, 1098
—, effect on ignition temperatures, 967, 968
—, hydration catalyst, 307, 314, 584
—, oxidation catalyst, for alcohols, 406, 530, 869, 870
—, —, for hydrocarbons, 852, 863, 864, 867, 872, 874, 875, 892, 918, 993
—, polymerization catalyst, 682
Platinum black, catalyst, pyrolysis of cyclopropane, 83
—, hydrogenation catalyst, 412, 656
—, oxidation catalyst, 847, 872
Platinum chloride, chlorination catalyst, 690, 691
—, reaction with nitrogen bases, 820, 821
Platinum-copper, oxidation catalyst, 869, 870
Platinum electrodes, chlorination of aromatics, 761, 762, 774
—, electrical ignition of methane, 970
—, oxidation of benzene, 927
Platinum gauze, catalyst, methane-steam reaction, 287
—, oxidation catalyst, 944
Platinum metals, catalysts, ethylene absorption in sulphuric acid, 343
Platinum nitrate, chlorination catalyst, 691
Platinum salts, action with acetylene, 667
Platinum sponge, catalyst, pyrolysis of cyclopropane, 83
Plumbite treatment of gasoline, 438, 439
Podbielniak apparatus, 1103-1115
Polish natural gas, analysis of, 15
—, pyrolysis of, 229
Polyalkylene glycol esters, production of, 527, 528
Polyalkylene glycol ethers, production of, 528
Polyalkylnaphthalenes, production of, 559
Polybrominated derivatives, of benzene, 768
—, of butane, 720
—, of cyclohexane, 749, 750
Polybutyl naphthalenes, 563, 564
Polychlorinated derivatives, of toluene, 775
Polychlorinated hydrocarbons, dissociation of, 816
Polychlorinated paraffins, dechlorination of, 804, 805
—, heating of, with alkalies, 818
—, production of, 728, 731
Polychloroprene, 639
Polycyclopentadiene, production and properties, 621, 622
Polydichloroethylene, 815
Polyesters from glycols, 521
Polyethylene glycol acetates, 541
Polyethylene polyamines, from ethylene dichloride, 474
Polyethylnapthalenes, production of, 563, 564
Polyglycols, by dehydration of 1,2-glycols, 512, 526-529
—, by hydration of olefins, 511
Polyglycols, dioxans from, 555
—, esterification of, 527, 528
—, from ethylene oxide, 537
—, from olefin oxides, 526
—, reactions of, 526
—, as solvents, 526
Polyhexenes, from hexenes, 383, 384
Polyhydric phenols, stabilizing agents, 575
Polyhydroxy compounds, condensation with alkylene oxides, 522
Polymerization, a bimolecular reaction, 98, 616, 617
—, effect of autoxidation on, 893
—, — methyl substitution on, 627
—, — phenyl substitution on, 619
—, effect on primary reactions of cracking, 98
—, in nitrous oxide-ethylene reaction, 299
—, in pyrolytic formation of aromatics, 162
—, in sulphur chloride-olefin reaction, 576
—, mechanism of, 589-592, 599, 618, 619
—, of acetylene, 81, 82, 106, 264, 267, 268, 272, 273, 274, 595
—, of allene, 272, 273, 615
—, of allylene, 273
—, of ammonia-ethylene dichloride, 474
—, of amylene, 195, 202, 267, 330, 380, 382, 1050
—, of aryl-substituted olefins, 610
—, of benzene, 269
—, of brown-coal tar, 202
—, of butadienes, effect of methyl groups, 619
—, of 1-butene, 202, 378, 379, 599
—, of 2-butene, 273, 316-318, 602
—, of cetene, 606
—, of chloroprene, 639, 640
—, of conjugated diolefins, 79, 612-622
—, of cracked gasoline, 78
—, of cyclohexadiene, 625
—, of cyclohexene, 597
—, of cyclopropane, 273, 559, 1009
—, of esters, 936
—, of ethane, silent discharge, 268
—, of ethylene, 66-69, 144, 169, 195-197, 264-266, 269, 272, 273, 274, 336, 346, 592-597, 610
—, of ethyl mercaptan, silent discharge, 265
—, of 3-ethyl-2-pentene, 385
—, of formaldehyde, 861
—, of glycol esters with dibasic acids, 520
—, of 3-heptene, 607
—, of hexadecene, 78, 80, 606, 607
—, of hexylene, 78, 383, 384, 606, 607
—, of hydrocarbons, by aluminum chloride, 191
—, —, during cracking, 93
—, of indene, 591
—, of isobutylene, 202, 266, 316, 378, 596, 599, 600, 601
—, of isoprene, 203, 272, 273, 617, 618, 619, 624
—, of methylacetylene, 272
—, of methylheptene, 386, 607
—, of mineral oils, by aluminum chloride, 202
—, of naphthenes by aluminum chloride, 193
—, of nitrogen compounds, 822
—, of octenes, 386, 507, 606
—, of olefins, by α-radiation, 273, 589, 595, 599, 602
—, —, by aluminum chloride, 144, 190, 194, 195, 197, 200-204, 570, 1050
—, —, by boron fluoride, 197, 595-597
—, —, by cathode ray, 274
—, —, by electric discharges, 255, 264, 267-269, 589, 591, 594, 599, 610
—, —, by excited mercury atoms, 594
—, —, by mercury light, 272
—, —, by sulphuric acid, 80, 82, 104, 105, 325, 326, 336, 346, 347, 350, 354, 376, 378-384, 391, 590, 593, 596
—, —, by ultraviolet light, 589, 611
—, —, effect of pressure, 80, 82, 104, 105, 588, 590, 593, 596
—, —, in refining, 1012
—, —, thermal, 80, 82, 93, 94, 97, 104, 105, 350, 588, 590, 593, 594, 599, 609, 611, 616-618
—, —, to cycloparaffins, 80
—, of olefin oxides, 547
—, of pentadiene, 621, 622
—, of pentenes, 382, 606

Polymerization of propylene, 264, 273, 309, 325, 326, 347, 376, 596, 597, 599, 608
—, of resin-forming constituents, 987
—, of stilbene, 613
—, of styrene, 588, 591, 610-612
—, of tetramethylethylene, 606, 607
—, of trimethylethylene, 606
—, of turpentine, 264
—, of unsaturated hydrocarbons during cracking, 104
—, —, from oil gas, 116
—, of vinyl acetate, 588
—, of vinylacetylene, 273
—, prevention of, 350, 354
—, removal of gum by, 902
—, secondary reaction in cracking, 97
Polymerization products, use of, 613, 614, 615, 1024
Polymerized bodies in sludges, 1013
Polymerized hydrocarbons, cracking of, 97
Polymerized olefins, by oxidation of hydrocarbons, 852
—, decomposition of, 79, 80
—, separation of olefins by, 144
—, types of olefins resistant to, 620
—, velocity of, effect of temperature, 98
Polymerized residues, from cracking, as paint vehicle, 97
Polymerized sulphones, from sulphur dioxide and diolefins, 575
Polymers, alkyl halides freed from, 371
—, in crude isopropyl alcohol, 359, 360, 370
—, liquid, from conjugated dienes, 616-622
—, of acrylic acid, 586
—, of cyclopentadiene, 623
—, of olefins, extraction from secondary alcohols, 394
—, —, use, 613
—, separation from alkylsulphuric acid, 356
—, types of, 590
—, —, from diolefins, 614
Polynaphthenes, in lubricating oil, 30, 1012
Polynaphthenic acids, from naphthenic hydrocarbons, 1064
Polynuclear naphthenes, sulphonation of, 1007, 1020
Polyprene, 639
Polystyrene, 610-613
Polysulphides formed during sweetening, 440
—, from ethyl sulphide, 457
—, from mercaptans, 433, 438, 457
—, in petroleum oils, 421
—, plastics from, 474, 475
Polyvinyl alcohol, 522, 538
Polyvinyl bromide, 680, 681
Pontianac, solubility in secondary hexyl acetate, 402
Porcelain, catalyst, carbon dioxide-methane reaction, 282
—, —, methane-steam reaction, 277
—, —, pyrolysis of chloro hydrocarbons, 803, 816
—, effect of, ethylene absorption in sulphuric acid, 339
—, —, in cracking, 106
—, —, pyrolysis of paraffins, 40, 43, 45, 50, 53, 64, 122, 208, 951
—, —, pyrolysis of olefins, 65, 75
—, oxidation catalyst, 936, 951
Porous materials, catalysts, methane chlorination, 696-608
Positive column, glow discharge methane, 849
Positive rays, action on hydrocarbons, 274
Potash, alcoholic, action on chlorinated undecanaphthene, 752
—, —, action on trichlorocyclohexane, 749
—, reaction with halogenated compounds, 633, 682
Potash-lime, hydrolysis of methyl chloride, 782
Potassium, catalyst, diolefin-ammonia reaction, 656
—, electrodes of, 264
—, desulphurization catalyst, 458
—, oxidation catalyst, 945
Potassium acetate, use in glycol formation, 507
—, use in esterification of amyl chlorides, 793, 795
—, use in hydrolysis of methyl chloride, 784, 786
Potassium benzenesulphonate, use in glycol formation, 507
Potassium benzoate, esterification of chlorinated paraffins, 795
Potassium bifluoride, treatment petroleum residues, 598
Potassium bisulphite, addition to olefins, 575
Potassium butyrate, use in esterification of amyl chlorides, 793
Potassium carbide, hydrolysis of, 662
Potassium carbonate, dehydration of isopropyl alcohol, 357
—, oxidation catalyst, 909
—, removal of hydrogen sulphide, 424
—, salting-out effect on isopropyl alcohol, 360
Potassium chloride, oxidation catalyst, 878, 886, 892
Potassium chlorate, oxidation catalyst, 883
Potassium chromium sulphate, catalyst, diphenyl production, 189
Potassium cyanide, action on chlorohydrins, 496, 502
—, reaction with alkyl chlorides, 810
Potassium dichromate, action on mercaptans, 447
—, catalyst, methane-steam reaction, 276
—, oxidation of hydrocarbons with, 924, 933, 948, 949
Potassium ethoxide, antidetonant, 983
—, effect on oxidation, 980
Potassium ferricyanide, action on mercaptan, 447
—, catalyst, ethylene absorption in sulphuric acid, 342, 357
—, removal of gasoline gum by, 903
Potassium ferrocyanide, catalyst, ethylene absorption sulphuric acid, 342, 357
Potassium fluoride, salting-out effect on isopropyl alcohol, 360
Potassium formate, from methyl chloride, 782
Potassium hydrogen sulphate, methane chlorination in, 698
Potassium hydroxide, absorption of hydrogen sulphide, 424
—, action on styrene chlorohydrin, 558
—, — oil oxidation products, 905
—, catalyst, pyrolysis of hydrocarbons, 134
—, dechlorination with, 947
—, determination of carbon dioxide with, 1094
—, extraction of aldehydes with, 939
—, — mercaptans, 436
—, hydration catalyst, 312, 677
—, hydrolysis of ethyl chloride, 787
—, — ozonized oil by, 938
—, oxidation catalyst, 939
—, polymerization of olefin oxides, 548
—, production of diacetone alcohol, 410
—, reaction with chloroparaffins, 948
—, — β-chloro-β-phenylvinylphosphinic acid, 685
—, — trimethylethylene chlorohydrin, 503
—, use in purification of acetylene, 664
—, *see also* Potash

Q

Quaternary paraffins, nitration of, 1040, 1041, 1043
Quarternary salts, from nitrogen bases, 820
Quartz, catalyst, ammonia-hydrocarbon reaction, 296
—, —, nitric oxide-ethylene reaction, 299
—, —, oxidation of methane, 867
—, effect, pyrolysis of ethane, 130
—, —, pyrolysis of hexadecane, 131
—, —, pyrolysis of methane, 41, 43, 148, 149, 167
—, —, pyrolysis of octenes, 76
—, —, pyrolysis of paraffins, 135
—, —, pyrolysis of propane, 50, 130
—, —, pyrolysis of propylene, 70
Quinhydrone, effect on ignition of cotton, 890
Quinizarine, from anthraquinone, 924
Quinol, antioxidant for transformer oils, 909
—, carboxylation of, 930
—, from benzene, 927
—, ignition of cotton retarded by, 890
—, oxidation inhibitor, 984
—, stabilizing agent, butadiene-sulphur dioxide reaction, 575
Quinoline, action on chlorocyclohexane, 749, 801
—, — chlorodecanaphthenes, 752
—, antioxidant for lubricating oils, 908
—, catalyst, chlorination of aromatics, 761
—, pickling inhibitors, 829
Quinones, condensation with dienes, 650, 653
—, from benzene, 927
—, inhibitors of butadiene polymerization, 630
—, — gum formation, 897

R

Rags, oxidized, 1004
Ragusa crude, cracking of, 92
Ramage process, cracking, 111
Ranger gas oil, decomposition of, 99
Rangoon gasoline, n-heptane from, 24
Rangoon paraffin wax, cracking with aluminum chloride, 191
—, pyrolysis of, 63
—, vapor-phase cracking of, 120
Rare-earth compounds, catalysts, ammonia-hydrocarbon reaction, 297
Rare-earth metal chlorides, catalysts, chlorination hydrocarbons, 702, 713
—, —, oxidizing methane-hydrogen chloride, 701
Rare-earth metals, activators for nickel, 288
Rate of burning, effect on yield of carbon black, 241
Rate of cure, rubber compositions with carbon blacks, 248
Rate of decomposition, pyrolysis of residual oils, 133
Rate of distillation, control of, 1108, 1109
Rate of flow, effect in cracking spray oil, 163
—, — production of ethylene, 125
—, — pyrolysis of ethane, 44
—, — pyrolysis of hexadecane, 131
—, — pyrolysis of methane, 40, 42, 43, 121, 168
Rate of reaction, oxidation of acetaldehyde, 932
—, — olefins, 880, 881
—, sulphuric acid absorption of pentenes, 382
Reaction velocity, alcohol synthesis, 305
—, bromohydrin formation, 499
—, coefficient, of cracking, 98
Reagents for gas analysis, 1094, 1095
Rearrangement of hydrocarbons, by aluminum chloride, 191
Rectification of hydrocarbons, analytical, 1116
Recycling of gases, 103, 124, 130, 132, 133
Red gels, extraction of sulphur compounds, 459
Red lead, effect in oxidation of transformer oils, 909
Reduced copper, catalyst in pyrolysis, 123
Reduced crudes, definition of, 93
Reduction, catalytic, carbon monoxide, 184, 186, 276
—, nitro compounds, 1050-1052
—, olefin dibromides to olefins, 478
Redwood viscometer, 1152
Refinery gases, oxidation of, 834
—, Gyro process, 113
Refining, naphthenic acids, 1067
—, hydrocarbons, 9, 274, 933, 934
—, oxidation methods, 987, 988
—, use of adsorbent materials, 1012 1065
—, with sulphuric acid, 1005, 1006
Refining agents, effect on sulphur compounds, 458-461
Reforming hydrocarbons, 112, 292, 844
Refrigerants, characteristics of, 707
—, chlorinated methanes, 703, 704
—, dichlorodifluoromethane, 707
—, dichloroethylene, 675, 704
—, ethyl chloride, 703, 715
—, fluorochloro methanes, 707, 710
—, isopropyl chloride, 371
—, methyl bromide, 706
—, toxicity, 709
Rennin, 367
Residual affinities, conjugated diolefins, 641
Residual cracking gases, carbon black from, 183, 184
—, oxygenated organic compounds from, 183
Residual gases, acetylene from, 150
—, olefins in, 355
—, recycling of, 130
Residual oils, pyrolysis of, 133
Residual olefins, extraction of, 349
Residues, aluminum chloride cracking process, 191
—, cracking of hexanes, 194
—, from cracked distillates, oxidation of, 841
—, sulphur content of, 421
Resin-forming constituents, polymerization by oxygen, 987
—, removal with ozone, 988
Resinates, oxidation catalysts, 926, 938
Resinic sulphur in oil shale, 463
Resinification, of esters, 936
—, of oxidized petroleum, 837
Resins, as source of petroleum, 36
—, by nitration, 814, 1052, 1053
—, by oxidation processes, 997
—, by sulphonation of naphthenes, 1009
—, decomposition, electric arc, 262
—, emulsification, 375, 1025-1027
—, formation, 567, 573, 934
—, from acetylene, silent discharge, 267
—, from cracked petroleum, 998
—, from dimethylol urea, 498
—, from diolefins, 204, 616-620, 642
—, from diphenylolpropanetetracarbinol, 498
—, from divinylacetylene, 670
—, from ethylene, silent discharge, 264
—, from ethylene oxide, 541
—, from isoprene, 624
—, from methane, silent discharge, 264

Resins, from methyl ether, silent discharge, 265
—, from olefins, 203, 204, 353, 564, 582, 614, 624, 844, 1126
—, from oxidized pinene, 889
—, from petrolatum, 949
—, from phthalic acid, 922
—, from sludges, 353, 1067, 1068
—, from styrene, 146
—, from tertiary alcohols, 392
—, from transformer oils, 909
—, from unsaturates and formaldehyde, 586, 587
—, from vinylacetylene, 670
—, from vinyl esters, 679, 681
—, from xylenes, 204
—, in oils, protective action of, 906
—, methylene dichloride-phenols condensation, 705
—, oxidation of, 993
—, solubility in ethylene glycol diacetate, 520
—, — isopropyl alcohol, 362, 366
—, — isopropyl ether, 370
—, — propylene chlorohydrins, 500
—, — trichloroethylene, 674
—, sulphonation of naphthenes, 1010
—, unsaponifiable, 624
—, use in lacquers, 498
—, — varnishes, 624, 1030
Resorcinol, carboxylation, 930
—, reaction, boron fluoride, 596
—, stabilization of gasoline, 897
Rhapontic, 365
Rhodium catalyst, ammonia-hydrocarbon reaction, 297
Rhodium compounds, catalysts, ethylene absorption sulphuric acid, 342
Rhodium salts, action with acetylene, 667
Rincker-Wolter process, 208, 209
Ring closure, in pyrolytic formation of aromatics, 162, 168
Rittman process, 111, 162, 165
Roller process for carbon black, 234, 237, 241, 246
Rosin, dechlorination of hydrocarbons, 741
—, mixture with paraffin oxidized, 997
—, purification of, 16
—, reaction with chlorohydrins, 498
—, — ethylene oxide, 541
—, solubility in diethylene glycol acetate, 527
—, — isopropyl alcohol, 366
—, — sec. hexyl acetate 402
Rosin phthalic glyceride, 996
Rotating disc process, for carbon black, 237, 241
Rubber, blown residues used in, 999
—, depolymerization, 625
—, destructive distillation, 154, 627
—, dispersing agents, 1026
—, in chewing-gum base, 740
—, isoprene from, 154
—, properties, 626, 627
—, pyrolysis, isoprene from, 635
—, solubility in dichloroethylene, 675
—, — thioethers, 452
—, — trichloroethylene, 674
—, solvents, 452, 614, 675
—, synthetic, from divinylacetylene, 670, 671
—, —, production, 614, 616-620, 625-629, 633
—, —, properties, 626, 627, 628
—, —, structure, 626
—, trimethylethylene from, 154
—, vulcanization, 627, 628
Rubber compositions, carbon blacks in, 236, 239, 248, 252
Rubber-like substances, from acetylene, 667
—, from petroleum, 576, 841, 1030
—, polymers, 616-620, 623
Rubbing alcohol, use of isopropyl alcohol in, 365
Rubidium carbide, hydrolysis of, 662
Rumanian crude oils, gases from, 18
—, naphthenic acids in, 1062, 1076, 1079, 1081, 1084
—, thiophene in, 454
Rumanian distillates, naphthenic acid content of, 1064
Rumanian gasoline, 21, 836
Rumanian kerosene, aromatic hydrocarbons in, 34
Rumanian petroleum, methylcyclopentane from, 23
—, nitration of, 1042, 1043
—, sulphur content of, 421
Russian gas oil, oxidation of, 1034
Russian gasoline, n-pentane from, 24
Russian mineral oil, production, 1013
Russian natural gases, analysis of, 15
Russian petroleum, naphthenic acids from, 1062, 1064
—, nitration of, 1053
—, pyrolysis of, 86, 163, 227
Russian shale oil, sulphur compounds in, 463
Rust-preventatives, 1031
Ruthenium, dehydrogenation catalyst, 87
—, oxidation of cyclohexene, 892
Ruthenium compounds, catalyst, ethylene absorption, 342
Ruthenium oxide, oxidation catalyst, 833

S

Sabinene, to terpineol-4, 301
Safranine, stabilization of gasoline by, 897
Salicylic acid, addition to amylene, 330
—, as an antioxidant, 909
—, esterification of pinene, 331
—, from cresol, 915
Salicylaldehyde, from cresol, 915
Salicylic phthalic glyceride, 996
Salting-out, isopropyl alcohol, 360
—, tertiary butyl alcohol, 378
Salts, double compounds with olefins, 582-584
—, metallic, catalysts, polymerization of olefins, 589
—, molten, use in cracking hydrocarbons, 135
—, of keto acids, driers, 1059
Samarium oxide, catalyst, oxidation of alcohols, 869
—, —, oxidation of methane, 863
Sand, catalyst, olefin-chlorine addition, 469
Sandarac, solvents for, 366, 373, 525
Saponifiable matter, separation from oxidized wax, 953
Saponifiable products, from mineral oils, 1066
Saponification, effect of oxidation on, 936
—, of alkyl chlorides, 781, 783, 784
—, of ethyl naphthenate, 1070
Saturated acids from oxidized paraffin oil, 934
Saturated gaseous hydrocarbons, pyrolysis of, 129
Saturated hydrocarbons, by hydrolysis of metallic carbides, 662
—, chlorination, 699
—, conversion to aromatics, 165-177
—, from cracking gas, 139
—, from lower olefins, 145
—, from olefins and hydrogen sulphide, 425
—, from unsaturated hydrocarbons, 289, 290
—, in reformed butane, 292
—, nature of halogenation, 686
—, oxidation in presence of olefins, 832
—, pyrolysis, 135
—, substitution compounds from, 1039
—, *see also* Hydrocarbons and Paraffins
Saturated oils, lubricant qualities, 906
Sawdust, oxidized, 1004
—, removal of oil from isopropyl alcohol, 351
Saxon lignite, hydrocarbons from, 227
Saybolt chromometer, 1148
Scandium oxides, catalysts for pyrolysis, 157, 158
Schiff reagent, test for paraffin, 958
Scouring soaps, from dichlorodiethyl ether, 498
Seaweed, suggested source of petroleum, 36
Secondary alcohols, by hydration of olefins, 781
—, distinguished from primary and tertiary, 371, 391, 392, 393
—, from olefins, 332, 346, 355, 356, 377-390, 401, 792
—, from wax acids, 998
—, higher, manufacture of, 389, 390
—, ketones from, 404, 408

Secondary alcohols, oxidation of, 391, 416
—, properties of, 391
—, reaction with hydrochloric acid, 393
—, *see also* Alcohols
Secondary chlorides, relative rate of decomposition, 789
Secondary halogen derivatives, hydrolysis of, 788, 793
Secondary reactions, effect on velocity coefficients, 98
—, electric arc, 257
—, in cracking, 96, 97, 101
—, —, effect of pressure on, 104
—, silent discharge, 267, 268
Selective solvents, extraction of aromatics, 34
Selenic acid, catalyst, oxidation of aromatics, 930
Selenide dichlorides, hydrolysis of, 577
Selenides, dehydrogenation catalyst, alcohols, 405
Selenium, aromatization catalyst, 183
—, catalyst, chlorination toluene, 775
—, —, diphenyl production, 189
—, —, hydrocarbon pyrolysis, 136
—, —, nuclear substitution of toluene, 771
—, —, polymerization of acetylene, 668
—, —, production of ethylene, 125
—, —, pyrolysis of methane, 150
—, reaction with paraffin, 956
—, use in oxidation of mercaptans, 432
Selenium chloride, reaction with olefins, 577
Selenium compounds, aromatization catalysts, 183
—, as antioxidants, 909
Selenium diethyl, effect on ignition temperatures, 969
Selenium dioxide, in olefin-sulphur oxychloride reaction, 577
—, oxidation of olefins, 876, 877, 879
Selenium oxychloride, reaction with olefins, 576, 577
—, removal of unsaturated hydrocarbons with, 577
—, selective solvent for aromatics, 34
Selenium vapor, effect on ignition temperatures, 979
Semicarbazide, condensation with unsaturated compounds, 585
Semicarbazone, formation, 1085
Semi-corona discharge, action on hydrocarbons, 269
Seminole gas oil, decomposition of, 99
Separation, acetylene, 152
—, analytical, of hydrocarbons, 1099
—, butadiene, 160
—, butene isomers, 328
—, butylene, 138, 143
—, diolefins, 141, 159-160
—, ethylene, 141, 142
—, higher alcohols from oils, 389
—, hydrocarbons, 1101
—, —, effect of electric arc, 143
—, methane, 140
—, methyl chloride from methane, 696
—, methylene dichloride from methyl chloride, 704
—, olefins, 137-142
—, —, by absorbing liquids, 141-143
—, —, by adsorption, 143
—, of paraffins by distillation, 1101
—, products of methane chlorination, 696, 698
—, propylene, 140, 142, 355, 390
—, secondary from tertiary olefins, 390
Sesquiterpene alcohols, formation, 650
Shale, hydrocarbons from, 933
—, hydrogen from, 209
—, pyrolysis of, 209
Shale-distillation gases, oxidation of, 864
Shale gasoline, removing gum-forming constituents, 988
Shale oil, disinfectants from, 1037
—, isolation of bases from, 825
—, sulphonation of, 1036-1038
—, sulphur compounds in, 421, 450, 462, 463
Shale-tar oils, sulphonated, 1019
Shale tars, bases from, 827
Shampoos, use of isopropyl alcohol in, 362, 365
Shellac, solvents for, 366, 373, 394, 395, 402, 525, 798
Shoe polishes, use of oxidized paraffin, 996, 997
Short blacks, definition, 244
Short channel carbon blacks, 252
Short inks, production of, 245, 252
Side chains, effect of, thermal stability of aromatics, 89
—, nitration of, 1046
—, splitting of, effect of temperature on, 163
Silent discharge, action on acetylene, 264, 267, 268
—, — amylene, 266, 267
—, — benzene, 269
—, — butane, 268
—, — butylene, 595, 602
—, — cyclic hydrocarbons, 270
—, — decanaphthalene, 270
—, — ethane, 264, 268
—, — ethylene, 264, 265, 268, 595
—, — hydrocarbons, 255, 264-272
—, — hydrocarbons, mechanism of, 270
—, — methane, 264, 268-270
—, — propane, 268
—, — propylene, 264, 599
—, — toluene, 267
—, — unsaturated hydrocarbons, 270
—, — water gas, 267
—, activating methane chlorination, 687, 701
—, dehydrogenation in, 264, 268, 269
—, hydrogenation in, 269
—, polymerization with, 255, 264, 269, 589, 591, 599
Silica, aromatization catalyst, 186
—, catalyst, condensation of olefins with aromatics, 564
—, —, esterification of olefins, 324
—, —, ethylene absorption in sulphuric acid, 335
—, —, graphitization of coke, 228
—, —, hydrolysis of methyl chloride, 782, 785
—, —, isomerization of isopropylethylene, 74, 603
—, —, oxidation of hydrocarbons, 866, 867, 872
—, —, polymerization of propylene, 599
—, —, production of ethylene, 125
—, —, pyrolysis of acetylene, 180
—, —, — methane, 150
—, effect, chlorination of benzene, 763
—, —, cracking, 106
—, —, polymerization of acetylene, 82
—, —, pyrolysis of butane, 53, 54, 123
—, —, — n-butane-isobutane mixture, 57
—, —, — butylene, 71, 72
—, —, — ethane, 45, 46, 122
—, —, — ethylene, 67, 68
—, —, — n-hexane, 60
—, —, — isobutane, 56
—, —, — methane, 39-42, 121
—, —, — paraffin hydrocarbons, 64, 217
—, —, — propane, 49, 50, 123, 127
Silica gel, adsorption of gases by, 1116
—, — hydrogen sulphide by, 425
—, — mercaptans by, 446
—, catalyst, chlorination of pentane, 727, 729, 730
—, —, condensation of olefins and ammonia, 571
—, —, decomposition of hydrocarbons, 222
—, —, formation of acetylene dichloride, 675
—, —, — ethylidene bromide from vinyl bromide, 478
—, —, hydrogen sulphide-olefin reaction, 425, 584
—, —, hydrolysis of phenyl chloride, 767
—, —, isomerization of olefin oxides, 547
—, —, — methane, 849
—, —, — olefins, 547
—, —, oxidation of olefins, 875, 878, 879
—, —, polymerization of butadiene, 629, 630
—, —, — olefins, 589, 602
—, —, pyrolysis of benzene homologues, 146
—, —, — cyclohexane, 85
—, —, — 2-pentene, 74
—, catalyst stabilizer, 345
—, conversion of butyl mercaptan to thiophene with, 426
—, effect, ethylene absorption in sulphuric acid, 339
—, —, pyrolysis of acetylene, 82

Silica gel, effect, pyrolysis of 1-butene, 72
—, —, — ethylene, 67
—, —, — propylene, 71
—, evaluation of transformer oils with, 911
—, extraction of sulphur compounds with, 459
—, purification of acetylene by, 152, 664
—, — isopropyl alcohol by, 359
—, — phthalic acid by, 923
—, refining of transformer oils with, 910
—, removal of polymers from gasoline with, 608
—, separation of olefins with, 143
—, use in ozonizing oils, 988
Silicates, catalysts, in cracking, 113
—, —, methane-steam reaction, 291
—, —, oxidation of hydrocarbons, 915
—, —, — olefins, 878
—, oxidation catalyst, 834
—, use in hydrocarbon pyrolysis, 136
Siliceous earths, catalysts, polymerization of amylenes, 598
Silicic acid, catalyst, pyrolysis of methane, 40
—, effect in pyrolysis of methane, 166
Silicon, aromatization catalyst, 182, 187
—, catalyst, hydrocarbon pyrolysis, 136
—, —, in cracking, 113
—, —, olefins-acetylene pyrolysis, 187
—, —, oxidation of methane, 872
—, —, polymerization of olefins, 610
Silicon carbide, aromatization catalyst, 182
—, catalyst, in cracking, 107
—, —, pyrolysis of hydrocarbons, 134, 136
—, use in grinding compositions, 1031
Silicon dioxide, catalyst, formation of acetone, 678
—, oxidation catalyst, 243, 843
Silicon hydrides, purification of acetylene, 664
Silicon nitride, formation of, 294
Silicon tetrachloride, effect on aluminum chloride cracking, 191
—, — inflammability limits, 964
Silicotungstic acid, catalyst, thiophene formation, 887
Silk, artificial, processing of, 1028, 1029
—, copper ammonium, reaction with ethylene oxide, 539
Sillimanite, catalyst, pyrolytic formation of naphthalene, 184
—, use in pyrolysis of paraffins, 135
Silver, aromatization catalyst, 186
—, catalyst, ammonia-hydrocarbon reaction, 297
—, —, decomposition of hydrocarbons, 221
—, —, dehydrogenation of alcohols, 396
—, —, formation of ethylene oxides, 536
—, —, — methyl ethyl ketone, 415
—, —, — vinyl ethers, 682
—, —, glycol production, 511
—, —, hydration of ethylene, 307
—, —, — propylene, 307, 314
—, —, hydrogenation of acetone, 413
—, —, oxidation of acenaphthane, 929
—, —, — alcohols, 405, 406, 869, 870
—, —, — hydrocarbons, 875, 876
—, —, — methane, 847, 863-865, 867
—, —, — methyl alcohol, 868, 869
—, —, — toluene, 919, 920
—, —, pyrolysis of hydrocarbons, 224
—, determination of, 1123
—, effect on ignition temperature of hydrocarbons, 967
—, formaldehyde in recovery of, 860
—, molten, hydrocarbon decomposition by, 220
—, oxidation catalyst, 833, 834, 838
Silver acetate, action on monochlorocyclohexane, 749
Silver chloride, absorption of acetylene by, 1122
—, catalyst, methane chlorination, 690, 693
Silver chloride complexes, 600
Silver chromate, oxidation catalyst, 992
Silver-copper, catalyst, oxidation of alcohols, 869, 870
Silver cyanamide, oxidation catalyst, 833
Silver hydroxide, catalyst, oxidation of alkylbenzenes, 926
Silver naphthalenedisulphonate, catalyst, hydration of propylene, 314
Silver nitrate, absorption of ethylene by, 1122, 1123
—, reaction with acetylene polymers, 268
—, scrubbing of coal gas with, 142
—, test for mercaptans, 439
Silver oxide, action on monochlorocyclohexane, 749
—, catalyst, formation of dioxan, 555
—, —, oxidation of aldehydes, 857
—, —, — methane, 863, 864
—, —, production ethylene oxide, 533
—, —, pyrolysis of paraffins, 135
—, catalyst activator, 345
—, reaction with sulphonium compounds, 451
Silver peroxide, oxidation of quinone, 916
Silver phosphate, catalyst, hydration of monovinylacetylene, 669
Silver-quartz, aromatization catalyst, 186
Silver salts, absorption of ethylene by, 582
—, action on ethyl alcohol, 304
—, addition to acetylene, 666
—, catalyst, ethylene absorption in sulphuric acid, 142, 341
—, double compounds of olefins with, 582
—, for determination of acetlyene, 1094
Silver salt solutions, absorption of olefins, 142
—, diolefin separation, 160
Silver sulphate, catalyst, ethylene absorption, 336, 337, 338, 1118
—, —, formation of ketene, 414
—, —, hydration of ethylene, 308, 311, 322
—, —, — propylene, 314
—, —, recovery of, 337, 341
Silver sulphide, removal of mercaptans, 440
Silver surfaces, effect on ignition temperatures, 968
Silver vanadate, oxidation catalyst, 677, 933
Slack wax, purification with higher alcohols, 398
Slag, catalyst, pyrolysis of residual oils, 133
Sludge, cause of formation, in transformer oils, 909, 910
—, extraction from transformer oils, 911
—, lubricating oils from, 1030
Soap making, naphthenic acids in, 1085
—, products of oxidized mineral oils in, 936
Soap odor, elimination of, 938
Soap solution, solvent, separation of hydrocarbons, 143
Soaps, as water-proofing materials, 837
—, chlorinated paraffins in, 1022
—, from chlorinated paraffins, 740, 814
—, from hydroxy-acids, 959
—, from kerosene, 939
—, from mineral oils, 1022, 1023, 1024
—, from oxidized hydrocarbons, 940
—, from oxidized paraffin, 994, 995
—, from oxidized petroleum, 836
—, from paraffin, 945, 950
—, from wax acids, 941, 942, 945, 960
—, oil-soluble, 565
—, separation of, 942
—, sulphonates, comparison of detergent power, 1023
—, use in hydrolysis of chloropentanes, 790, 791
—, use of higher alcohols in, 1059
—, — isopropyl alcohol in, 366
Soda-lime, dehalogenation with, 633, 634
—, effect in bromination of butanes, 720
—, formation of isoprene from chlorinated isopentane, 154
—, use in hydrolysis of ethyl chloride, 786
—, use in removal of carbon monoxide, 209
Sodamide, catalyst, polymerization of isoprene, 626
—, condensation of ethyl chloride with, 807
—, effect, alkylation of ammonia, 806, 807
Sodium, catalyst, condensation of glycol and chlorinated hydrocarbons, 817
—, —, — toluene and butadiene, 652
—, —, desulphurization of petroleum oils, 448, 458
—, —, ethylacetylene from methylallene, 632
—, —, isomerization of allenes, 632
—, —, oxidation of naphthenes, 945
—, —, — paraffin, 945

Sodium, catalyst, oxidation of petrolatum, 945
—, —, polymerization of allene, 616
—, —, — cyclohexadiene, 623
—, —, — ethylene, 67, 593
—, —, — isoprene, 626, 628, 652
—, —, — olefins and diolefins, 625
—, —, reaction of butadiene with ammonia, 656
—, —, — olefin oxides and glycols, 539
—, detection of sulphur with, 1151
—, fused, use in purification of hydrogen, 229, 230
—, purification of amylacetate, 796
—, — amyl alcohols, 791, 796
—, reaction with alcohols, 392
—, use in extraction of disulphides, 449
—, use in refining hydrocarbons, 609
Sodium acetate, action on chlorinated decanaphthenes, 752
—, — mercaptans, 447
—, catalyst, production of glycols, 507
—, from acetylene, 678
—, hydrolysis of amyl chloride, 796, 797
—, treatment of thiophene, 455
—, use in hydrolysis of chloropentanes, 790, 792-797
—, — methyl chloride, 784, 786
Sodium alcoholate, reaction with chlorohydrins, 523
—, — β,β'-dichlorodiethyl ether, 498
—, — olefin oxides, 523
Sodium amalgam, reduction of olefin oxides with, 548
Sodium benzoate, catalyst, condensation olefin oxides with benzoic acid, 541
—, reaction with chlorinated paraffins, 796
Sodium bicarbonate, hydrolysis of ethylene, 506
—, — propylene chlorohydrins with, 500
—, reaction with ethylene chlorohydrin, 496, 508, 509
Sodium bisulphate as catalyst, hydration of ethylene, 308
—, polymerization of olefin oxides, 548
—, reaction of olefin oxides and organic acids, 519
Sodium bisulphite, addition to olefins, 575
—, decomposition of ozonides with, 883
—, extraction of aldehydes with, 937, 939
—, reaction with olefins, 574-576
—, use, purification of benzaldehyde, 920
Sodium bisulphite-formaldehyde addition compound, 861
Sodium borate, use in chlorohydrin formation, 493
Sodium butyrate, esterification of amyl chlorides with, 793, 796
—, — ethyl chloride with, 787
Sodium carbide, hydrolysis of, 662
Sodium carbonate, catalyst, oxidation of Grozny paraffin, 943
—, —, — transformer oils, 909
—, dechlorination of hydrocarbons with, 805
—, hydrolysis of alkyl chlorides with, 781
—, — ethylene dichloride with, 506, 507
—, removal of hydrogen sulphide with, 423, 424
—, use in chlorination of cyclohexane, 748
—, — hydrolysis of chloropentanes, 790, 791
—, — purification of hydrogen, 229, 230
—, — sweetening, 444
Sodium chloride, catalyst, oxidation of hydrocarbons, 933, 946
—, effect on chlorohydrin formation, 489
—, formation of complexes with oils, 192
—, use in isolation of chlorohydrins, 493
—, — purification of hydrogen, 229, 230
Sodium compounds, effect on cracking by aluminum chloride, 191
Sodium cyanide, production of, 292, 293
—, reaction with amyl chloride, 811
—, — butyl bromide, 810
—, — propylene chlorohydrins, 501
—, use, removal of iron compounds from maleic acid, 918
Sodium dichromate, oxidation of alcohols, 843-844
Sodium electrodes, 264
Sodium ethoxide, effect on liquid-phase oxidation, 980
—, catalyst, formation of fulvenes, 658
—, reaction with butadiene tetrabromide, 644
—, — halogeno-olefins, 483
—, — isoprene tetrabromide, 645
Sodium ethylene carbide, formation of, 593
—, —, during pyrolysis of ethylene, 67
Sodium ferrocarbonyl-pentacyanide, catalyst, olefin absorption, 342, 358
Sodium formate, formation, from hydrocarbons, 854
—, from carbon monoxide, 942
—, use in hydrolysis of alkyl chlorides, 792
Sodium hydride, catalyst, polymerization of diolefins, 628
Sodium hydrogen sulphite, treatment of shale oil with, 463
Sodium hydroxide, action on mercaptans, 447
—, catalyst, chlorination of montan wax, 740
—, —, condensation of olefin oxides with polyhydric alcohols, 538
—, —, etherification of glycols, 539
—, —, hydration of ethylene, 312
—, —, photo-chemical oxidation, 939
—, —, polymerization of olefin oxides, 547, 548
—, dechlorination of hydrocarbons with, 805
—, dehydration of isopropyl alcohol with, 359, 360
—, desulphurization of industrial gases with, 460
—, evaluation of transformer oils with, 911
—, extraction of mercaptans with, 436
—, — oxidation products with, 911
—, — wax acids with, 946
—, hydrolysis of benzyl chloride with, 920
—, — chloropentanes with, 790, 791, 793
—, naphthenic acids from petroleum with, 1064, 1066
—, oxidation catalyst, 909, 940, 950
—, reaction with acetylene, 677, 678
—, — alkyl 2-bromoethyl ethers, 682
—, — ethylene oxide, 555
—, — hydrocarbon peroxides, 900
—, — vinyl chloride, 678
—, removal of acids from oxidized oil with, 936
—, — carbon monoxide with, 231
—, — gum from gasolines with, 901
—, — sulphur with, 426
—, solvent for sulphonated hydroxy-acids, 1024
—, treatment of petroleum distillates with, 461
—, — shale oil with, 463
—, use in hydrolysis of ethylene chlorohydrin, 509
—, — oxidation of benzene, 925
—, — purification of acetylene, 664
—, — sweetening, 444
—, washing of acid-treated oil with, 1065
Sodium hypochlorite, action on alkyl sulphides, 459
—, — mercaptans, 459
—, bleaching of brown soap, 942
—, desulphurization, 459
—, oxidation of paraffins, 949
—, reaction with ethylene, 488, 510
—, — olefins, 488, 491, 510
Sodium iodide, effect of, caproic acid synthesis, 811
—, reaction with ethylene chlorohydrin, 496
Sodium iodoacetate, 432
Sodium isopropylate, reaction with sulphuryl chloride, 372
Sodium linoleate, resin from, 498
Sodium mercaptide, from sour distillates, 435
Sodium methoxide, hydrolysis of p-dichlorobenzene, 767
Sodium mineral oil sulphonate, use in insecticide, 1027, 1028
Sodium naphthenate, properties and uses, 1088
Sodium nitroprusside, catalyst, olefin absorption, 342, 357
—, determination of sulphur by, 1151
Sodium octanaphthenate, properties, 1087
Sodium oleate, hydrolysis of amyl chloride, 796
—, — chloropentanes, 791, 793
—, polymerization of isoprene by, 627, 628
—, use in lubricants, 1031
Sodium oxalate, catalyst, oxidation of wax, 946

Sodium oxide, reaction with ethylene bromide, 533
Sodium palmitate, triacontane by electrolysis of, 958
—, use in emulsification of olefins, 947
Sodium perborate, catalyst, polymerization of vinylacetylene, 670
Sodium peroxide, oxidation of petrolatum, 941
—, polymerization of isoprene by, 625, 629
Sodium phosphate, catalyst, dehydration of 1,3-butylene glycol, 634
—, —, reaction of chlorine with olefins, 493
—, detergent power, 1024
—, hydrolysis of ethylene dihalides, 507
—, use removal of hydrogen sulphide, 424
Sodium plumbite, action on mercaptans, 447
—, extraction of sulphur compounds with, 461
—, solutions of, 426, 427
Sodium polysulphides, use removal of sulphur from petroleum, 426, 427
Sodium propionate, esterification of monochlorinated paraffins, 795
—, from propylene, 814
Sodium prussoarsenite, 342
Sodium resinate, purification of sulphonates, 1016
Sodium salts, catalysts, oxidation of xylene, 922
—, use in separation of soap emulsion, 1067, 1068
Sodium silicate, detergent power, 1024
Sodium soaps, from lignite paraffin, 949
Sodium stearate, hydrolysis of chloropentanes, 791, 792, 793
Sodium sulphate, catalyst for oxidation, 933
—, hydrolysis of amyl chloride, 796
—, removal of acid from sulphonation products, 1033
—, use in isolation of chlorohydrins, 493
—, — polymerization of diolefins, 629
Sodium sulphide, reaction with ethylene chlorohydrin, 487, 496
—, — propylene chlorohydrin, 501
—, removal of sulphur by, 426
Sodium sulphite, autoxidation of, 851
—, reaction with olefins, 574-576
Sodium sulphonates, from acid sludges, 1015
Sodium tetrathionate, removal of hydrogen sulphide with, 423
Sodium thiosulphate, antioxidant, for lubricating oils, 907
—, formation in sweetening, 441
Sodium p-toluenesulphochloroamide, 1131
Sodium vapor, catalyst, methane chlorination, 699
—, effect on ignition temperatures, 979
—, extraction of sulphur from gasoline, 427
Sodium zincate, action on mercaptans, 447
—, extraction of sulphur compounds by, 462
Softening agents, by halogenation of ethers, 809
—, by sulphonation of ethers, 809
—, from ethanolamines, 553
Solar oil, diluent in acid absorption of olefins, 355
—, oxidation of, 935
—, pyrolysis of, 127
—, sulphonation of, 1019
Solvent extraction, sulphur compounds, 458
—, use of ethylene chlorohydrin, 498
—, — isopropyl alcohol, 362, 365
Solvents, acetylated oxygenated hydrocarbons, 996
—, by oxidation of petroleum distillates, 830, 840, 991, 992
—, effect of, halogen addition to dienes, 642, 643
—, effect on mercaptan pyrolysis, 457
Soot, from natural gas or oil vapors, 212, 213
—, in methane-steam reaction, 279
—, production of, 234
Sorbitol, condensation with olefin oxides, 538
—, hexahydroxyethyl ether of, 995
South American oils, nitrogen content, 819
South Russian crude, gases from, 18
—, gasoline from, 21
Sour distillates, treatment of, 427, 435
Sovental, use in detergent, 1022
Soya-bean oil, dechlorination of petroleum products with, 804
Soya-bean proteins, adhesive from, 742
Space velocity, effect on hydrocarbon vapor pyrolysis, 136, 151
Sparks, induction, ignition with, 969
Specific gravity, of carbon blacks, 244, 246, 254
Speed of flame, in hydrocarbon mixtures, 972
Speeds, law of, for flames, 976
Spent doctor, for removal of sulphur, 426
—, phenols from, 448
Spermacetti, sulphonation of, 1033
Spindle oil, acids from, 939
—, arachidic acid from, 1076
—, chlorination of, 939
—, soaps from, 939
Spindle oil extract, petroleum acids from, 1063
Spindle top gas oil, velocity constant of pyrolysis, 99
Spray oil, cracking of, 163
Spreading arc, 218
Stability, actual, of hydrocarbons, 95, 96
—, chloromethane, 710
—, diisopropyl sulphate, 348
—, fluoromethanes, 710
Stabilization of chlorinated hydrocarbons, 704
Stabilizers, for catalysts, 345, 915
Stannates, dehydrogenation catalysts, alcohols, 405
Stannic acid, catalyst, partial oxidation of wax, 943
—, — stabilizer, 345
Stannic chloride, catalyst, addition hydrogen chloride to cracked gasoline, 330
—, —, addition of hydrogen chloride to pentenes, 398
—, —, chlorination of toluene, 775
—, —, condensation of olefins and organic chlorides, 569, 570
—, —, in cracking, 193
—, —, polymerization of cyclopentadiene, 623
—, —, — diolefins, 618, 619
—, —, — olefins, 597
—, —, reaction of ethylene oxide and aldehydes, 556
—, —, — ethylene oxide and ketones, 556
—, —, — olefins and aromatics, 559
—, compound with dioxan, 556
—, formation of complexes with oils, 192
—, use in stabilization of gasoline, 898
Stannic halide, use in refining cracked distillates, 609
Stannic oxide, catalyst, oxidation of methane, 848
Stannic vanadate, catalyst, oxidation toluene, 921
Stannous chloride, catalyst, condensation of olefins and organic chlorides, 569
—, —, polymerization of acetylene, 668
—, diolefins separation with, 160
—, effect on autoxidation, 890
—, reaction with cyclohexene peroxide, 899
Stannous compounds, antioxidants, for lubricating oils, 907
Stannous oxide, oxidation catalyst, 843
Starch, catalyst, oxidation of transformer oils, 909
—, —, polymerization of diolefins, 619
—, dehydrated with isopropyl alcohol, 366
Starch hydrolysis, effect of ethylene chlorohydrin on, 496
Steam, diluent, chlorination hydrocarbons, 713
—, —, hydrocarbon oxidation, 833, 836, 839, 872, 917, 919
—, —, methane-carbon dioxide reaction, 283
—, —, oxidation of ethyl alcohol, 869
—, —, — ethylene, 874
—, —, — methane, 867
—, —, pyrolysis of hydrocarbons, 135, 146, 158, 181, 183
—, —, — natural gas, 213, 214, 215
—, effect on adsorption of olefins, 143
—, — electrical decomposition of methane, 260
—, — oxidation of acetylene, 886
—, purification of ichthyolsulphonic acids with, 1037
—, reaction with carbon monoxide, 232
—, — ethane, 276
—, — hydrocarbons, 276-281
—, — methane, 206, 220, 276, 277
—, — naphtha, 277
—, — petroleum, 210
—, — propane, 276
—, separation of wax acids with, 954

Steam, use in decomposition of hydrocarbons, 214-217
—, — polymerization of acetylene, 668
—, — purification of carbon, 225
—, — pyrolysis oils and tars, 209
—, — removal of carbon dioxide from hydrogen, 233
Steam distillation, for separation of methane homologues, 33
—, of bisulfite compounds, 939
—, of volatile acids, 933
Steam-methane equilibrium, 277, 280
Steam-methane reaction, 276, 279, 280
Stearic acid, by oxidation of lignite tar, 938
—, foam-producing material in ethylene absorption, 341
—, from Ishikari distillates, 1076
—, from paraffin wax, 944
—, from spindle oil extract, 1063
—, ketone from, 998
—, oxidation catalyst, 881, 960
—, oxidized, 959, 1003
—, use in hydrolysis of alkyl chlorides, 790, 792
—, — oxidation of wax, 952
—, — production of cuprene, 672
Stearic anhydride hydrogenated, 990
Stearic esters, by hydrolysis of alkyl chlorides, 792
Stearin soaps, reaction with isethionic condensation products, 1034
Steel, effect on oxidation of petroleum, 905
—, use in hydrocarbon decomposition, 217
Steel bars, ignition temperatures with, 968
Stilbene, by pyrolysis of toluene, 88
—, polymerization of, 613
—, reaction with nitrogen pentoxide, 581
—, — nitrogen trichloride, 579
Still gases, removal of hydrogen sulphide from, 424
Still residues, cracked by submerged combustion, 1000
Straw oils, use as insecticides, 1028
Strontium, catalyst, pyrolysis of benzene homologues, 146
Strontium carbide, hydrolysis of, 662
Strontium chloride, oxidation catalyst, 866
Strontium compounds, absorption of hydrogen sulphide by, 424
Strontium sulphate, catalyst, production of ketene, 414
Styrene, action of ozone on, 930
—, by pyrolysis of acetylene, 81, 82, 180
—, — butanes, 57, 174
—, — ethylene-benzene mixture, 89
—, carboxylation of, 930
—, condensation with hydrogen cyanide, 585
—, — naphthalene, 564
—, — phenols, 566
—, — phosgene, 570
—, — xylenes, 1128
—, from coal oils, 146
—, from ethylbenzene, 146, 147
—, from halogenated alkylbenzenes, 142
—, from methylphenylcarbinol, 147
—, from mineral oils, 146
—, glycols from, 510
—, gutta percha from, 625
—, oxidation of, 893
—, phenylglycol from, 510
—, polymerization of, 588, 591, 592, 598, 610, 611, 612
—, production by pyrolysis, 146
—, reaction with bisulphites, 575
—, — hydrogen persulphide, 585
—, — nitrogen trichloride, 579
—, resins from, 146
—, styrene chlorohydrin from, 504
Styrene chlorohydrin, 504, 558
Styrene dichloride, 558
Styrene oxide, catalyst, polymerization, 611
—, isomerization of, 547, 558
—, reaction with hydrogen cyanide, 546, 558
—, reduction of, 548
Styrene peroxide, polymerization of, 611
Styrene polymers, uses, 613
Styrenes, from alkylbenzene-benzene mixture, 147
—, from ethylbenzenes, 146
Styrolene, 610
Styroxylene, 1128
Styrylxylenes, 563
Submerged combustion, 1000
Succinic acid, by nitration of naphthenes, 1047
—, by oxidation of hydrocarbons, 838, 856
—, from acetylene trimer, 268
—, from cyclohexanol, 929
—, from ethylene dichloride, 473
—, from stearic acid, 959
—, from triacontane, 958
—, reaction with ethylene oxide, 541
—, — olefin oxides, 538
Succinic anhydride, from lignin, 949
Succinonitrile, from ethylene dichloride, 473
Sugars, dehydrated with isopropyl alcohol, 366
—, hydrolysis of, theory of petroleum origin, 36
—, precipitated by isopropyl alcohol, 367
Sulphated olefins, formation of, 350
Sulphates, acid, catalysts, esterification of olefins, 328
—, conversion of nitrogen bases to, 825, 826
—, dialkyl, catalysts for glycol ether formation, 538
—, of heavy metals, catalysts, esterification of olefins, 328
Sulphation, defined, 1005
Sulphato-sulphonic acids, 1008, 1010
Sulphides, catalyst poisons, 298
—, dehydrogenation catalysts, 405
—, metallic, oxidation catalysts, 834
—, reaction with acetylene, 684
Sulphinic acids from sulphonic acids, 1021
Sulphites, addition to unsaturated acids, 574
—, reaction with olefins, 574-576
—, — styrene, 575
Sulphoacetic acid, selective solvent, 34, 1135, 1143
—, use in determination of aromatics, 1135
—, — production of vinyl esters, 681, 682
Sulpho-acid, manganese salts of, oxidation catalysts, 935
Sulphoaromatic acids, fat-hydrolyzing agents, 1025
Sulphoaromatic compound for breaking emulsions, 1027
p-Sulphobenzoic acid, from p-toluenesulphonic acid, 928
Sulphobromides, from mercaptans, 432
Sulpho compounds, 1005
Sulphoferricyanic acid, catalyst, ethylene absorption, 342, 357
Sulphoglycol, nitration of, 517
Sulphonal, preparation of, 412, 433, 811, 812
Sulphonamides from alkylsulphonic acids, 1011
Sulphonated compounds, extracted with isopropyl alcohol, 366
Sulphonated cresol, condensation with ethylene, 566
Sulphonated derivatives of paraffin hydrocarbons, 817
Sulphonated mineral oils, 1022-1028
Sulphonated oxidized hydrocarbons, 1000, 1001, 1002
Sulphonates, from acid sludges, 1014, 1015
—, from hydrocarbons, 1005
—, textile cleansing agents, 1028, 1029
Sulphonating agents, 1005
Sulphonation, aromatics, 1136
—, defined, 1005
—, isopropyl alcohol, 372
—, naphthalene, 564
—, nitrogen compounds, 822
—, olefins, 1019
—, paraffin hydrocarbons, 817, 1007, 1008
—, with chlorosulphonic acid, 1061
Sulphones, by oxidation of petroleum oils, 1151
—, from alkyl sulphides, 459
—, from mercaptans, 432
—, from sulphur dioxide and diolefins, 575, 654, 655
—, from thioethers, 451
—, from thiophanes, 452, 453
—, from trimethylene sulphide, 453
—, reaction with ethyl iodide, 453

Sulphonethylmethane, use in insecticide, 1028
Sulphonic acids, alkali salts of, detergents from, 1023, 1024
—, alkyl, from sulphite-olefin reaction, 575
—, aromatic, alkylated compounds of, 563, 564
—, α, β and γ compounds, 1021
—, as demulsifying agents, 1026, 1027
—, by condensation of sulphuric acid with naphthenic acids, 1064, 1065
—, by oxidation of products from unsaturated hydrocarbons and sulphur, 429
—, condensation with olefins, 563
—, effect of molecular weight on detergent power, 1023
—, emulsification of hydrocarbons by, 952
—, emulsifying agents from, 1022
—, fat-hydrolyzing agents, 1025
—, formation during refining, 1011, 1012
—, from Galician petroleum, 1035
—, from mercaptans, 432, 433
—, from naphthenes, 1035
—, from olefin-sulphite reaction, 574-576
—, from olefins, 1034
—, from petrolatum, 1014
—, halogen-substituted, 1019
—, hydration of ethylene by, 307, 311
—, hydrolysis of calcium salts of, in formation of petroleum, 36
—, mineral oil, detergents from, 1022-1024
—, —, emulsifying agents, 1026
—, —, stabilizers for emulsions, 1025
—, —, use in plastic compositions, 1031
—, —, use in textile treatments, 1028-1029
—, properties, 1011, 1020
—, purification, 1015, 1016, 1017, 1018
—, recovery from sludges, 1013, 1014, 1015, 1016
—, use in oxidation of hydrocarbons, 952
—, use in varnishes, 1030
—, wetting agents from, 1022
Sulphonic acid salts, effect on oxidation of oils, 910
—, use in breaking emulsions, 1026, 1027
Sulphonium compounds, from disulphides, 449
—, from thioethers, 451
Sulphoparaffins, from acid sludge, 1013
Sulphostearic acid, use in hydration of ethylene and propylene, 311
Sulphothalassolic acid, from shale oil, 1037
Sulphoxides from thioethers, 451
Sulphur, absorption by carbon, 458
—, adsorption by iron, 461
—, — nickel, 461
—, adsorption from liquid naphthas, 461
—, — vaporized naphthas, 462
—, as an antioxidant, 907, 909
—, carbon disulphide from, 185
—, catalyst, chlorination of toluene, 772, 773
—, —, hydrocarbon pyrolysis, 135, 136
—, —, oxidation of hydrocarbons, 875
—, —, — mercaptans, 441
—, —, polymerization of isoprene, 626
—, corrosion by, 422, 426
—, dehydrogenation of paraffin by, 956
—, effect, autoxidation, 890
—, —, cracking by aluminum chloride, 192, 203
—, —, ignition of cotton, 890
—, —, oxidation of paraffin oil, 934
—, elemental, from petroleum, 426, 428
—, —, in distillates, 421, 422, 448
—, —, in petroleum, 31
—, —, tests for, 1149
—, formation from hydrogen sulphide, 424, 426
—, formation of complexes with oil, 192
—, from butyl sulphide, 457
—, from isoamyl mercaptan, 456
—, in American oil shale, 462
—, in Colorado oil shale, 462
—, in doctor test, 439
—, in mineral oils, electrolytic oxidation of, 1151
—, liquid temperature control with, 919
—, permissible content, 422
—, promoter, polymerization of styrene, 611
—, reaction with acetylene, 684
—, — mercury, 1149
—, — naphthenes, 429, 430
—, — octanaphthenes, 629
Sulphur, reaction with olefins, 429
—, — paraffins, 428, 956, 1061
—, removal by metallic oxides, 459
—, removal from heavy distillates, 448
—, — petroleum, 426
—, tests for, 1149, 1151
—, total, determination of, 1150
—, treatment of oils with, 950
—, use, vulcanization of rubber, 627, 628
Sulphur black, manufacture, 766
Sulphur chloride, catalyst, carbon disulphide chlorination, 705

—, uses, 476, 706
Tetrachloroethylene, dewaxing oils with, 706
—, germicide, 706
—, natural gas chlorination, 690
—, stabilization with butyl mercaptan, 456
Tetrachlorodioxanes, 556
Tetrachloromethane, from diisoamyl, 735
—, from kerosene, 738
Tetrachloropropane, from propane, 717, 721
—, from propylene, 479
Tetrachlorotoluene, 770
Tetrachloro-o-xylene, 779
Tetracosane, separation from triacontane, 33
Tetracyclopentadiene, 621, 622
Tetradecanaphthene, from amylene, 78
Tetradecene, sulphonation of, 1033
Tetraethylbenzene, 560
Tetraethylene glycol, 527, 529
Tetraethylene glycol monophenyl ether, 539
Tetraethyl ferrocyanide, catalyst, ethylene absorption, 342
Tetraethyl lead, production of, 712, 813
Tetraethyl lead-ethylene dibromide, antiknock, 478
Tetrahalides, from diolefins, 643
Tetrahydroacetophenone, 569
Tetrahydroanthraquinones, 650, 653
Tetrahydrobenzaldehyde, 651
Tetrahydrobenzene, autoxidation of, 893
—, butadiene from, 156, 157
—, condensation with naphthalene, 563
—, pyrolysis of, 158
Tetrahydrobenzophenone, 569
Tetrahydronaphthalene, condensation with cyclohexene, 561
—, — olefins, 563
—, α-hydroxytetrahydronaphthalene from, 930
—, α-ketotetrahydronaphthalene from, 930
—, pyrolysis of, 84
—, reaction with butadiene, 653
—, use in preparation of detergents, 1024
Tetrahydroquinizarin, 653
Tetrahydroquinoline, 684
Tetrahydroquinoline ring, in nitrogen bases, 820
Tetrahydrothiophene, 453
Tetraisobutene, 600, 601
Tetraisopropylbenzene, 561
Tetraisopropylnaphthalene, 563
Tetralkylethylene glycols, 531, 532
Tetralkylethylenes, glycols from, 532
Tetrameric acetylene, in polymerization of acetylene, 669
Tetramethylallene, polymerization of, 615
1,2,3,4-Tetramethyl-1,3-butadiene, polymerization of, 619, 620, 627
Tetramethylcyclohexane, from 1,3-diethylcyclohexane, 199
Tetramethylenediamine, butadiene from, 634
Tetramethylethylene, addition of mineral acids, 325
—, chlorination of, 484
—, hydration of, 384, 385
—, polymerization of, 606, 607
—, reaction with mercuric salts, 1132
—, — nitrogen pentoxide, 581
—, — nitrosyl chloride, 579
Tetramethylethylene chlorohydrin, 503
Tetramethylethylene dichloride, 637
Tetramethylethylene glycol, 531, 532
Tetramethylethylene oxide, 534, 542
2,3,4,4-Tetramethyl-2-hexene, oxidation of, 880
Tetramethylmethane, bromination of, 723, 726
—, halogenation of, 725, 726
—, in natural-gas gasoline, 17, 32
2,3,6,7-Tetramethylquinizarin, 653
Tetramethyl sulphide, from Persian petroleum, 453
Tetraphenylethylene, reaction with nitrogen trichloride, 579
Tetrasulphides (organic), 449, 450
Tetravalent lead compounds, as antidetonants, 984
Tetravinylacetylene, 671
Tetronal, from ethyl mercaptan, 812
Texas petroleum, carboxylic acids from, 1073
—, naphthenic acids from, 1079, 1081
—, sulphur content of, 421
Textile assistants, 1028, 1029
Textile dressings, oxidized-wax emulsions, 994
Textile oils, 1028, 1029
Textile reagents, 1028, 1029
—, from polyethylene glycols and amines, 543
Textile treatment, with mineral-oil sulphonates, 1028-1029
Thalassol, from shale oil, 1037
Thallene, 226
Thallic chloride, catalyst for chlorination of benzene, 758, 759
—, catalyst for chlorination of methane, 701
Thallium, aromatization catalyst, 183
—, catalyst for chlorination, 703, 713, 766
Thallium compounds, aromatization catalysts, 183
—, as antidetonants, 983
—, catalysts for pyrolysis, 125, 150
Thallium oxide, oxidation catalyst, 833
Thallium vapors, effect on ignition temperatures, 979
Thermal chlorination of hydrocarbons, 711-713, 716, 719, 723-725
Thermal decomposition, *see* Pyrolysis
Thermal relationships in combustion of methane, 235
Thermal stability, of aromatic hydrocarbons, 87, 89, 90, 95

—, of naphthenes, 87, 95
—, of paraffin hydrocarbons, 90, 95, 96, 97, 205
Thermatomic carbon black, 245, 250, 253, 254
Thermatomic process, 210, 212, 234
—, yield of carbon black, 241
Thermax carbon black, 212, 250
Thermodynamic considerations, of cracking, 93-95
—, of methane chlorination, 687
—, of pyrolysis of hydrocarbons, 64, 65, 93
Thermodynamic properties, of dichlorodifluoromethane, 709
Thermodynamic stability, of acetylene, 93, 94, 147, 162, 256
—, of petroleum hydrocarbons, 94
Thiocarbanilide, stabilization of gasoline with, 898

Thiocarbonates, from carbon disulphide and mercaptides, 445
Thiocresol, from methylcyclohexane, 430, 1061
Thiocyanates, selective solvent for separation of paraffins and naphthenes, 35
Thiocyanogen, 585
Thiodiphenylamine, stabilization of gasolines with, 897
Thiodiglycol, from ethylene chlorohydrin, 487, 496
—, from propylene chlorohydrin, 501
Thioethers, as solvents, 452
—, estimation of, 451
—, formation in hydrogen sulphide-olefin reaction, 584
—, from alkyl chlorides with alkali sulphides, 811
—, from mercaptans, 426, 436
—, from olefins and hydrogen sulphide, 425
—, in petroleum oils, 421, 422, 450
—, mixed, 451
—, properties of, 450, 452
Thioglucose, 434
Thioindigo, 434
Thio-β-naphthol, pickling inhibitor, 434
Thionyl chloride, reaction with mercaptans, 433
Thiophanes, 452-453
—, in petroleum oils, 421, 452
—, oxidation of, 452, 453
—, properties of, 452-453
—, reactions of, 453
Thiophene, action of hypochlorites on, 459
—, adsorption by nickel oxide, 462
—, brominated, oxidation of, 917
—, determination of, 1152
—, effect on aniline points of hydrocarbons, 1137
—, extraction from benzene, 460
—, — petroleum distillates, 455, 462
—, from acetylene and hydrogen sulphide, 426, 684, 887
—, from butyl sulphide, 457
—, from hydrogen sulphide-olefin reaction, 425, 584, 585
—, from reaction of paraffins and sulphur, 428
—, in ichthyol, 1036
—, in naphtha, 455
—, oxidation of, 987
—, pyrolysis of, 457
—, reactions of, 454, 455
Thiophenes, corrosion by, 422
—, formation in hydrogen sulphide-olefin reaction, 584
—, from isoamyl sulphide, 456
—, in petroleum oils, 31, 421, 422, 454
—, in shale oils, 463
Thiophenol, manufacture, 767
—, pickling inhibitor, 434
Thiophthenes, 428, 429
2-Thiotolene, in shale oil, 463
Thiourea, condensation with formaldehyde, 860
2,3-Thioxene, in shale oil, 463
Thio-m-xylene, from dimethylcyclohexane and sulphur, 430
Thoria, catalyst activator, 280
—, catalyst, hydration of olefins, 303, 307, 311, 314, 316
—, —, hydrolysis of phenyl halides, 767
—, —, oxidation of methane, 849
Thorium, catalyst, chlorination of benzene, 759
—, —, condensation of olefins and phenols, 567
—, desulphurization of hydrocarbon gases with, 460
—, oxidation catalyst, 833
Thorium carbide, hydrolysis of, 662
Thorium chloride, catalyst, chlorination of benzene, 759
Thorium compounds, catalysts, condensation of amines with acetylene, 684
—, —, oxidation of paraffin wax, 953
Thorium dioxide, catalyst, dechlorination, 673
Thorium oxide, catalyst, acetylene-steam reaction, 407, 408
—, —, carbon monoxide-hydrogen reaction, 232
—, —, condensation of acetylene with amines, 684
—, —, dehydrogenation of hydrocarbons, 223
—, —, hydration of olefins, 303, 307, 311, 314, 316
Thorium oxide, catalyst, methane-steam reaction, 280, 292
—, —, oxidation of alcohols, 406
—, —, petroleum pyrolysis, 157, 158
—, —, synthesis of higher alcohols, 345
—, desulphurization of hydrocarbon gases with, 460
Thorium potassium carbonate, catalyst, acetylene-steam reaction, 408
Thymol, preparation of, 367, 375, 566
—, properties, 375
—, stabilization of gasoline with, 897
Tiglic aldehyde, synthesis of nitrogen base from, 822, 823
Time of contact, effect on high-temperature chlorination of methane, 689, 692
—, — production of acetylene, 148, 149
—, — production of aromatics by cracking, 103
—, — pyrolysis of aromatics, 89
—, — pyrolysis of ethane, 44, 47
—, — pyrolysis of methane, 38, 40, 42, 121, 166, 168
—, — pyrolysis of olefins, 70, 71, 72, 73
—, — pyrolysis of paraffins, 64, 130, 135, 164, 173
—, — pyrolysis of propane, 53, 123, 128
—, — pyrolysis of straight-run gasoline, 130, 131
—, — yield of cracked gasoline, 103
—, function of degree of cracking, 101
Time-pressure curves, flame propagation, 976
Time-temperature index, effect on pyrolysis of gas oil, 132, 145, 146
—, influence on cracking, 102, 103, 125
—, — gas-gasoline ratio in cracking, 103
Tin, catalyst, chlorination of hydrocarbons, 691, 758, 759
—, —, formation of butadiene, 635, 680
—, —, formation of glycol, 511
—, —, formation of olefin oxides, 536
—, —, in cracking, 107
—, —, oxidation of hydrocarbons, 863, 909
—, —, polymerization of olefins and acetylene, 610, 668
—, —, pyrolysis of olefins and acetylene, 187
—, effect on ignition temperatures, 967
—, extraction of sulphur compounds with, 462
—, removal of gum from gasoline with, 902
—, use in distillation of butadiene, 641
Tin borate, oxidation catalyst, 833, 864
Tin chlorides, catalysts for methane chlorination, 690
Tin compounds, catalysts for ethylene absorption, 340
—, catalysts for acetylene-amine reaction, 684
Tin halides, catalysts for polymerization olefins, 594
Tin naphthenates, 1090
Tin oxides, catalysts for oxidation of alcohols, 406
—, catalysts for polymerization of mineral oils, 629
—, effect on polymerization of acetylene, 82
Tin oxychloride, removal of gum from gasoline with, 903
Tin phosphate, catalyst for hydration of ethylene, 308
—, oxidation catalyst, 833, 864
Tin salts, action with acetylene, 667
Tin soap, anticatalyst for oxidation of oils, 909
Tin sulphides, adsorption of mercaptans, 445
—, catalysts for diphenyl production, 189
Tin tetrachloride, catalyst, chlorination of benzene, 758
—, —, condensation of benzene with monochloroacetone, 777
—, —, polymerization of olefin oxides, 547
Tin vanadate, catalyst, formation of acetic acid, 677, 933
—, —, oxidation of alcohols, 869
—, —, oxidation of nitrotoluene, 929
Tinned iron, catalyst for polymerization of acetylene, 668
Tinting power of carbon blacks, 212, 250, 254
Titania, catalyst, hydrolysis of phenyl halides, 767
Titanium, catalyst, hydration of olefins, 311
—, —, ammonia-carbon monoxide reaction, 298
—, —, in cracking, 107, 113
—, oxidation catalyst, 833, 942

Titanium chloride, catalyst, in cracking, 193
—, —, olefin-organic chloride condensation, 569, 570
—, extraction of sulphur compounds from oils with, 461
—, use in refining, 609
Titanium compounds as catalysts, diphenyl production, 189
—, for ethylene absorption, 340
Titanium dioxide as catalyst, olefins from chloro-compounds, 803
—, oxidation of methane, 849
Titanium halides, catalysts for cyclopentadiene polymerization, 623
Titanium oxide, catalyst activator, 288
—, catalysts, diolefins from paraffins, 157, 158
—, —, methane-steam reaction, 292
—, oxidation catalyst, 843, 864, 929
Titanium salts, effect on oxidation of lignite paraffin, 949
Titanium tetrachloride, reaction with thioethers, 450
Toilet preparations, use of isopropyl alcohol in, 363, 365
Toluene, amyltoluene from, 561
—, anthraquinone from, 925
—, as antidetonant, 964, 983
—, bacterial oxidation of, 1004
—, benzaldehyde from, 918, 919, 920, 921, 927, 928, 930
—, benzoic acid from, 918, 919, 921, 928, 929, 930
—, bromination of, 777, 778
—, by oxidation of petroleum, 842
—, by pyrolysis of acetylene, 81, 82, 180, 668
—, — n-butane-isobutane mixture, 57, 170, 174
—, — butenes, 72, 73, 179, 180, 602
—, — ethane-propane mixtures, 44, 170
—, — gaseous paraffins, 175
—, — petroleum distillates, 86, 162, 164, 165
—, chlorination of, 755, 761, 764, 768-771, 773-776
—, condensation with ethylene, 560
—, — hexene, 1128
—, — isubutylene, 567
—, — isoprene, 652
—, — propylene, 561, 564
—, cresol from, 928
—, cyclohexene derivative, 561
—, cymenes from, 561
—, decomposition in electric arc, 257
—, effect on aniline point, 1137
—, — pressure oxidation of paraffin wax, 942
—, ethylated compounds of, 560
—, from benzene, 199
—, from p-ter.-butyl-toluene, 200
—, from cumene, 88
—, from p-cymene, 200
—, from ethylene, 177
—, from isoprene, 79
—, from methane, 40, 166
—, from methylcyclohexane, 85, 181
—, from methylenecyclohexane, 85
—, from 4-phenyl-1-butene, 89
—, from propane, 170
—, from propylene, 70, 71, 179
—, from xylene, 88, 89, 200
—, halogen derivatives of, oxidation of, 928, 929
—, hot-wire ignition curves, 969
—, p-hydrotoluoin from, 928
—, in cracked gasoline, 118
—, in cracked oil gas, 116
—, in kerosene, 27
—, in natural-gas gasoline, 18
—, in straight-run gasoline, 22, 25, 26, 27, 914
—, inflammability limits, 961
—, maleic acid from, 916
—, p-nitrobenzoic acid from, 929
—, oxidation of, 35, 856, 915, 916, 918-921, 927, 928
—, oxidation with carbon dioxide, 930
—, picric acid from, 929
—, production from coal gas, 161
—, production from coke-oven gas, 161
—, pyrolysis of, 88, 89
—, reaction with bleaching powder, 776
Toluene, reaction with butadiene, 652
—, — ter.-butyl hypochlorite, 774
—, — 2,3-dimethylbutadiene, 653
—, — hypochlorous acid, 775
—, — isoprene, 204
—, — lead ammonium chloride, 774
—, — nitrogen pentoxide, 1044
—, — phosphorus pentachloride, 771
—, — sulphuryl chloride, 774, 775, 776
—, refining by oxidation, 987
—, separation of wax acids with, 954
—, solubility of hydrogen sulphide in, 423
—, solvent action of, 1116
—, solvent in chlorohydrin formation, 493
—, — olefin-phosgene condensation, 570
—, sulphur dyes from, 431
—, thermal stability of, 90
—, p-toluenesulphonic acid from, 928
—, p-toluic acid from, 928
—, trinitrotoluene from, 34, 161, 165
—, xylenes from, 561
—, p-xyloquinol from, 928
Toluene fraction, Borneo petroleum, nitration of, 34
—, cracked petroleum, production of TNT from, 165
Toluene homologues, bromination of, 780
—, chlorination of, 778, 779
Toluene-nitrobenzene mixture, solvent action of, 1116
Toluene-p-sulphonic acid, from toluene, 928
—, use in hydration of propylene, 314
p-Tolualdehyde, from toluene, 928
p-Toluic acid, from p-cymene, 926
—, from toluene, 928
Toluidine, purification of naphthenic acids with, 1067
—, solvent for diolefin separation, 160
—, stabilization of gasoline with, 897, 898
5-p-Tolyl-1-chloropentane, 1057
p-Tolylcyclopentane, 1057
p-Tolyl ethyl ketone, 1056
Tolylmethyl alcohol, from toluene, 928
p-Tolyl methyl ketone, from p-cymene, 926
o-Tolylnitromethane, 1046
Toners, use with carbon blacks, 252
Tonsil, catalyst, condensation of olefin oxides, with acids, 541
—, —, condensation of olefins and carbazole, 573
—, —, condensation of olefins and phenols, 566
—, use in decolorization of naphthenic acids, 1069
Topped crudes, definition of, 93
Tournante oil, substitute for, 937
Toxicity of alcohols, 393, 394
— ammonia, 709
— carbon dioxide, 709
— carbon tetrachloride, 706
— chloromethanes, 710
— diethylene glycol dinitrate, 527
— ethylene chlorohydrin, 495
— ethylene glycol, 514
— fluoromethanes, 709, 710
— glycol dinitrate, 517
— isopropyl alcohol, 362, 363, 364
— methanol, 786
— methyl chloride, 709
— refrigerants, 709
— sulphonated oxidized hydrocarbons, 1001
Transformer oils, evaluation of, 910-912
—, formation of sludge, causes of, 910
—, mechanism of oxidation of, 909
—, oxidation of, 908-912, 987
—, refining of, 908, 909, 910
—, removal of sulphur from, 448
—, stability tests, 910, 911
—, use in polymerization of acetylene, 668
Triacontane, oxidation of, 958
—, separation from eicosane and tetracosane, 33
Trialkyl borates, in Friedel-Crafts reaction, 1060
Triamylenes, halogenation of, 1126
Triazoethyl alcohol, 497
Triazoethylene, from triazoethyl alcohol, 497
Tribenzyl borate, 1060
Tribromoacetone, from isopropyl alcohol, 374
1,2,4-Tribromobenzene, 768

Tribromobutane, from methylcyclopropane, 746
Tribromo compounds, from allyl bromides, 633
2,4,6-Tribromo-1,3-dimethyl-5-ethylbenzene, 754
Tribromoisobutane, 483
Tribromopseudocumene, 754
Tributenylamine, 656
Tributyltoluene, from p-ter.-butyltoluene, 200
Trichloroacetic acid, addition to amylene, 330
—, use in hydration of olefins, 312
Trichloroacetone, from isopropyl alcohol, 373
1,2,4-Trichlorobenzene, 758, 760, 763, 764
2,4,5-Trichlorobenzylidene dichloride, 774
Trichlorobutane, 501
Trichlorocyclohexanes, from cyclohexane, 748, 749
—, pyrolysis of, 816, 817
Trichlorocyclopentane, 648, 747
1,1,1-Trichloroethane, from ethane, 472
1,1,2-Trichloroethane, dichloroethylene from, 674, 675
—, from acetylene, 680
—, from ethylene dichloride, 475
—, from vinyl chloride, 475, 680
—, physical properties, 475, 476
—, uses, 476
Trichloroethanes, from ethane, 713
—, from ethylene, 469
Trichloroethylene, from tetrachloroethane, 673
—, properties of, 674
—, stability of, 673
—, stabilization of, 456, 674
—, uses of, 674, 1034
Trichlorofluoromethane, 707, 709, 710
Trichlorohexane, 736
Trichlorinated hard paraffin wax, 811
Trichloromesitylene, 779
Trichloro pentanes, 730
Trichloropropanes, from cyclopropane, 745
—, chlorination of, 717
1,2,2-Trichloropropane, from propylene, 479
1,2,3-Trichloropropane from propylene dichloride, 799
Trichlorotoluenes, 769-771, 774
3,5,6-Trichloro-1,2,4-trimethylbenzene, 779
Trichloro-m-xylene, 779
Tricresol, stabilization of gasoline with, 897
Tricyclic monocarboxylic acids, in petroleum, 1073
Tricyclopentadiene, 621, 622
Tridecanaphthene, chlorinated products of, 753
Tridecylsulphonic acid, properties, 1011
Triethanolamine, absorption of hydrogen sulphide, 425
—, condensation with olefin oxides, 522
—, detergents from, 1023, 1024
—, hydroxyethyl ethers of, 642
—, production of, 129, 541, 551, 552
—, properties, 552
—, uses, 1026, 1088
Triethanolamine soaps, 554
Triethylamine, from ethyl chloride-ammonia reaction, 806
—, effect on oxidation of olefins, 881
—, reaction with nitrogen pentoxide, 1044
Triethylbenzene, production, 560, 561
Triethylcarbinol, 385, 386
Triethylmethane, nitration of, 1044
Triethylene glycol, 512, 527, 528, 529, 537
Triethylphosphine, catalyst, polymerization of olefin oxides, 547
Triisobutylene, from isobutylene, 77, 378, 600
—, constitution of, 884
—, properties, 601
Triisopropylbenzene, 561
Triisopropylphenol, 566
Trimellitic anhydride from lignin, 949
Trimethylacetic acid, from diisobutylene ozonide, 884
Trimethylacetaldehyde, from diisobutylene ozonide, 884
Trimethylallene, polymerization of, 615
1,1,2-Trimethylallyl alcohol, 646
Trimethylamine, catalyst, polymerization of olefin oxides, 547
Trimethylbenzene, 1128
Trimethylbutadiene, reaction with maleic acid and anhydride, 660
2,2,3-Trimethylbutane, from isobutene, 266
Trimethylcarbinol, *see* ter. Butyl alcohol
1,2,4-Trimethylcyclohexane, chlorination of, 751, 752, 753
—, in straight-run gasoline, 25
—, nitration of, 1049
—, tribromopseudocumene from, 754
3,3,4-Trimethylcyclopentanone-1, 1080, 1081
1,1,2-Trimethyl-2-cyclopentene, 568
3,3,4-Trimethylcyclopentylacetic acid, 1081
1,2,3-Trimethylcyclopropane, 198
Trimethylene, *see* Cyclopropane
Trimethylene sulphide, chemical reactions of, 453
Trimethylethylene, absorption in sulphuric acid, 381, 382, 389
—, analysis of, 1127
—, bromination of, 465, 1129
—, chlorination of, 483, 484
—, chlorohydrins from, 502
—, condensation with acetyl chloride, 568
—, — aniline, 572
—, — isoprene, 657
—, critical solution temperature, 1136
—, demethanation of, 75
—, from amyl alcohols, 635
—, from amylene, 881
—, from diamylene, 604
—, from 1,1-dimethylcyclopropane, 83, 746
—, from isoamyl chloride, 803
—, from isopentane, 155
—, from isopropylethylene, 381, 590
—, from rubber, 154
—, from turpentine, 154
—, hydration of, 403
—, intermediate, methylisopropylcarbinol-hydrogen halide reaction, 402
—, isoprene from, 155
—, mutual polymerization with isoprene, 624
—, oxidation of, 880, 889, 893
—, polymerization of, 382, 602, 603, 604, 605, 606, 1127
—, pyrolysis of, 74, 75, 603
—, reaction with acetic acid, 331
—, —aniline cobaltohalides, 572
—, — hydrogen bromide, 300, 321
—, — hypochlorous acid, 502
—, — mineral acids, 325
—, — nitrogen trichloride, 578
—, — nitrosyl chloride, 579
—, thermal stability of, 74, 603
—, trimethylethylene glycol from, 505
Trimethylethylene chlorohydrin, 502, 503
Trimethylethylene dichloride, 484, 485
Trimethylethylene glycol, from trimethylethylene, 505
—, methyl isopropyl ketone from, 531
Trimethylethylene nitrosochloride, 580
Trimethylethylene oxide, isomerization of, 419, 546
—, condensation with hydrocarbons, 1059
Trimethylethylmethane, in natural-gas gasoline, 17
—, nitration of, 1043, 1051
Trimethylnaphthalene, from kerosene, 27
2,2,4-Trimethylpentane, knock rating, 985
—, oxidation of, 855
2,4,4-Trimethyl-1-pentene, presence in diisobutylene, 601, 602, 884
2,2,4-Trimethyl-2-pentene, presence in diisobutylene, 601, 602, 884
—, oxidation of, 880
Trimethylpropylmethane, nitration of, 1043
2,4,6-Trimethylpyridine, 827
2,3,8-Trimethylquinoline, action of bromine on, 824
—, isolation of, 822
2,4,8-Trimethylquinoline, isolation of, 826
Trinitromethylbutane, 1042
Trinitro-ter.-butyltoluene, 400
Trinitromethylpentane, 1043, 1045
Trinitrotoluene, 161, 165, 430, 832, 1053
Trinitro-m-xylene, 430
Trional, 812
Trioxymethylene, formation of methylal of glycol, 512
—, reaction with olefins, 586-587
—, purification of phthalic anhydride, 924

Trioxyterpan, from α-pinene, 890
Triphenylcarbinol, stabilization of gasoline with, 898
Triphenylethylene, reaction with nitrogen trichloride, 579
Triphenylethylene glycol, 534
Triphenylethylene oxide, 534
Triphenylmethane, anthraquinone from, 924
—, carboxylation of, 930
Triphenylmethyl chloride, reaction with phenol, 810
Triphenyl phosphate, stabilization of gasoline with, 898
Trisulphides, organic, 450
Tube and tank process of cracking, 109
Tumenolsulphones, 1037
Tumenolsulphonic acids, 1037, 1038
Tungstates, catalysts, diphenyl production, 189
—, oxidation catalysts, 834
Tungsten, catalyst, ammonia-carbon monoxide reaction, 298
—, —, hydration of olefins, 307, 314
—, —, pyrolysis of hydrocarbons, 40, 134, 136, 146, 150, 166, 182
—, effect of, in cracking, 106
—, oxidation catalyst, 833, 929
Tungsten alloys, catalysts, methane-steam reaction, 291
Tungsten compounds, as catalysts, acetylene-amine reaction, 684
—, —, hydration of acetylene, 677
Tungsten electrodes, 261
Tungsten heating element, pyrolysis of methane, 148
Tungstic acid, catalyst for ethylene absorption, 334
Tungsten oxide, catalyst, alcohol-hydrogen reaction, 345
—, —, condensation of phenols and olefins, 567
—, —, hydration of olefins, 307, 310, 311, 314, 315
—, —, hydrolysis of phenyl halides, 767
—, —, isomerization of olefin oxides, 547
—, —, oxidation of alcohols, 869, 870
—, —, pyrolysis of hydrocarbons, 157, 158, 182
—, oxidation catalysts, 406, 833, 843, 864, 883, 914, 915, 921, 925
Tung oil, use in varnishes, 1030
Turbine oils, oxidation of, 912-913
Turbulence, effect during electric decomposition, 261
—, effect in pyrolysis of hydrocarbons, 130
—, effect on speed of combustion, 981
Turkey-red oils, 341, 627, 628, 629, 1019
Turner Valley, natural gases from, 14
Turpentine, action of aluminum chloride on, 195, 1050
—, cymene from, 891
—, effect on oxidation of hydrocarbons, 936, 957, 958, 960
—, hydrogen from, 209
—, hydrogenated, silent electric discharge, 264
—, isoprene from, 154, 635
—, oxidation of, 889, 890, 891
—, polymerization of, 264, 598
—, presence of peroxides in, 439
—, pyrolysis of, 154, 209, 635
—, trimethylethylene from, 154
—, uses, 614, 1030
Turpentine peroxides, catalysts for polymerization, 630
—, decolorization of indigo by, 889
Turpentine substitute, from olefins and ozone, 844
Turpentine wax, oxidation of, 957
Tustanowic petroleum, cyclohexanes in, 25
Twitchell reagents, 1025

U

Ultraviolet light, action on cracking gas, 188
—, — hydrocarbons, 272, 274
—, chlorination of hydrocarbons in, 693, 694, 699, 714, 727, 728, 729, 739
—, desulphurization of petroleum hydrocarbons, 461
Ultraviolet light, effect in sweetening, 443, 444
—, nitrosyl chloride reactions, 1055
—, olefins polymerized by, 589, 611, 625, 626
—, oxidation of hydrocarbons in, 837, 940, 948
—, use in carbon black production, 238

—, promoter, oxidation of methane, 848
Vanadium salts, benzene oxidation, 927
—, oxidation of lignite paraffin, 949
Vanadium tetrachloride, catalyst, 758
Vanadium trichloride, catalyst, 322
Vapon, 362
Vapor-phase chlorination, of ethane, 713
—, of paraffins, 719
—, of pentane, 723
—, of toluene, 772
Vapor-phase conversion, of ethylene chlorohydrin to oxide, 536
Vapor-phase cracking, definition of, 92
—, petroleum distillates, 130, 132, 133, 134
Vapor-phase hydrolysis, ethylene chlorohydrin, 509
Vapor-phase oxidation, factors affecting, 834
—, of hydrocarbons, 835-838
—, of isopropyl alcohol, 406
—, of petroleum distillates, 830, 931, 937, 938
Varnishes, drying oils for, 613
—, from acid sludge, 1030
—, manufacture, 541
—, methanol as solvent for, 785
—, tetrachloroethane as solvent for, 673
—, use of carbon black, 252
—, — isopropyl alcohol, 366
—, — metallic salts, 995
—, — oxidized petroleum in, 995, 996
Varnish gums, oxygenated solvents for, 992
Varnish materials, from mineral-oil distillates, 741
Vaseline, composition of, 29
Vaseline oil, cracking of, 100
Vaux natural gas, chlorination, 692
Vegetable oils, hydrolyzed with isopropylated aromatics, 375
—, latex from, 629
—, solubility in isopropyl alcohol, 365
—, — isopropyl ether, 370
Velocity of coke-formation, 101
Velocity of cracking, 96, 100, 101
—, effect of charging stock, 101, 108
—, — pressure, 104
Velocity of polymerization, effect of temperature, 98
Velocity coefficients, bromination olefins, 465, 466
Velocity constants, polymerization of dienes, 617
Verbenone, from α-pinene, 891
Veronal, 364
Victoria green, made oil-soluble, 1029
Vinyl acetate, 681-682
—, catalysts for, 681
—, chlorination of, 682
—, ethylidene diacetate from, 682
—, polymerization, 588, 681
—, reaction with monomethylamine, 656
—, resinous materials from, 679, 681
Vinylacetylene, drying oils from, 670
—, from amylene-hydrogen, 266
—, polymerization catalysts for, 670
—, polymerized, 273, 670
—, reaction with hydrochloric acid, 638
—, — mercuric salts, 685
Vinylbenzene, *see* Styrene
Vinyl bromide, 477, 478, 635, 680
—, polymerization of, 627
Vinyl chloride, chlorine addition, 475, 680
—, from acetylene, 680
—, from ethylene dichloride, 473, 680, 816
—, reaction with aluminum chloride, 680
—, — hydrogen chloride, 680
—, resinous materials from, 679

Vinyl chloride, sodium acetate from, 678
Vinyl chloroacetate, 679
Vinyl compounds, 1,3-butadiene from, 680
—, from acetylene, 667
Vinyl cyanide, from acetylene, 684
Vinylcyclohexenes, from butadiene, 629
Vinyl esters, halogenation of, 682
—, polymerization of, 679
—, production of, 681
—, resinous polymers from, 679
Vinyl ethers, 679, 682
Vinyl group, effect on polymerization, 627
Vinyl halides, catalysts for, 680
—, intermediate in dehalogenation of ethylene dihalides, 663
—, polymerization, 592
—, production of, 679, 680
Vinyl ketones, production, 599, 570
Vinylnapthalene, 147
Vinyl phenyl ether, 682
5-Vinylpyrazoline, preparation, 652
Vinylsulphuric acid, from acetylene, 679
Virdine, from hydrocarbon pyrolysis, 226
Viscosity, effect on condensation of olefins, 565
—, index of, 1152
—, of hydrocarbons, 30
—, of petroleum oils, 1152-1153
—, voltolized oils, 271
Viscosity units, 1152
Volatile matter, carbon black, 244, 246
Voltolization, 255, 270, 271
Voltolized oils, 270, 271
Voltols, 270, 271
Vulcanization, of rubber, 627, 628
Vulcanization accelerator, compounds of diolefins, 656
—, use of isopropyl xanthate, 394

W

Waste acid, cracking of, 456
Waste oils, sulphonation of, 1017
Water, addition to acetylene, 666
—, carbon removal by, 219
—, catalyst, chlorination of aromatics, 760, 773
—, —, formation of ethylene oxide, 541
—, diluent in pyrolysis of olefins, 223
—, effect on cracking by aluminum chloride, 192
—, — ethylene bromination, 465, 477
—, — flame propagation, 977
—, — hydrogen chloride addition to olefins, 330
—, — methane chlorination, 693, 694, 698, 700
—, — natural gas chlorination, 691
—, — pyrolysis of oils and tars, 133
—, for washing carbon, 224, 228, 229
—, impurities in gases removed by, 209
—, promoter of nuclear chlorination of aromatics, 756, 771
—, reaction with hydrocarbons, 276-281
—, — olefin oxides, 537, 558
—, — ozonides, 882, 883
—, removal from carbon black, 219
—, removal of gum in gasolines by, 903
—, use in cracking, 212
—, used in diolefin polymerization, 629
Water content, of carbon black, 246
Water formation, combustion of fuels, 978, 979, 981
Water gas, carbureted, manufacture of, 37
—, diluent in ethane oxidation, 872
—, from hydrocarbons, 216
—, generators for, 208, 216
—, hydrogen from, 230
—, use in hydrocarbon pyrolysis, 209
Water-gas equilibrium, 283, 284
Water gas-ethylene, ethyl chloride from, 322
Water gas-olefins, pyrolysis of, 187
Water-gas reaction, 283, 286
Waterproofing ingredients, from acid sludge, 1031
Water spray, use in carbon black production, 239
Water vapor, effect on acetylene polymerization, 82
—, — adsorption of olefins, 143
Water-vapor content, natural gas, 236
Wax, cracking of, 104
—, oxidation of, 830, 943, 960, 993
Wax, oxidation of, effect of pressure, 960
—, oxidizing agents for, 960
—, paraffin, composition of, 29
—, —, in lubricating oils, 29
—, —, mechanism of pyrolysis, 60
—, —, production of, 29
—, —, pyrolysis of, 60, 63
—, solvents for, 614, 674, 948
Wax acids, by electrolytic oxidation of wax, 960
—, constitution of, 959
—, definition of, 941
—, esterification with ethylene glycol, 944
—, esters of hydroxyalkyl ethers, 995
—, from Grozny paraffin, 941
—, from lignite, 948, 949
—, from montan wax, 948
—, from ozokerite, 948
—, from paraffin wax, 931
—, identification of, 943, 945, 960
—, liberation of, from soaps, 941, 942
—, methods of decolorization, 952, 955, 956
—, processes for separation, 941, 942, 944, 946, 947, 950, 953, 954, 955
—, soaps from, 941, 942, 960, 994
—, solubility of, 949
—, synthetic fats from, 960
—, synthetic waxes from, 998
Wax alcohols, from oxidized wax, 943
—, synthetic waxes from, 998
Wax distillates, oxidation of, 992
Wax-like substances, by oxidation processes, 997
Waxes, by oxidation processes, 837, 997
—, emulsification of, 1025, 1026
—, hydrolyzed with isopropylated aromatics, 375
—, solubility in isopropyl ether, 370
—, synthesis from oxidation products, 998
Welding, gas mixture used in, 216
Wetting agents, ter.-butylbenzene sulphonic acid, 400
—, by sulphonation, 1019
—, di-ethers of diethylene glycol, 528
—, effect of acid anhydrides on, 1024
—, — aliphatic chlorides on, 1024
—, esters of monoalkyl ethers and sulphonated acids, 525
—, from chlorinated petroleum, 808
—, from dichlorodiethyl ether, 498
—, from ethylene chlorohydrin, 498
—, from glycol and chlorinated petroleum, 817
—, from mineral oils, 1022, 1024
—, from naphthenic acids, 1086
—, from petroleum sulphonic acids, 1022, 1023, 1024
—, from sulphonated leather waste, 1024
—, from sulphonated polymerization products, 1024
—, isopropylated aromatics, 374
—, mono-ethers of diethylene glycol, 528
—, production of, 539, 543, 553, 559, 563, 564, 565, 817
—, sulphonated oxidized hydrocarbons, 1000, 1001, 1002
—, sulphonation of isopropyl alcohol, 372
—, textile, 1028
White flame arc, natural gas chlorination, 694, 695
White oil, insecticides from, 1020
—, oxidation of, 859
—, production of, 1012, 1013, 1020
—, refining of, 1016, 1017, 1018
—, sulphonated, 1002
—, sulphonic acids, emulsifying agents, 1025
Witch-hazel extract, isopropyl alcohol in, 365
Wood, destructive distillation of, 415
—, oxidized, 1004
Wood fillers, 548
Wood flour, adsorption of sulphonic acids, 1014
Wood preservatives, by oxidization of oils, 1002
—, from acid oils, 1031
Wood's metal, evaluation of oils with, 911
Wood stains, use of isopropyl alcohol in, 366
Wood-tar distillate, resin formation with cracked distillates, 998
Wood tar, gasoline stabilization with, 898
—, oxidation of, 839

X

Xanthation, of alkali-cellulose, 742
Xylene, ω-acetylstyrene-p-carboxylic acid from, 928
—, action of aluminum chloride on, 200
—, antiknock qualities, 964
—, bacterial oxidation, 1004
—, benzene from, 200
—, butylxylene from, 561

—, ethylation of, 560
—, from Bustenari petroleum, 1035
—, from p-cymene, 200
—, from gasoline, 914
—, from hexahydroxylene, 85, 181
—, from hydrocarbon oils, 608
—, from octanaphthene, 629, 1061
—, from toluene and propylene, 561
—, oxidation of, 915, 922, 928
—, phthalic acid from, 922
—, pyrolysis of, 88, 89
—, reaction with acetylene tetrachloride, 674
—, — ethylene, 560
—, — isoprene, 204
—, — phosphorus pentachloride, 780
—, resins from, 204
—, terephthalic acid from, 928
—, tolualdehyde from, 928
—, toluene from, 200
m-Xylene, by acetylene pyrolysis, 81, 180
—, by butene polymerization, 602
—, by butene pyrolysis, 72, 180
—, by propylene pyrolysis, 71, 179
—, chlorination of, 780
—, from 1,3-dimethylcyclohexane, 1010
—, from kerosene, 27
—, from octanaphthene, 430
—, in natural gas gasoline, 18
—, in straight-run gasoline, 25, 26, 27
—, photochlorination, 779
—, reaction with sulphur, 430
—, — sulphuryl chloride, 780
—, resins from, 204
o-Xylene, by acetylene pyrolysis, 81, 180
—, chlorination of, 780
—, dimercaptan, 432
—, in straight-run gasoline, 25, 27
—, resins from, 204
—, side-chain nitration, 1046
—, thermal stability of, 90
p-Xylene, by acetylene pyrolysis, 81, 82, 180
—, chlorination of, 780
—, from kerosene, 27
—, in straight-run gasoline, 25, 26, 27
—, reaction with lead ammonium chloride, 780
—, resins from, 204
p-Xylenol, from toluene, 928
—, from xylene, 928
Xylenol-sulphur chloride resins, 450
Xylidine, gasoline stabilization with, 898
Xylol, intermediate fractions of, 353
p-Xyloquinone, from toluene, 928
Xylyl chlorides, preparation of, 779, 789
Xylylene dichloride, preparation of, 779, 780
X-rays, effect on oxidation of mercaptans, 444
—, refining hydrocarbons, 274

Y

Yellow oils, sulphonation of, 1019
Yields, of carbon black, factors affecting, 239
Yperite, 576

Z

Zeolite catalysts, oxidation of anthracene, 924
—, — hydrocarbons, 915, 921, 922
—, pyrolysis of paraffins, 135
Zinc, aromatization catalyst, olefins-acetylene, 187
—, catalyst, acetylene dichloride by, 674
—, —, condensation of olefins with aromatics, 565
—, —, hydrocarbon pyrolysis, 136
—, —, in cracking, 113

—, —, pyrolysis of acetylene, 668
—, —, pyridine bases, 683
—, —, vapor-phase hydration of acetylene, 677
—, condensation of ketones with olefins, 574
—, — phenols with alcohols, 399
—, dehydration of alcohols, 393
—, — ethylene glycol, 533
—, effect on ethylene, 195
—, esterification of alcohols, 392
—, extraction of sulphur compounds, 460
—, polymerization of olefins, 195, 197
—, production of mesityl oxide, 409
—, promoter, production of ketones, 411

Zinc chloride. purification of phthalic anhydride, 924
—, removal of gum from gasoline. 903
Zinc chromate. methane-steam reaction, 276
—, oxidation of acetylene, 886
—, — methane to formaldehyde, 864
Zinc compounds, catalysts, nitriles. 684
Zinc-copper. catalyst, for oxidation of alcohols to aldehydes. 869-870
Zinc-copper couple, 1121
—, conversion of halogenated hydrocarbons to acetylene, 663
—, decomposition of bromides by, 1144
—, olefin dibromide debromination, 478
—, reduction of tetrabromides by, 640
Zinc diethyl, tetraethyl lead production, 813
Zinc dust, cauoprene bromides reaction, 627
—, reaction with 2,3-dibromo-1-propene. 632
Zinc ethyl mercaptan, 449
Zinc ethylsulphate, 449
Zinc halide, catalyst, polymerization olefins, 594
Zinc hydroxide. catalyst, hydrogen-carbon monoxide, 232
—, —, oxidation of alkylbenzenes, 926
—, extraction of sulphur compounds, 460
Zinc manganate, catalyst. oxidation of toluene. 919
Zinc molybdate. catalyst, oxidation of acetylene, 886
Zinc naphthenate. 935, 1089, 1090
Zinc nitrate, catalyst for natural gas chlorination, 691
Zinc oxide, activator for catalysts, 223. 281. 288
—. catalyst, acetic acid. 677
—, —, air-oxidation of alcohols, 396
—, —, for acetone, 677
—, —, for butadiene, 635
—, —. in cracking, 106
—, —, ketones, 416, 419
—, —, methane-steam reaction. 276
—, —, oxidation of acetaldehyde. 870
—, —, — alcohols, 406, 869
—. —, — sec.-butyl alcohol. 415
—. —, — hydrocarbons. 922
—. —. — methane, 848. 849
—, —, production of ketones. 407. 408. 411
—, —, pyridine bases, 684
—, —, pyrolysis of paraffins, 135
—, —. reduction naphthenic acids. 1084
—, chlorohydrin formation, 493
—, condensation of ketones with olefins. 574
—, effect in pyrolysis of ethylene. 67
—. hydration of ethylene, 307
Zinc oxide, hydrolysis of amyl chloride, 793
—, ethanol-forming catalyst, 989
—, oxidation catalyst, 406, 840
—, oxidation of anthracene, 925
—, preparation of aliphatic diamines. 818
—, reaction on methane, 849
—, reduction of, by ethylene, 67
—, vapor-phase hydration of acetylene, 676
Zinc oxychloride, removal of gum from gasoline, 903
Zinc phosphate, hydration of ethylene, 308
—, oxidation catalyst, 833
Zinc salts. action with acetylene, 667
—, of naphthenic acids, 1083
—, of oxidized paraffin, 995
—, preparation of aliphatic diamines. 818
Zinc soap, anticatalyst for oxidation, 909
Zinc stearate, catalyst for oxidation, 934, 945, 947
Zinc sulphate, catalyst, ammonia-olefin reaction. 571
—, —, hydrolysis of ethyl chloride. 787
—, hydration of olefins, 310, 315, 318
—, removal of hydrogen sulphide, 423
Zinc sulphide, catalyst, diphenyl production. 189
—, —, oxidation of mercaptans, 441
—, iodometric determination of, 1151
Ziinc sulphonates, prevention of emulsions with. 1027
Zinc vanadate as catalyst, oxidation of acetylene. 886
—, — hydrocarbons, 917
Zinc vapor, catalyst, methane chlorination. 699
Zincates, diphenyl production, 189
Zirconia, activator, methane-steam reaction, 280
—, catalyst, hydration reactions, 303
—, —, hydrolysis of phenyl chloride. 767
—, —, oxidation of alcohols, 406
—, hydration of propylene, 314
Zirconium, catalyst. chlorination of benzene. 759
—. pyrolysis of benzene homologues. 146
Zirconium chloride. formation of ethyl chloride. 715
Zirconium compounds. catalysts. diphenyl production, 189
—, —, for nitriles. 684
Zirconium oxide. activator methane-steam reaction, 280. 288
—, catalyst, 223
—, —, hydrolysis of methyl chloride. 782
—, —, methane-steam reaction, 292
—, —, oxidation of methane, 864
Zistersdorf petroleum, 163
